Contents

Preface xiii

About the Author xxii

Chapter 1 Basic Concepts and Computer Evolution 1

1.1 Organization and Architecture 2

1.2 Structure and Function 3

1.3 The IAS Computer 11

1.4 Gates, Memory Cells, Chips, and Multichip Modules 17

1.5 The Evolution of the Intel x86 Architecture 23

1.6 Embedded Systems 24

1.7 ARM Architecture 29

1.8 Key Terms, Review Questions, and Problems 34

Chapter 2 Performance Concepts 37

2.1 Designing for Performance 38

2.2 Multicore, MICs, and GPGPUs 44

2.3 Two Laws that Provide Insight: Ahmdahl's Law and Little's Law 45

2.4 Basic Measures of Computer Performance 48

2.5 Calculating the Mean 51

2.6 Benchmarks and SPEC 59

2.7 Key Terms, Review Questions, and Problems 66

Chapter 3 A Top-Level View of Computer Function and Interconnection 72

3.1 Computer Components 73

3.2 Computer Function 75

3.3 Interconnection Structures 90

3.4 Bus Interconnection 92

3.5 Point-to-Point Interconnect 94

3.6 PCI Express 99

3.7 Key Terms, Review Questions, and Problems 107

Chapter 4 The Memory Hierarchy: Locality and Performance 112

4.1 Principle of Locality 113

4.2 Characteristics of Memory Systems 118

4.3 The Memory Hierarchy 121

4.4 Performance Modeling of a Multilevel Memory Hierarchy 128

4.5 Key Terms, Review Questions, and Problems 135

Chapter 5 Cache Memory 138

- 5.1 Cache Memory Principles 139**
- 5.2 Elements of Cache Design 143**
- 5.3 Intel x86 Cache Organization 165**
- 5.4 The IBM z13 Cache Organization 168**
- 5.5 Cache Performance Models 169**

5.6 Key Terms, Review Questions, and Problems 173

Chapter 6 Internal Memory 177

- 6.1 Semiconductor Main Memory 178**
- 6.2 Error Correction 187**
- 6.3 DDR DRAM 192**
- 6.4 eDRAM 197**
- 6.5 Flash Memory 199**
- 6.6 Newer Nonvolatile Solid-State Memory Technologies 202**

6.7 Key Terms, Review Questions, and Problems 205

Chapter 7 External Memory 210

- 7.1 Magnetic Disk 211**
- 7.2 RAID 221**
- 7.3 Solid State Drives 231**
- 7.4 Optical Memory 234**
- 7.5 Magnetic Tape 240**

7.6 Key Terms, Review Questions, and Problems 242

Chapter 8 Input/Output 245

- 8.1 External Devices 247**
- 8.2 I/O Modules 249**
- 8.3 Programmed I/O 252**
- 8.4 Interrupt-Driven I/O 256**
- 8.5 Direct Memory Access 265**
- 8.6 Direct Cache Access 271**
- 8.7 I/O Channels and Processors 278**
- 8.8 External Interconnection Standards 280**
- 8.9 IBM z13 I/O Structure 283**

8.10 Key Terms, Review Questions, and Problems 287

Chapter 9 Operating System Support 291

- 9.1 Operating System Overview 292**

- 9.2 Scheduling 303**
- 9.3 Memory Management 309**
- 9.4 Intel x86 Memory Management 320**
- 9.5 ARM Memory Management 325**
- 9.6 Key Terms, Review Questions, and Problems 330**

Chapter 10 Number Systems 334

- 10.1 The Decimal System 335**
- 10.2 Positional Number Systems 336**
- 10.3 The Binary System 337**
- 10.4 Converting Between Binary and Decimal 337**
- 10.5 Hexadecimal Notation 340**
- 10.6 Key Terms and Problems 342**

Chapter 11 Computer Arithmetic 344

- 11.1 The Arithmetic and Logic Unit 345**
- 11.2 Integer Representation 346**
- 11.3 Integer Arithmetic 351**
- 11.4 Floating-Point Representation 366**
- 11.5 Floating-Point Arithmetic 374**
- 11.6 Key Terms, Review Questions, and Problems 383**

Chapter 12 Digital Logic 388

- 12.1 Boolean Algebra 389**
- 12.2 Gates 394**
- 12.3 Combinational Circuits 396**
- 12.4 Sequential Circuits 414**
- 12.5 Programmable Logic Devices 423**
- 12.6 Key Terms and Problems 428**

Chapter 13 Instruction Sets: Characteristics and Functions 432

- 13.1 Machine Instruction Characteristics 433**
- 13.2 Types of Operands 440**
- 13.3 Intel x86 and ARM Data Types 442**
- 13.4 Types of Operations 445**
- 13.5 Intel x86 and ARM Operation Types 458**
- 13.6 Key Terms, Review Questions, and Problems 466**
- Appendix 13A Little-, Big-, and Bi-Endian 472**

Chapter 14 Instruction Sets: Addressing Modes and Formats 476

14.1 Addressing Modes	477
14.2 x86 and ARM Addressing Modes	483
14.3 Instruction Formats	489
14.4 x86 and ARM Instruction Formats	497
14.5 Key Terms, Review Questions, and Problems	502

Chapter 15 Assembly Language and Related Topics	506
15.1 Assembly Language Concepts	507
15.2 Motivation for Assembly Language Programming	510
15.3 Assembly Language Elements	512
15.4 Examples	518
15.5 Types of Assemblers	523
15.6 Assemblers	523
15.7 Loading and Linking	526
15.8 Key Terms, Review Questions, and Problems	533

Chapter 16 Processor Structure and Function	537
16.1 Processor Organization	538
16.2 Register Organization	539
16.3 Instruction Cycle	545
16.4 Instruction Pipelining	548
16.5 Processor Organization for Pipelining	566
16.6 The x86 Processor Family	568
16.7 The ARM Processor	575
16.8 Key Terms, Review Questions, and Problems	581

Chapter 17 Reduced Instruction Set Computers	586
17.1 Instruction Execution Characteristics	588
17.2 The Use of a Large Register File	593
17.3 Compiler-Based Register Optimization	598
17.4 Reduced Instruction Set Architecture	600
17.5 RISC Pipelining	606
17.6 MIPS R4000	610
17.7 SPARC	616
17.8 Processor Organization for Pipelining	621
17.9 CISC, RISC, and Contemporary Systems	623
17.10 Key Terms, Review Questions, and Problems	625

Chapter 18 Instruction-Level Parallelism and Superscalar Processors	629
--	------------

18.1 Overview 630

18.2 Design Issues 637

18.3 Intel Core Microarchitecture 646

18.4 ARM Cortex-A8 652

18.5 ARM Cortex-M3 658

18.6 Key Terms, Review Questions, and Problems 663

Chapter 19 Control Unit Operation and Microprogrammed Control 669

19.1 Micro-operations 670

19.2 Control of the Processor 676

19.3 Hardwired Implementation 686

19.4 Microprogrammed Control 689

19.5 Key Terms, Review Questions, and Problems 698

Chapter 20 Parallel Processing 701

20.1 Multiple Processors Organization 703

20.2 Symmetric Multiprocessors 705

20.3 Cache Coherence and the MESI Protocol 709

20.4 Multithreading and Chip Multiprocessors 718

20.5 Clusters 723

20.6 Nonuniform Memory Access 726

20.7 Key Terms, Review Questions, and Problems 730

Chapter 21 Multicore Computers 736

21.1 Hardware Performance Issues 737

21.2 Software Performance Issues 740

21.3 Multicore Organization 745

21.4 Heterogeneous Multicore Organization 747

21.5 Intel Core i7-5960X 756

21.6 ARM Cortex-A15 MPCore 757

21.7 IBM z13 Mainframe 762

Preface

What's New in the Eleventh Edition

Since the tenth edition of this book was published, the field has seen continued innovations and improvements. In this new edition, I try to capture these changes while maintaining a broad and comprehensive coverage of the entire field. To begin this process of revision, the tenth edition of this book was extensively reviewed by a number of professors who teach the subject and by professionals working in the field. The result is that, in many places, the narrative has been clarified and tightened, and illustrations have been improved.

Beyond these refinements to improve pedagogy and user-friendliness, there have been substantive changes throughout the book. Roughly the same chapter organization has been retained, but much of the material has been revised and new material has been added. The most noteworthy changes are as follows:

- **Multichip Modules:** A new discussion of MCMs, which are now widely used, has been added to [Chapter 1](#).
- **SPEC benchmarks:** The treatment of SPEC in [Chapter 2](#) has been updated to cover the new SPEC CPU2017 benchmark suite.
- **Memory hierarchy:** A new chapter on memory hierarchy expands on material that was in the cache memory chapter, plus adds new material. The new [Chapter 4](#) includes:
 - Updated and expanded coverage of the principle of locality
 - Updated and expanded coverage of the memory hierarchy
 - A new treatment of performance modeling of data access in a memory hierarchy
- **Cache memory:** The cache memory chapter has been updated and revised. [Chapter 5](#) now includes:
 - Revised and expanded treatment of logical cache organization, including new figures, to improve clarity
 - New coverage of content-addressable memory
 - New coverage of write allocate and no write allocate policies
 - A new section on cache performance modeling.
- **Embedded DRAM:** [Chapter 6](#) on internal memory now includes a section on the increasingly popular eDRAM.
- **Advanced Format 4k sector hard drives:** [Chapter 7](#) on external memory now includes discussion of the now widely used 4k sector hard drive format.
- **Boolean algebra:** The discussion on Boolean algebra in [Chapter 12](#) has been expanded with new text, figures, and tables, to enhance understanding.
- **Assembly language:** The treatment of assembly language has been expanded to a full chapter, with more detail and more examples.
- **Pipeline organization:** The discussion on pipeline organization has been substantially expanded with new text and figures. The material is in new sections in [Chapters 16](#) (Processor Structure and Function), [17](#) (RISC), and [18](#) (Superscalar).
- **Cache coherence:** The discussion of the MESI cache coherence protocol in [Chapter 20](#) has been expanded with new text and figures.

Support of ACM/IEEE Computer Science and Computer Engineering Curricula

The book is intended for both an academic and a professional audience. As a textbook, it is intended as a one- or two-semester undergraduate course for computer science, computer engineering, and electrical engineering majors. This edition supports recommendations of the ACM/IEEE Computer Science Curricula 2013 (CS2013). CS2013 divides all course work into three categories: Core-Tier 1 (all topics should be included in the curriculum); Core-Tier-2 (all or almost all topics should be included); and Elective (desirable to provide breadth and depth). In the Architecture and Organization (AR) area, CS2013 includes five Tier-2 topics and three Elective topics, each of which has a number of subtopics. This text covers all eight topics listed by CS2013. **Table P.1** shows the support for the AR Knowledge Area provided in this textbook. This book also supports the ACM/IEEE Computer Engineering Curricula 2016 (CE2016). CE2016 defines a necessary body of knowledge for undergraduate computer engineering, divided into twelve knowledge areas. One of these areas is Computer Architecture and Organization (CE-CAO), consisting of ten core knowledge areas. This text covers all of the CE-CAO knowledge areas listed in CE2016. **Table P.2** shows the coverage.

Table P.1 Coverage of CS2013 Architecture and Organization (AR) Knowledge Area

IAS Knowledge Units	Topics	Textbook Coverage
Digital Logic and Digital Systems (Tier 2)	<ul style="list-style-type: none">• Overview and history of computer architecture• Combinational vs. sequential logic/Field programmable gate arrays as a fundamental combinational sequential logic building block• Multiple representations/layers of interpretation (hardware is just another layer)• Physical constraints (gate delays, fan-in, fan-out, energy/power)	— Chapter 1 — Chapter 12
Machine Level Representation of Data (Tier 2)	<ul style="list-style-type: none">• Bits, bytes, and words• Numeric data representation and number bases• Fixed- and floating-point systems• Signed and twos-complement representations• Representation of non-numeric data (character codes, graphical data)	— Chapter 10 — Chapter 11
Assembly Level Machine Organization (Tier 2)	<ul style="list-style-type: none">• Basic organization of the von Neumann machine• Control unit; instruction fetch, decode, and execution• Instruction sets and types (data manipulation, control, I/O)• Assembly/machine language programming• Instruction formats• Addressing modes• Subroutine call and return mechanisms (cross-	— Chapter 1 — Chapter 8 — Chapter 13 — Chapter

Objectives

This book is about the structure and function of computers. Its purpose is to present, as clearly and completely as possible, the nature and characteristics of modern-day computer systems.

This task is challenging for several reasons. First, there is a tremendous variety of products that can rightly claim the name of computer, from single-chip microprocessors costing a few dollars to supercomputers costing tens of millions of dollars. Variety is exhibited not only in cost but also in size, performance, and application. Second, the rapid pace of change that has always characterized computer technology continues with no letup. These changes cover all aspects of computer technology, from the underlying integrated circuit technology used to construct computer components

to the increasing use of parallel organization concepts in combining those components.

In spite of the variety and pace of change in the computer field, certain fundamental concepts apply consistently throughout. The application of these concepts depends on the current state of the technology and the price/performance objectives of the designer. The intent of this book is to provide a thorough discussion of the fundamentals of computer organization and architecture and to relate these to contemporary design issues.

The subtitle suggests the theme and the approach taken in this book. It has always been important to design computer systems to achieve high performance, but never has this requirement been stronger or more difficult to satisfy than today. All of the basic performance characteristics of computer systems, including processor speed, memory speed, memory capacity, and interconnection data rates, are increasing rapidly. Moreover, they are increasing at different rates. This makes it difficult to design a balanced system that maximizes the performance and utilization of all elements. Thus, computer design increasingly becomes a game of changing the structure or function in one area to compensate for a performance mismatch in another area. We will see this game played out in numerous design decisions throughout the book.

A computer system, like any system, consists of an interrelated set of components. The system is best characterized in terms of structure—the way in which components are interconnected, and function—the operation of the individual components. Furthermore, a computer's organization is hierarchical. Each major component can be further described by decomposing it into its major subcomponents and describing their structure and function. For clarity and ease of understanding, this hierarchical organization is described in this book from the top down:

- **Computer system:** Major components are processor, memory, I/O.
- **Processor:** Major components are control unit, registers, ALU, and instruction execution unit.
- **Control unit:** Provides control signals for the operation and coordination of all processor components. Traditionally, a microprogramming implementation has been used, in which major components are control memory, microinstruction sequencing logic, and registers. More recently, microprogramming has been less prominent but remains an important implementation technique.

The objective is to present the material in a fashion that keeps new material in a clear context. This should minimize the chance that the reader will get lost and should provide better motivation than a bottom-up approach.

Throughout the discussion, aspects of the system are viewed from the points of view of both architecture (those attributes of a system visible to a machine language programmer) and organization (the operational units and their interconnections that realize the architecture).

Example Systems

This text is intended to acquaint the reader with the design principles and implementation issues of contemporary operating systems. Accordingly, a purely conceptual or theoretical treatment would be inadequate. To illustrate the concepts and to tie them to real-world design choices that must be made, two processor families have been chosen as running examples:

- **Intel x86 architecture:** The x86 architecture is the most widely used for nonembedded computer systems. The x86 is essentially a complex instruction set computer (CISC) with some RISC features. Recent members of the x86 family make use of superscalar and multicore design principles. The evolution of features in the x86 architecture provides a unique case-study of the evolution of most of the design principles in computer architecture.
- **ARM:** The ARM architecture is arguably the most widely used embedded processor, used in cell phones, iPods, remote sensor equipment, and many other devices. The ARM is essentially a

reduced instruction set computer (RISC). Recent members of the ARM family make use of superscalar and multicore design principles.

Many, but by no means all, of the examples in this book are drawn from these two computer families. Numerous other systems, both contemporary and historical, provide examples of important computer architecture design features.

Plan of the Text

The book is organized into six parts:

- Introduction
- The computer system
- Arithmetic and logic
- Instruction sets and assembly language
- The central processing unit
- Parallel organization, including multicore

The book includes a number of pedagogic features, including the use of interactive simulations and numerous figures and tables to clarify the discussion. Each chapter includes a list of key words, review questions, and homework problems. The book also includes an extensive glossary, a list of frequently used acronyms, and a bibliography.

Instructor Support Materials

Support materials for instructors are available at the **Instructor Resource Center (IRC)** for this textbook, which can be reached through the publisher's Web site www.pearson.com/stallings. To gain access to the IRC, please contact your local Pearson sales representative via www.pearson.com/relocator. The IRC provides the following materials:

- **Projects manual:** Project resources including documents and portable software, plus suggested project assignments for all of the project categories listed subsequently in this Preface.
- **Solutions manual:** Solutions to end-of-chapter Review Questions and Problems.
- **PowerPoint slides:** A set of slides covering all chapters, suitable for use in lecturing.
- **PDF files:** Copies of all figures and tables from the book.
- **Test bank:** A chapter-by-chapter set of questions.
- **Sample syllabuses:** The text contains more material than can be conveniently covered in one semester. Accordingly, instructors are provided with several sample syllabuses that guide the use of the text within limited time. These samples are based on real-world experience by professors with the first edition.

Student Resources

For this new edition, a tremendous amount of original supporting material for students has been made available online. The **Companion Web Site**, at www.pearson.com/stallings, includes a list of relevant links organized by chapter and an errata sheet for the book. To aid the student in understanding the material, a separate set of homework problems with solutions are available at this site. Students can enhance their understanding of the material by working out the solutions to these problems and then checking their answers. The site also includes a number of documents and papers referenced throughout the text.

Projects and Other Student Exercises

For many instructors, an important component of a computer organization and architecture course is a project or set of projects by which the student gets hands-on experience to reinforce concepts from the text. This book provides an unparalleled degree of support for including a projects component in the course. The instructor's support materials available through the IRC not only includes guidance on how to assign and structure the projects but also includes a set of user's manuals for various project types plus specific assignments, all written especially for this book. Instructors can assign work in the following areas:

- **Interactive simulation assignments:** Described subsequently.
- **Research projects:** A series of research assignments that instruct the student to research a particular topic on the Internet and write a report.
- **Simulation projects:** The IRC provides support for the use of the two simulation packages: SimpleScalar can be used to explore computer organization and architecture design issues. SMPCache provides a powerful educational tool for examining cache design issues for symmetric multiprocessors.
- **Assembly language projects:** A simplified assembly language, CodeBlue, is used and assignments based on the popular Core Wars concept are provided.
- **Reading/report assignments:** A list of papers in the literature, one or more for each chapter, that can be assigned for the student to read and then write a short report.
- **Writing assignments:** A list of writing assignments to facilitate learning the material.
- **Test bank:** Includes T/F, multiple choice, and fill-in-the-blank questions and answers.

This diverse set of projects and other student exercises enables the instructor to use the book as one component in a rich and varied learning experience and to tailor a course plan to meet the specific needs of the instructor and students.

Interactive Simulations

An important feature in this edition is the incorporation of interactive simulations. These simulations provide a powerful tool for understanding the complex design features of a modern computer system. A total of 20 interactive simulations are used to illustrate key functions and algorithms in computer organization and architecture design. At the relevant point in the book, an icon indicates that a relevant interactive simulation is available online for student use. Because the animations enable the user to set initial conditions, they can serve as the basis for student assignments. The instructor's supplement includes a set of assignments, one for each of the animations. Each assignment includes several specific problems that can be assigned to students.

Acknowledgments

This new edition has benefited from review by a number of people, who gave generously of their time and expertise. The following professors provided a review of the entire book: Nikhil Bhargava (Indian Institute of Management, Delhi), James Gil de Lamadrid (Bowie State University, Computer Science Department), Debra Calliss (Computer Science and Engineering, Arizona State University), Mohammed Anwaruddin (Wentworth Institute of Technology, Dept. of Computer Science), Roger Kieckhafer (Michigan Technological University, Electrical & Computer Engineering), Paul Fortier (University of Massachusetts Dartmouth, Electrical and Computer Engineering), Yan Zhang (Department of Computer Science and Engineering, University of South Florida), Patricia Roden (University of North Alabama, Computer Science and Information Systems), Sanjeev Baskiyar (Auburn University, Computer Science and Software Engineering), and (Jayson Rock, University of Wisconsin-Milwaukee, Computer Science). I would especially like to thank Professor Roger Kieckhafer for permission to make use of some of the figures and performance models from his course lecture notes.

Thanks also to the many people who provided detailed technical reviews of one or more chapters: Rekai Gonzalez Alberquilla, Allen Baum, Jalil Boukhobza, Dmitry Bufistov, Humberto Calderón, Jesus Carretero, Ashkan Eghbal, Peter Glaskowsky, Ram Huggahalli, Chris Jesshope, Athanasios Kakarountas, Isil Oz, Mitchell Poplingher, Roger Shepherd, Jigar Savla, Karl Stevens, Siri Uppalapati, Dr. Sriram Vajapeyam, Kugan Vivekanandarajah, Pooria M. Yaghini, and Peter Zeno,

Professor Cindy Norris of Appalachian State University, Professor Bin Mu of the University of New Brunswick, and Professor Kenrick Mock of the University of Alaska kindly supplied homework problems.

Aswin Sreedhar of the University of Massachusetts developed the interactive simulation assignments.

Professor Miguel Angel Vega Rodriguez, Professor Dr. Juan Manuel Sánchez Pérez, and Professor Dr. Juan Antonio Gómez Pulido, all of University of Extremadura, Spain, prepared the SMPCache problems in the instructor's manual and authored the SMPCache User's Guide.

Todd Bezenek of the University of Wisconsin and James Stine of Lehigh University prepared the SimpleScalar problems in the instructor's manual, and Todd also authored the SimpleScalar User's Guide.

Finally, I would like to thank the many people responsible for the publication of the book, all of whom did their usual excellent job. This includes the staff at Pearson, particularly my editor Tracy Johnson, her assistant Meghan Jacoby, and project manager Bob Engelhardt. Thanks also to the marketing and sales staffs at Pearson, without whose efforts this book would not be in front of you.

About the Author

Dr. William Stallings

has authored 18 textbooks, and counting revised editions, over 70 books on computer security, computer networking, and computer architecture. In over 30 years in the field, he has been a technical contributor, technical manager, and an executive with several high-technology firms. Currently, he is an independent consultant whose clients have included computer and networking manufacturers and customers, software development firms, and leading-edge government research institutions. He has 13 times received the award for the best computer science textbook of the year from the Text and Academic Authors Association.

He created and maintains the Computer Science Student Resource Site at ComputerScienceStudent.com. This site provides documents and links on a variety of subjects of general interest to computer science students (and professionals). He is a member of the editorial board of *Cryptologia*, a scholarly journal devoted to all aspects of cryptology.

Dr. Stallings holds a PhD from MIT in computer science and a BS from Notre Dame in electrical engineering.

1.8 Key Terms, Review Questions, and Problems

Learning Objectives

After studying this chapter, you should be able to:

- Explain the general functions and structure of a digital computer.
- Present an overview of the evolution of computer technology from early digital computers to the latest microprocessors.
- Present an overview of the evolution of the x86 architecture.
- Define embedded systems and list some of the requirements and constraints that various embedded systems must meet.

1.1 Organization and Architecture

In describing computers, a distinction is often made between *computer architecture* and *computer organization*. Although it is difficult to give precise definitions for these terms, a consensus exists about the general areas covered by each. For example, see [VRAN80], [SIEW82], and [BELL78a]; an interesting alternative view is presented in [REDD76].

Computer architecture refers to those attributes of a system visible to a programmer or, put another way, those attributes that have a direct impact on the logical execution of a program. A term that is often used interchangeably with computer architecture is **instruction set architecture (ISA)**. The ISA defines instruction formats, instruction opcodes, registers, instruction and data memory; the effect of executed instructions on the registers and memory; and an algorithm for controlling instruction execution. **Computer organization** refers to the operational units and their interconnections that realize the architectural specifications. Examples of architectural attributes include the instruction set, the number of bits used to represent various data types (e.g., numbers, characters), I/O mechanisms, and techniques for addressing memory. Organizational attributes include those hardware details transparent to the programmer, such as control signals; interfaces between the computer and peripherals; and the memory technology used.

For example, it is an architectural design issue whether a computer will have a multiply instruction. It is an organizational issue whether that instruction will be implemented by a special multiply unit or by a mechanism that makes repeated use of the add unit of the system. The organizational decision may be based on the anticipated frequency of use of the multiply instruction, the relative speed of the two approaches, and the cost and physical size of a special multiply unit.

Historically, and still today, the distinction between architecture and organization has been an important one. Many computer manufacturers offer a family of computer models, all with the same architecture but with differences in organization. Consequently, the different models in the family have different price and performance characteristics. Furthermore, a particular architecture may span many years and encompass a number of different computer models, its organization changing with changing technology. A prominent example of both these phenomena is the IBM System/370 architecture. This architecture was first introduced in 1970 and included a number of models. The customer with modest requirements could buy a cheaper, slower model and, if demand increased, later upgrade to a more expensive, faster model without having to abandon software that had already been developed. Over the years, IBM has introduced many new models with improved technology to replace older models, offering the customer greater speed, lower cost, or both. These newer models retained the same architecture so that the customer's software investment was protected. Remarkably, the System/370 architecture, with a few enhancements, has survived to this day as the architecture of IBM's mainframe product line.

In a class of computers called microcomputers, the relationship between architecture and organization is very close. Changes in technology not only influence organization but also result in the introduction of more powerful and more complex architectures. Generally, there is less of a requirement for generation-to-generation compatibility for these smaller machines. Thus, there is more interplay between organizational and architectural design decisions. An intriguing example of this is the reduced instruction set computer (RISC), which we examine in [Chapter 15](#).

This book text examines both computer organization and computer architecture. The emphasis is perhaps more on the side of organization. However, because a computer organization must be designed to implement a particular architectural specification, a thorough treatment of organization requires a detailed examination of architecture as well.

1.2 Structure and Function

A computer is a complex system; contemporary computers contain millions of elementary electronic components. How, then, can one clearly describe them? The key is to recognize the hierarchical nature of most complex systems, including the computer [SIMO96]. A hierarchical system is a set of interrelated subsystems; each subsystem may, in turn, contain lower level subsystems, until we reach some lowest level of elementary subsystem.

The hierarchical nature of complex systems is essential to both their design and their description. The designer need only deal with a particular level of the system at a time. At each level, the system consists of a set of components and their interrelationships. The behavior at each level depends only on a simplified, abstracted characterization of the system at the next lower level. At each level, the designer is concerned with structure and function:

- **Structure:** The way in which the components are interrelated.
- **Function:** The operation of each individual component as part of the structure.

In terms of description, we have two choices: starting at the bottom and building up to a complete description, or beginning with a top view and decomposing the system into its subparts. Evidence from a number of fields suggests that the top-down approach is the clearest and most effective [WEIN75].

The approach taken in this book follows from this viewpoint. The computer system will be described from the top down. We begin with the major components of a computer, describing their structure and function, and proceed to successively lower layers of the hierarchy. The remainder of this section provides a very brief overview of this plan of attack.

Function

Both the structure and functioning of a computer are, in essence, simple. In general terms, there are only four basic functions that a computer can perform:

- **Data processing:** Data may take a wide variety of forms, and the range of processing requirements is broad. However, we shall see that there are only a few fundamental methods or types of data processing.
- **Data storage:** Even if the computer is processing data on the fly (i.e., data come in and get processed, and the results go out immediately), the computer must temporarily store at least those pieces of data that are being worked on at any given moment. Thus, there is at least a short-term data storage function. Equally important, the computer performs a long-term data storage function. Files of data are stored on the computer for subsequent retrieval and update.
- **Data movement:** The computer's operating environment consists of devices that serve as either sources or destinations of data. When data are received from or delivered to a device that is directly connected to the computer, the process is known as *input–output* (I/O), and the device is referred to as a *peripheral*. When data are moved over longer distances, to or from a remote device, the process is known as *data communications*.
- **Control:** Within the computer, a control unit manages the computer's resources and orchestrates the performance of its functional parts in response to instructions.

The preceding discussion may seem absurdly generalized. It is certainly possible, even at a top level of computer structure, to differentiate a variety of functions, but to quote [SIEW82]:

There is remarkably little shaping of computer structure to fit the function to be performed. At the root of this lies the general-purpose nature of computers, in which all the functional specialization

occurs at the time of programming and not at the time of design.

Structure

We now look in a general way at the internal structure of a computer. We begin with a traditional computer with a single processor that employs a microprogrammed control unit, then examine a typical multicore structure.

SIMPLE SINGLE-PROCESSOR COMPUTER

Figure 1.1 provides a hierarchical view of the internal structure of a traditional single-processor computer. There are four main structural components:

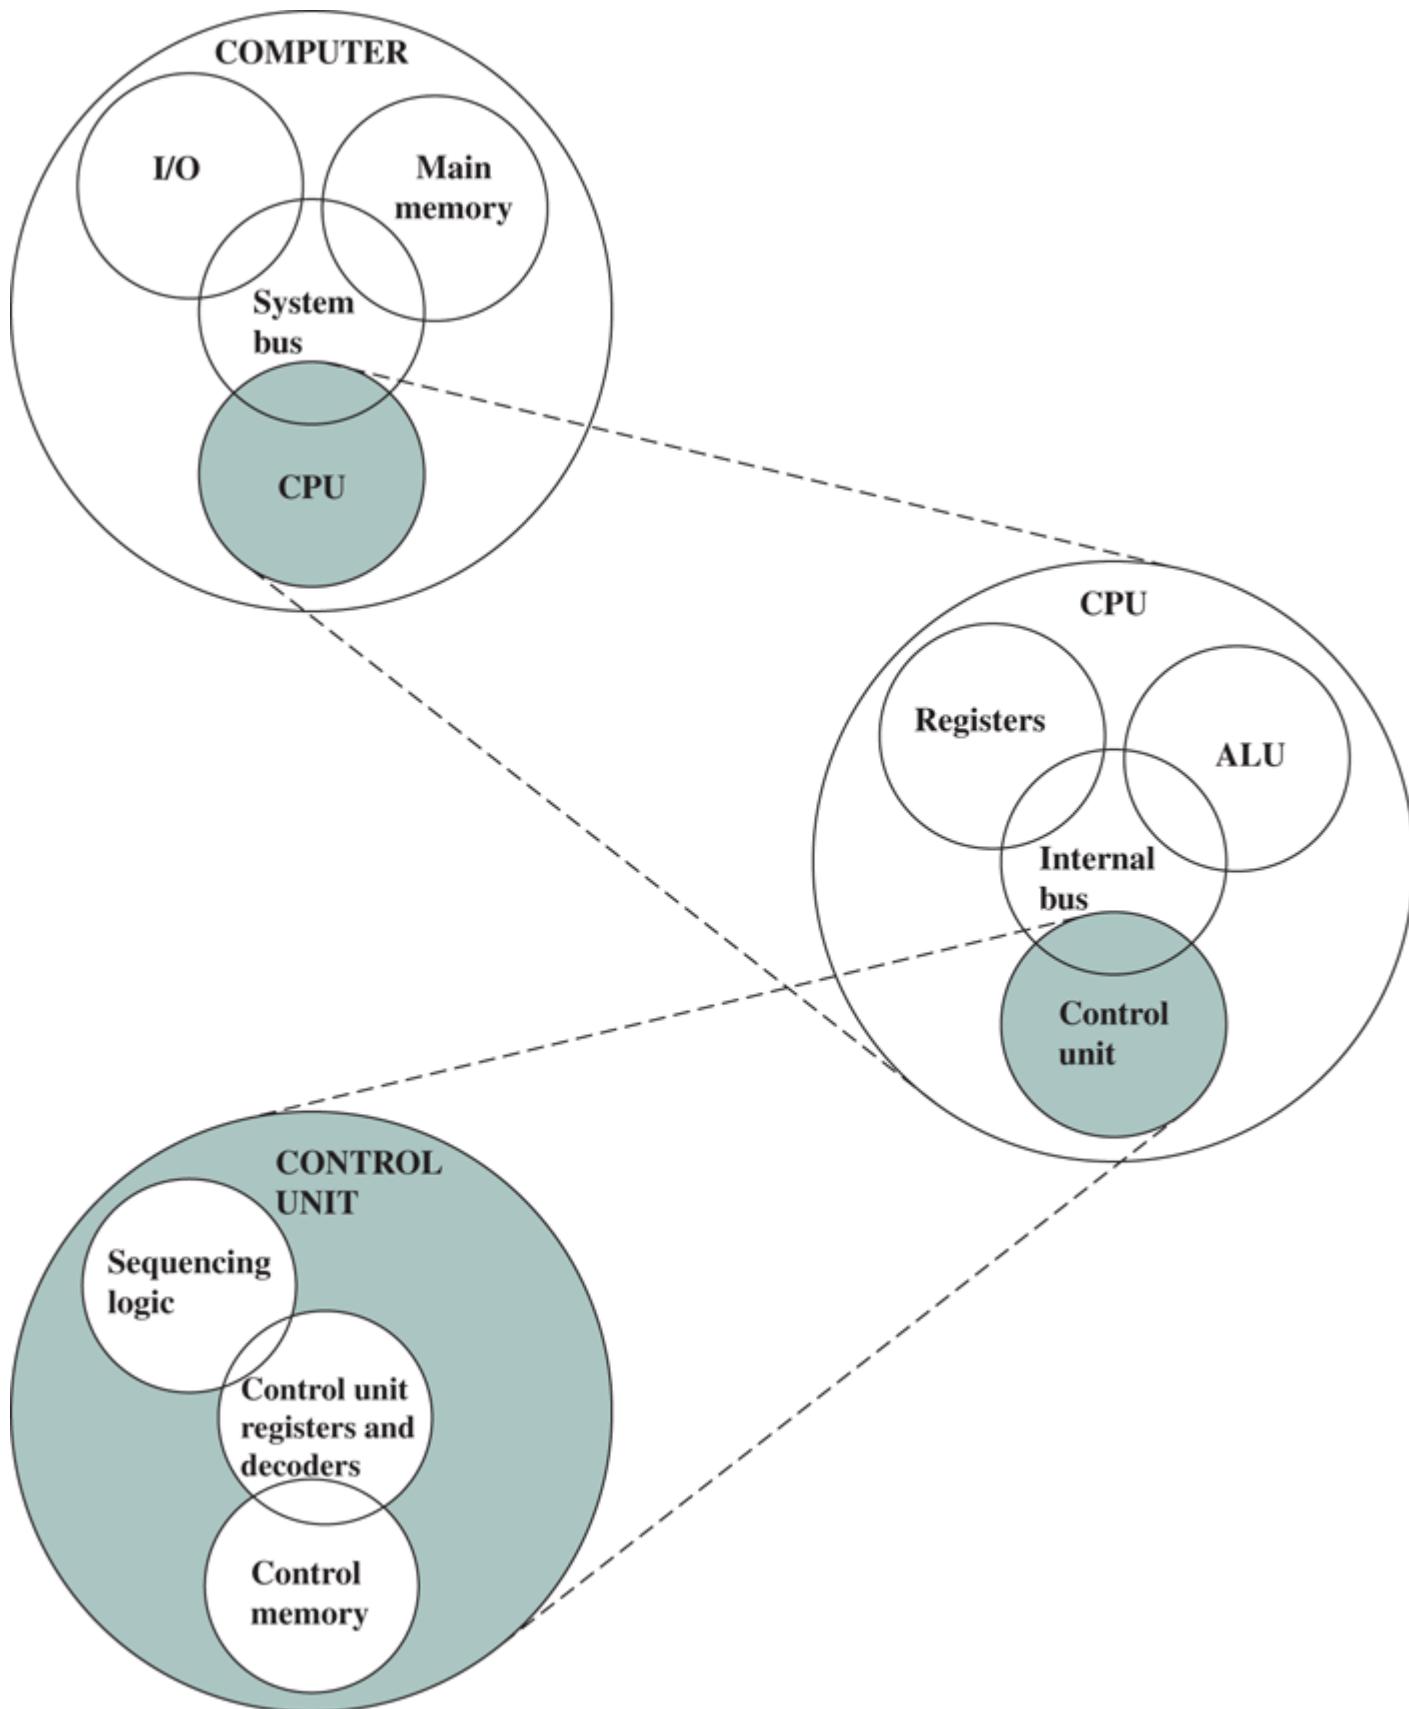

Figure 1.1 The Computer: Top-Level Structure

- **Central processing unit (CPU):** Controls the operation of the computer and performs its data processing functions; often simply referred to as **processor** .
- **Main memory:** Stores data.
- **I/O:** Moves data between the computer and its external environment.
- **System interconnection:** Some mechanism that provides for communication among CPU, main memory, and I/O. A common example of system interconnection is by means of a **system bus** ,

consisting of a number of conducting wires to which all the other components attach. There may be one or more of each of the aforementioned components. Traditionally, there has been just a single processor. In recent years, there has been increasing use of multiple processors in a single computer. Some design issues relating to multiple processors crop up and are discussed as the text proceeds; Part Five focuses on such computers.

Each of these components will be examined in some detail in Part Two. However, for our purposes, the most interesting and in some ways the most complex component is the CPU. Its major structural components are as follows:

- **Control unit:** Controls the operation of the CPU and hence the computer.
- **Arithmetic and logic unit (ALU):** Performs the computer's data processing functions.
- **Registers:** Provides storage internal to the CPU.
- **CPU interconnection:** Some mechanism that provides for communication among the control unit, ALU, and registers.

Part Three covers these components, where we will see that complexity is added by the use of parallel and pipelined organizational techniques. Finally, there are several approaches to the implementation of the control unit; one common approach is a *microprogrammed* implementation. In essence, a microprogrammed control unit operates by executing microinstructions that define the functionality of the control unit. With this approach, the structure of the control unit can be depicted, as in [Figure 1.1](#). This structure is examined in Part Four.

MULTICORE COMPUTER STRUCTURE

As was mentioned, contemporary computers generally have multiple processors. When these processors all reside on a single chip, the term *multicore computer* is used, and each processing unit (consisting of a control unit, ALU, registers, and perhaps cache) is called a *core*. To clarify the terminology, this text will use the following definitions.

- **Central processing unit (CPU):** That portion of a computer that fetches and executes instructions. It consists of an ALU, a control unit, and registers. In a system with a single processing unit, it is often simply referred to as a *processor*.
- **Core:** An individual processing unit on a processor chip. A core may be equivalent in functionality to a CPU on a single-CPU system. Other specialized processing units, such as one optimized for vector and matrix operations, are also referred to as cores.
- **Processor:** A physical piece of silicon containing one or more cores. The processor is the computer component that interprets and executes instructions. If a processor contains multiple cores, it is referred to as a [multicore processor](#).

After about a decade of discussion, there is broad industry consensus on this usage.

Another prominent feature of contemporary computers is the use of multiple layers of memory, called *cache memory*, between the processor and main memory. [Chapter 4](#) is devoted to the topic of cache memory. For our purposes in this section, we simply note that a cache memory is smaller and faster than main memory and is used to speed up memory access, by placing in the cache data from main memory, that is likely to be used in the near future. A greater performance improvement may be obtained by using multiple levels of cache, with level 1 (L1) closest to the core and additional levels (L2, L3, and so on) progressively farther from the core. In this scheme, level n is smaller and faster than level $n + 1$.

[Figure 1.2](#) is a simplified view of the principal components of a typical multicore computer. Most computers, including embedded computers in smartphones and tablets, plus personal computers, laptops, and workstations, are housed on a motherboard. Before describing this arrangement, we need to define some terms. A [printed circuit board \(PCB\)](#) is a rigid, flat board that holds and

interconnects chips and other electronic components. The board is made of layers, typically two to ten, that interconnect components via copper pathways that are etched into the board. The main printed circuit board in a computer is called a system board or **motherboard**, while smaller ones that plug into the slots in the main board are called expansion boards.

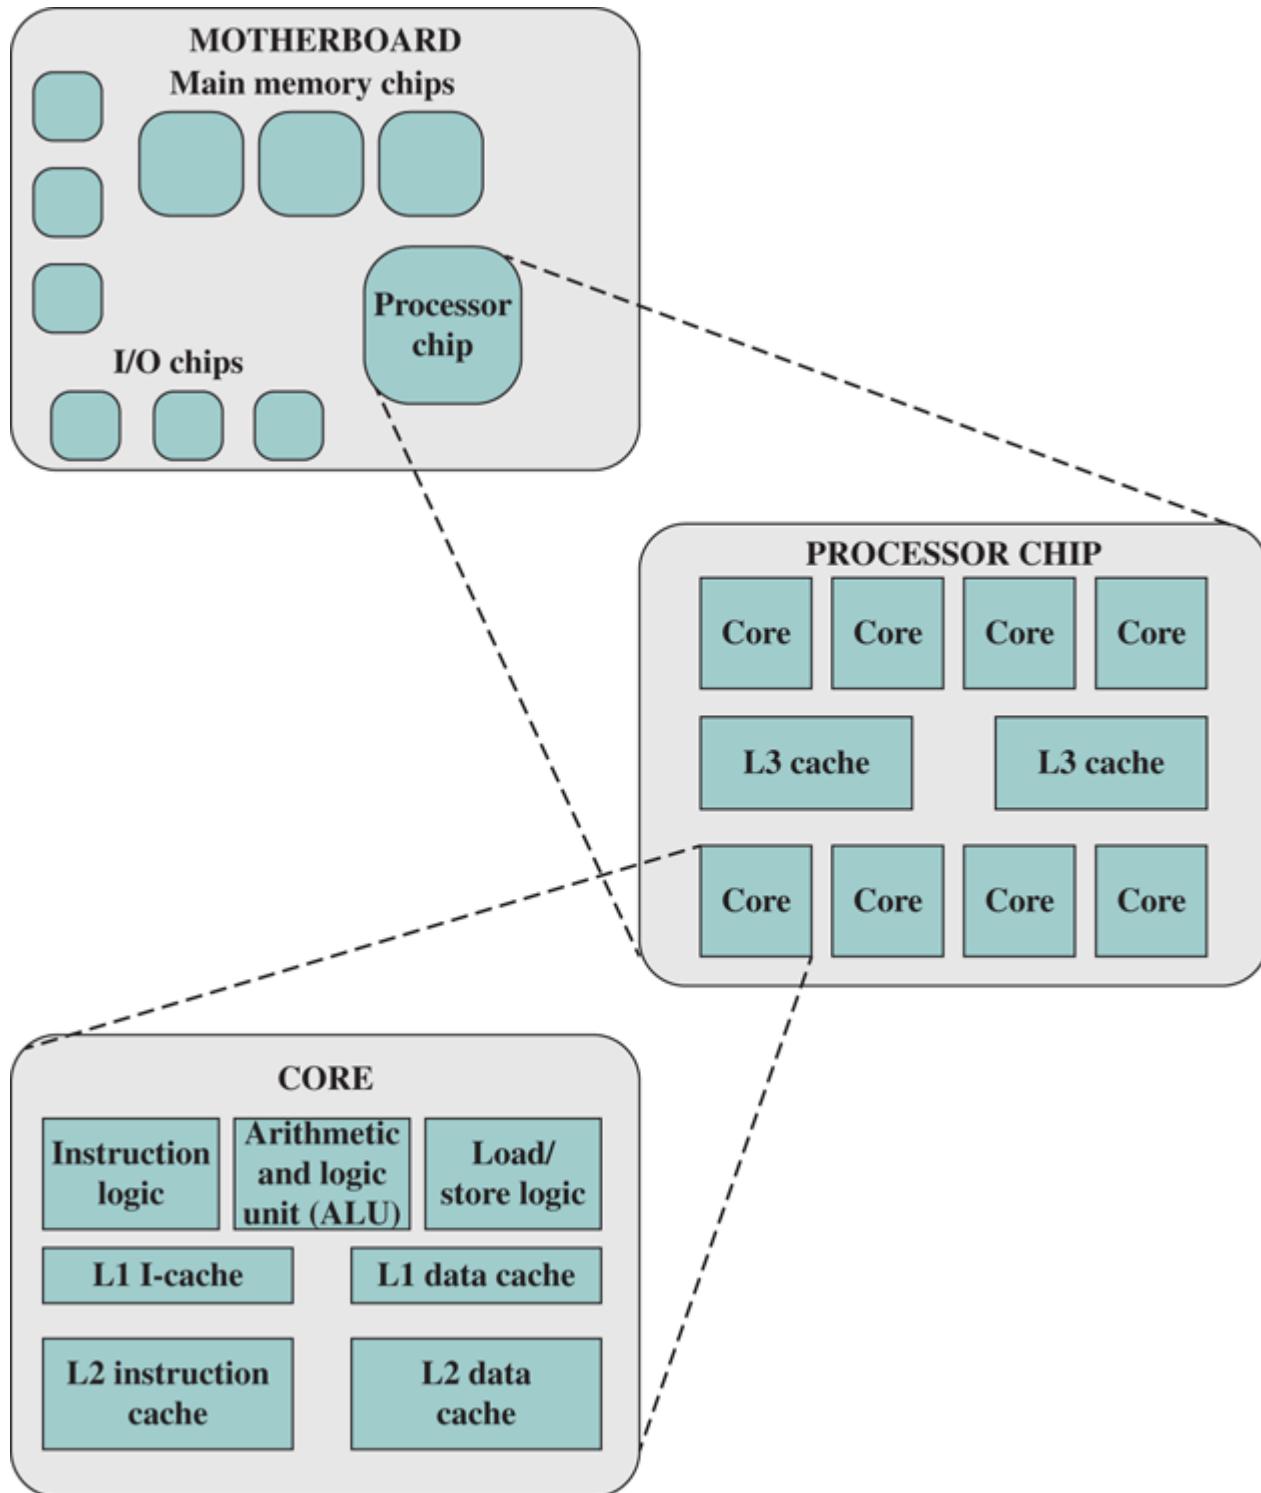

Figure 1.2 Simplified View of Major Elements of a Multicore Computer

The most prominent elements on the motherboard are the chips. A **chip** is a single piece of semiconducting material, typically silicon, upon which electronic circuits and logic gates are fabricated. The resulting product is referred to as an **integrated circuit**.

The motherboard contains a slot or socket for the processor chip, which typically contains multiple individual cores, in what is known as a *multicore processor*. There are also slots for memory chips, I/O controller chips, and other key computer components. For desktop computers, expansion slots enable

the inclusion of more components on expansion boards. Thus, a modern motherboard connects only a few individual chip components, with each chip containing from a few thousand up to hundreds of millions of transistors.

Figure 1.2 shows a processor chip that contains eight cores and an L3 cache. Not shown is the logic required to control operations between the cores and the cache and between the cores and the external circuitry on the motherboard. The figure indicates that the L3 cache occupies two distinct portions of the chip surface. However, typically, all cores have access to the entire L3 cache via the aforementioned control circuits. The processor chip shown in **Figure 1.2** does not represent any specific product, but provides a general idea of how such chips are laid out.

Next, we zoom in on the structure of a single core, which occupies a portion of the processor chip. In general terms, the functional elements of a core are:

- **Instruction logic:** This includes the tasks involved in fetching instructions, and decoding each instruction to determine the instruction operation and the memory locations of any operands.
- **Arithmetic and logic unit (ALU):** Performs the operation specified by an instruction.
- **Load/store logic:** Manages the transfer of data to and from main memory via cache.

The core also contains an L1 cache, split between an instruction cache (I-cache) that is used for the transfer of instructions to and from main memory, and an L1 data cache, for the transfer of operands and results. Typically, today's processor chips also include an L2 cache as part of the core. In many cases, this cache is also split between instruction and data caches, although a combined, single L2 cache is also used.

Keep in mind that this representation of the layout of the core is only intended to give a general idea of internal core structure. In a given product, the functional elements may not be laid out as the three distinct elements shown in **Figure 1.2**, especially if some or all of these functions are implemented as part of a microprogrammed control unit.

EXAMPLES

It will be instructive to look at some real-world examples that illustrate the hierarchical structure of computers. **Figure 1.3** is a photograph of the motherboard for a computer built around two Intel Quad-Core Xeon processor chips. Many of the elements labeled on the photograph are discussed subsequently in this book. Here, we mention the most important, in addition to the processor sockets:

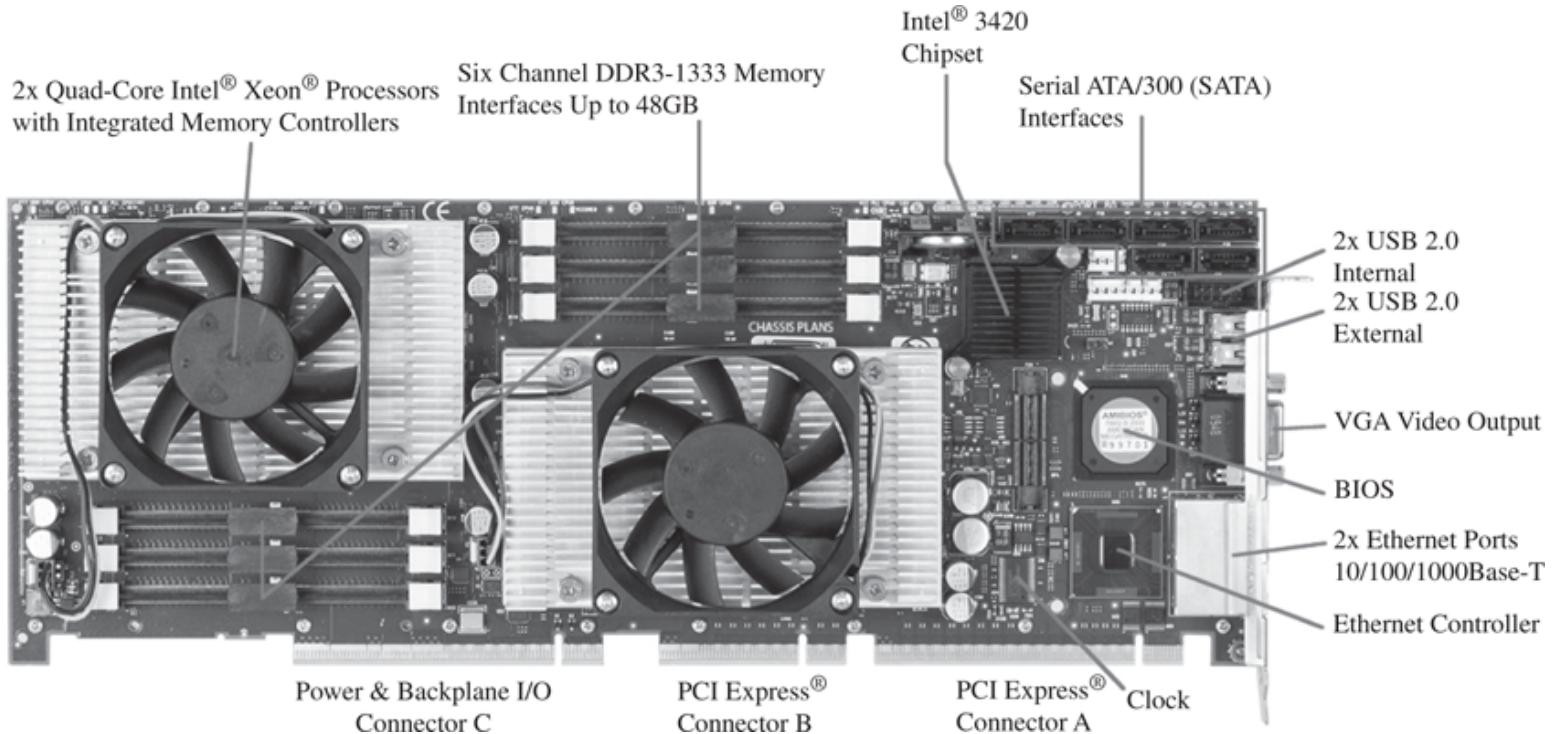

Figure 1.3 Motherboard with Two Intel Quad-Core Xeon Processors

Source: Courtesy of Chassis Plans Rugged Rackmount Computers

- PCI-Express slots for a high-end display adapter and for additional peripherals ([Section 3.6](#) describes PCIe).
- Ethernet controller and Ethernet ports for network connections.
- USB sockets for peripheral devices.
- Serial ATA (SATA) sockets for connection to disk memory ([Section 7.7](#) discusses Ethernet, USB, and SATA).
- Interfaces for DDR (double data rate) main memory chips ([Section 5.3](#) discusses DDR).
- Intel 3420 chipset is an I/O controller for direct memory access operations between peripheral devices and main memory ([Section 7.5](#) discusses DDR).

Following our top-down strategy, as illustrated in [Figures 1.1](#) and [1.2](#), we can now zoom in and look at the internal structure of a processor chip, referred to as a processor unit (PU). For variety, we look at an IBM chip instead of the Intel processor chip. [Figure 1.4](#) is a to-scale layout of the processor chip for the IBM z13 mainframe computer [LASC16]. This chip has 3.99 billion transistors. The superimposed labels indicate how the silicon surface area of the chip is allocated. We see that this chip has eight cores, or processors. In addition, a substantial portion of the chip is devoted to the L3 cache, which is shared by all eight cores. The L3 control logic controls traffic between the L3 cache and the cores and between the L3 cache and the external environment. Additionally, there is storage control (SC) logic between the cores and the L3 cache. The memory controller (MC) function controls access to memory external to the chip. The GX I/O bus controls the interface to the channel adapters accessing the I/O.

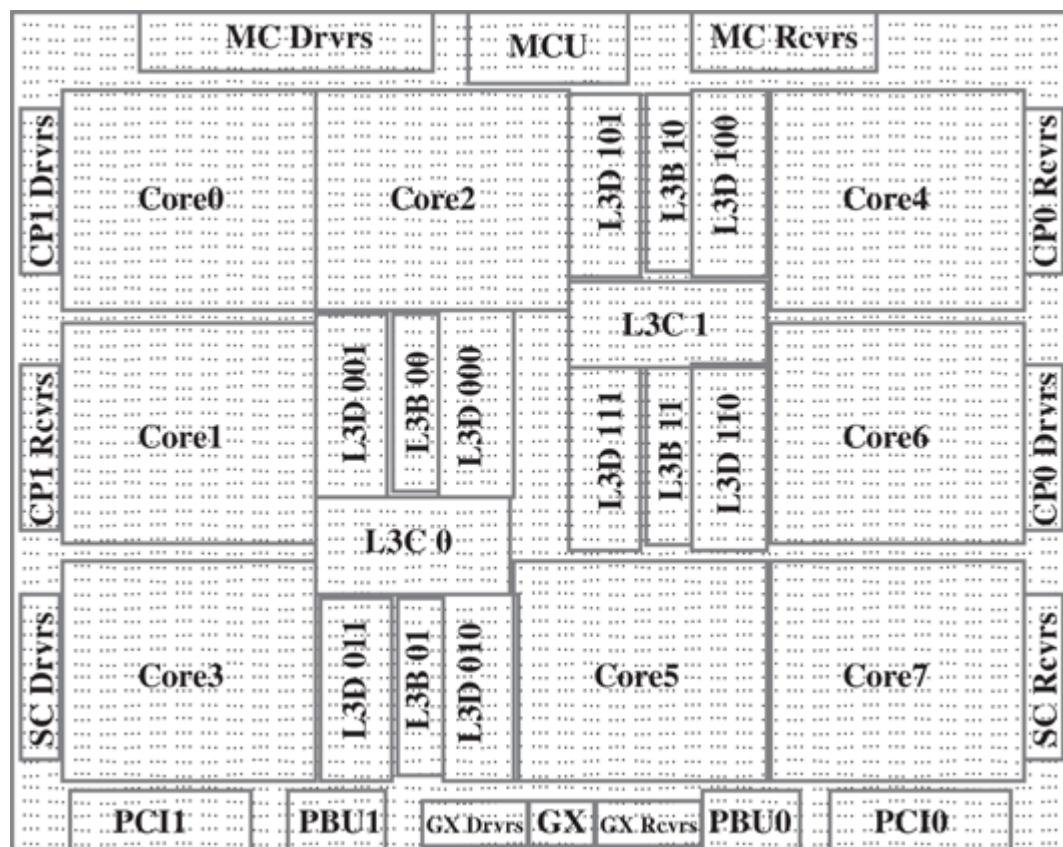

Figure 1.4 IBM z13 Processor Unit (PU) Chip Diagram

Going down one level deeper, we examine the internal structure of a single core, as shown in the photograph of [Figure 1.5](#). The core implements the z13 instruction set architecture, referred to as the z/Architecture. Keep in mind that this is a portion of the silicon surface area making up a single-processor chip. The main sub-areas within this core area are the following:

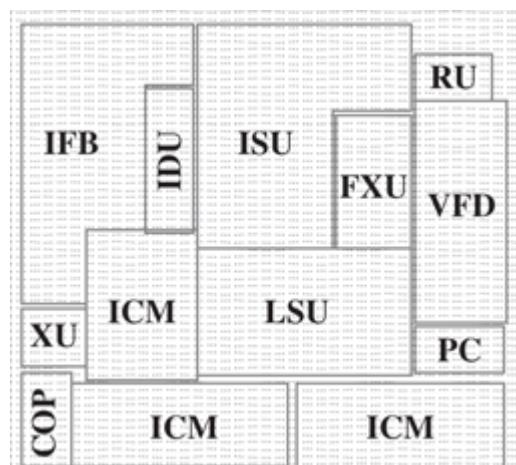

Figure 1.5 IBM z13 Core Layout

- **ISU (instruction sequence unit):** Determines the sequence in which instructions are executed in what is referred to as a superscalar architecture. It enables the out-of-order (OOO) pipeline. It tracks register names, OOO instruction dependency, and handling of instruction resource dispatch. These concepts are discussed in [Chapter 16](#).
- **IFB (instruction fetch and branch) and ICM (instruction cache and merge)** These two subunits contain the 128-kB¹ instruction cache, branch prediction logic, instruction fetching controls, and buffers. The relative size of these subunits is the result of the elaborate branch prediction design.

kB = kilobyte = 1048 bytes. Numerical prefixes are explained in a document under the “Other Useful” tab at ComputerScienceStudent.com.

- **IDU (instruction decode unit):** The IDU is fed from the IFU buffers, and is responsible for the parsing and decoding of all z/Architecture operation codes.
- **LSU (load-store unit):** The LSU contains the 96-kB L1 data cache, and manages data traffic between the L2 data cache and the functional execution units. It is responsible for handling all types of operand accesses of all lengths, modes, and formats as defined in the z/Architecture.
- **XU (translation unit):** This unit translates logical addresses from instructions into physical addresses in main memory. The XU also contains a translation lookaside buffer (TLB) used to speed up memory access. TLBs are discussed in [Chapter 8](#).
- **PC (core pervasive unit):** Used for instrumentation and error collection.
- **FXU (fixed-point unit):** The FXU executes fixed-point arithmetic operations.
- **VFU (vector and floating-point units):** The binary floating-unit part handles all binary and hexadecimal floating-point operations, as well as fixed-point multiplication operations. The decimal floating-unit part handles both fixed-point and floating-point operations on numbers that are stored as decimal digits. The vector execution part handles vector operations.
- **RU (recovery unit):** The RU keeps a copy of the complete state of the system that includes all registers, collects hardware fault signals, and manages the hardware recovery actions.
- **COP (dedicated co-processor):** The COP is responsible for data compression and encryption functions for each core.
- **L2D:** A 2-MB L2 data cache for all memory traffic other than instructions.
- **L2I:** A 2-MB L2 instruction cache.

As we progress through the book, the concepts introduced in this section will become clearer.

1.3 The IAS Computer

The first generation of computers used vacuum tubes for digital logic elements and memory. A number of research and then commercial computers were built using vacuum tubes. For our purposes, it will be instructive to examine perhaps the most famous first-generation computer, known as the IAS computer. This example illustrates many of the fundamental concepts found in all computer systems.

A fundamental design approach first implemented in the IAS computer is known as the *stored-program concept*. This idea is usually attributed to the mathematician John von Neumann. Alan Turing developed the idea at about the same time. The first publication of the idea was in a 1945 proposal by von Neumann for a new computer, the EDVAC (Electronic Discrete Variable Computer).²

² The 1945 report on EDVAC is available at box.com/COA11e.

In 1946, von Neumann and his colleagues began the design of a new stored-program computer, referred to as the IAS computer, at the Princeton Institute for Advanced Studies. The IAS computer, although not completed until 1952, is the prototype of all subsequent general-purpose computers.³

³ A 1954 report [GOLD54] describes the implemented IAS machine and lists the final instruction set. It is available at box.com/COA11e.

Figure 1.6 shows the structure of the IAS computer (compare with **Figure 1.1**). It consists of

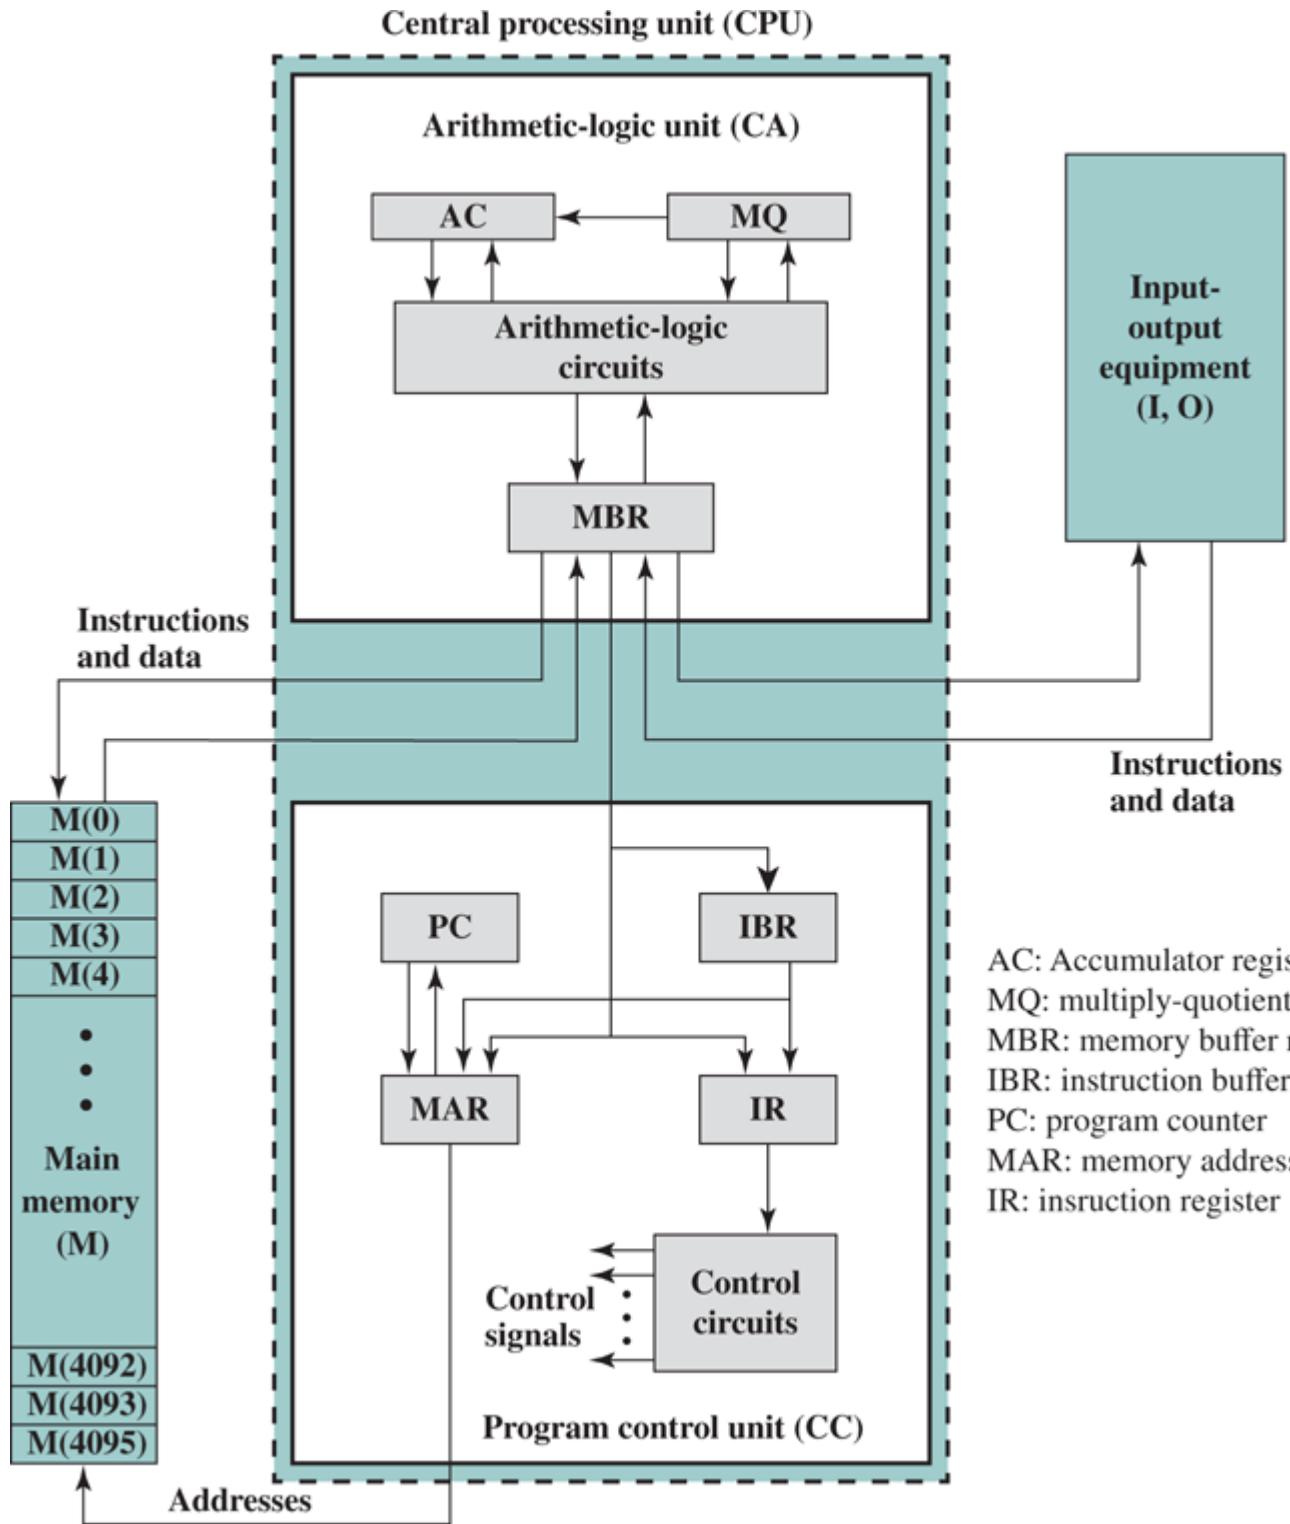

Figure 1.6 IAS Structure

- A **main memory**, which stores both data and instructions⁴

⁴ In this book text, unless otherwise noted, the term *instruction* refers to a machine instruction that is directly interpreted and executed by the processor, in contrast to a statement in a high-level language, such as Ada or C++, which must first be compiled into a series of machine instructions before being executed.

- An **arithmetic and logic unit (ALU)** capable of operating on binary data
- A **control unit**, which interprets the instructions in memory and causes them to be executed
- **Input–output (I/O)** equipment operated by the control unit

This structure was outlined in von Neumann's earlier proposal, which is worth quoting in part at this

AC: Accumulator register
 MQ: multiply-quotient register
 MBR: memory buffer register
 IBR: instruction buffer register
 PC: program counter
 MAR: memory address register
 IR: instruction register

point [VONN45]:

2.2 First: Since the device is primarily a computer, it will have to perform the elementary operations of arithmetic most frequently. These are addition, subtraction, multiplication, and division. It is therefore reasonable that it should contain specialized organs for just these operations.

It must be observed, however, that while this principle as such is probably sound, the specific way in which it is realized requires close scrutiny. At any rate a *central arithmetical* part of the device will probably have to exist, and this constitutes *the first specific part: CA*.

2.3 Second: The logical control of the device, that is, the proper sequencing of its operations, can be most efficiently carried out by a central control organ. If the device is to be *elastic*, that is, as nearly as possible *all purpose*, then a distinction must be made between the specific instructions given for and defining a particular problem, and the general control organs that see to it that these instructions—no matter what they are—are carried out. The former must be stored in some way; the latter are represented by definite operating parts of the device. By the *central control* we mean this latter function only, and the organs that perform it form *the second specific part: CC*.

2.4 Third: Any device that is to carry out long and complicated sequences of operations (specifically of calculations) must have a considerable memory . . .

The instructions which govern a complicated problem may constitute considerable material, particularly so if the code is circumstantial (which it is in most arrangements). This material must be remembered.

At any rate, the total *memory* constitutes *the third specific part of the device: M*.

2.6 The three specific parts CA, CC (together C), and M correspond to the *associative* neurons in the human nervous system. It remains to discuss the equivalents of the *sensory* or *afferent* and the *motor* or *efferent* neurons. These are the *input* and *output* organs of the device.

The device must be endowed with the ability to maintain input and output (sensory and motor) contact with some specific medium of this type. The medium will be called the *outside recording medium of the device: R*.

2.7 Fourth: The device must have organs to transfer information from R into its specific parts C and M. These organs form its *input*, the *fourth specific part: I*. It will be seen that it is best to make all transfers from R (by I) into M and never directly from C.

2.8 Fifth: The device must have organs to transfer from its specific parts C and M into R. These organs form its *output*, the *fifth specific part: O*. It will be seen that it is again best to make all

transfers from M (by O) into R, and never directly from C.

With rare exceptions, all of today's computers have this same general structure and function and are thus referred to as *von Neumann machines*. Thus, it is worthwhile at this point to describe briefly the operation of the IAS computer [BURK46, GOLD54]. Following [HAYE98], the terminology and notation of von Neumann are changed in the following to conform more closely to modern usage; the examples accompanying this discussion are based on that latter text.

The memory of the IAS consists of 4,096 storage locations, called *words*, of 40 binary digits (bits) each.⁵ Both data and instructions are stored there. Numbers are represented in binary form, and each instruction is a binary code. [Figure 1.7](#) illustrates these formats. Each number is represented by a sign bit and a 39-bit value. A word may alternatively contain two 20-bit instructions, with each instruction consisting of an 8-bit operation code (opcode) specifying the operation to be performed and a 12-bit address designating one of the words in memory (numbered from 0 to 999).

⁵ There is no universal definition of the term *word*. In general, a word is an ordered set of bytes or bits that is the normal unit in which information may be stored, transmitted, or operated on within a given computer. Typically, if a processor has a fixed-length instruction set, then the instruction length equals the word length.

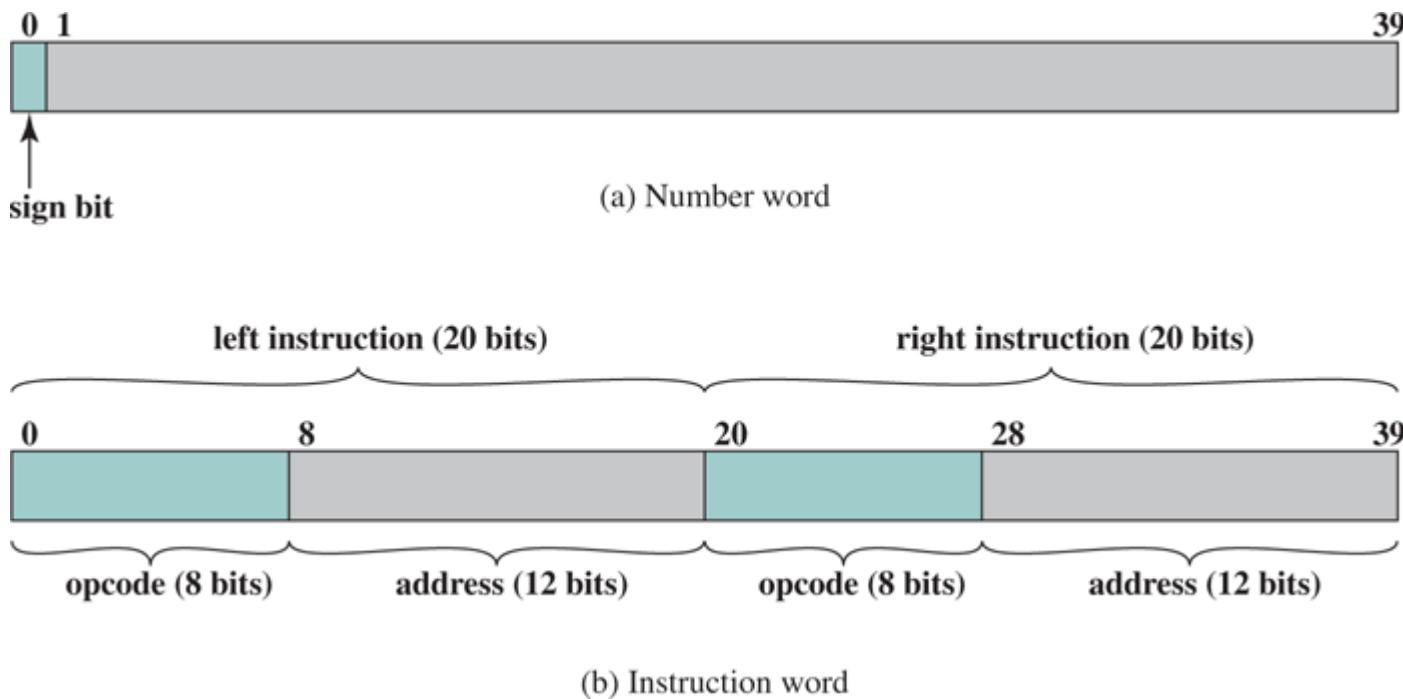

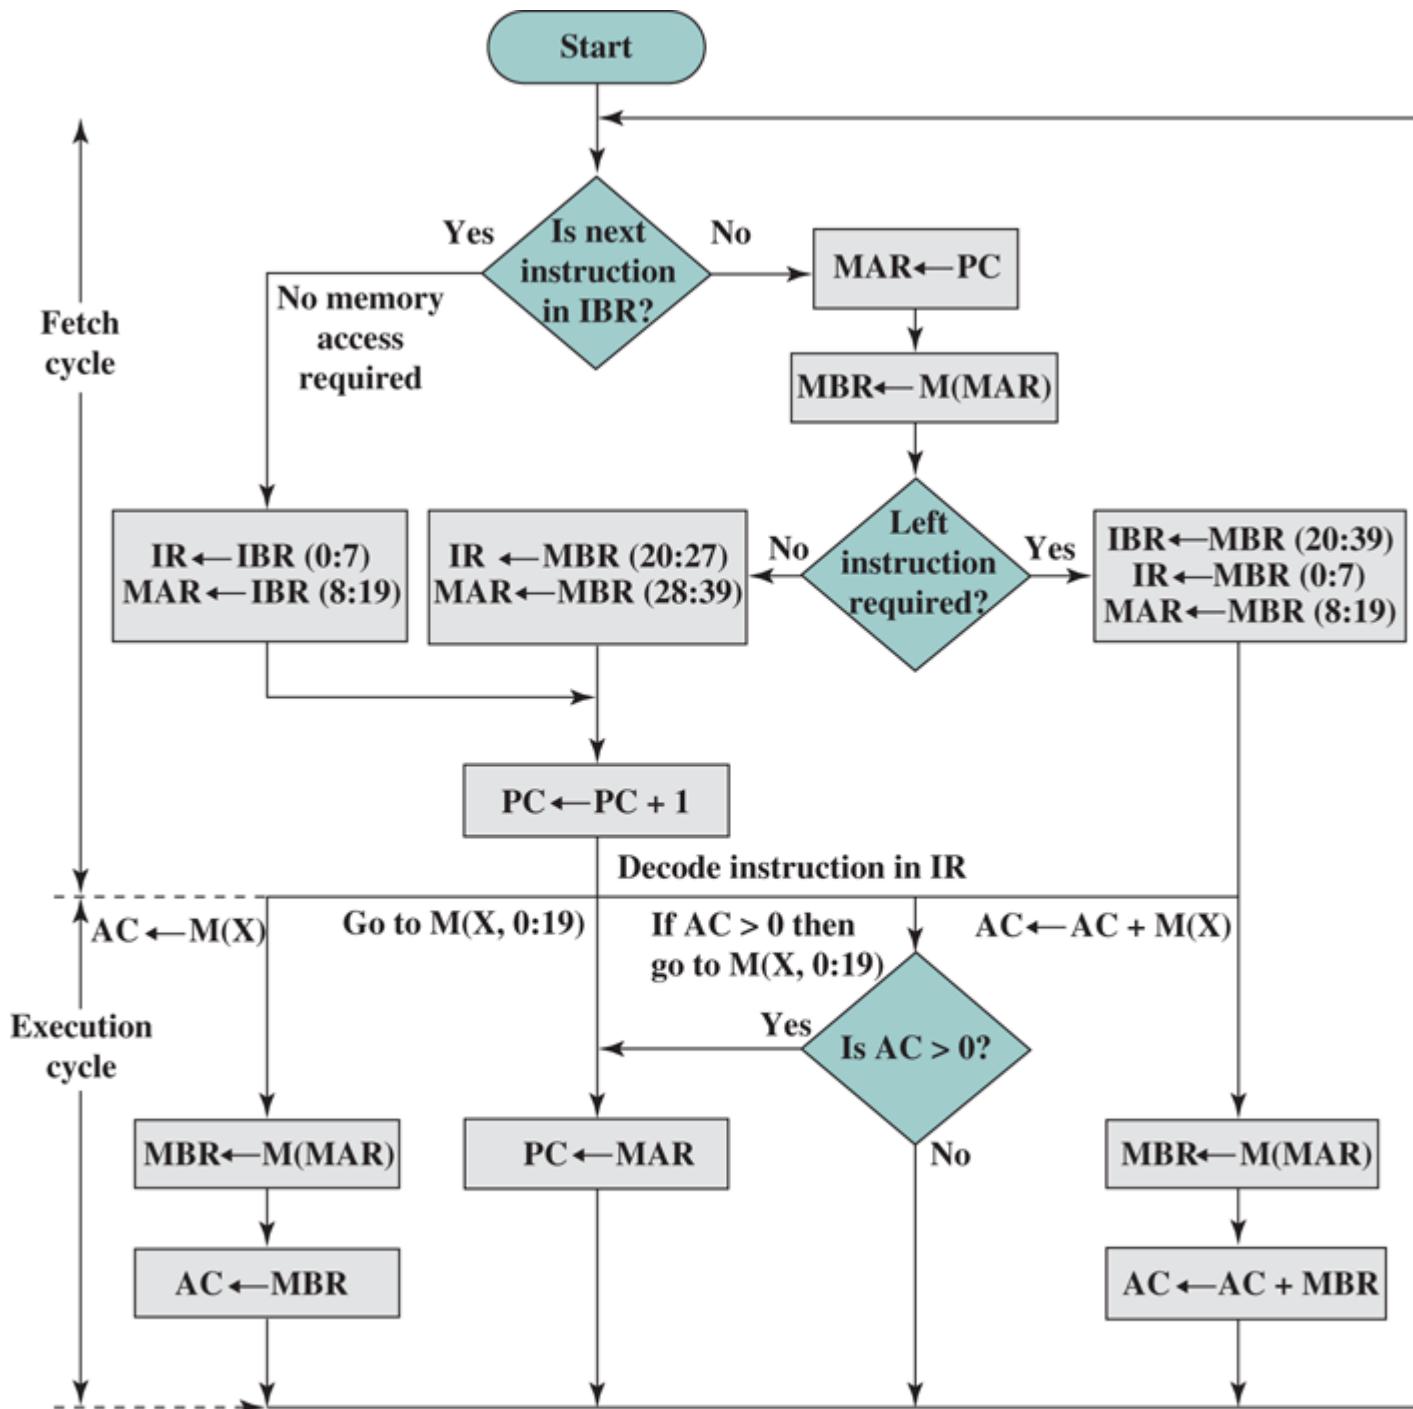

Figure 1.7 IAS Memory Formats

The control unit operates the IAS by fetching instructions from memory and executing them one at a time. We explain these operations with reference to [Figure 1.6](#). This figure reveals that both the control unit and the ALU contain storage locations, called *registers*, defined as follows:

- **Memory buffer register (MBR):** Contains a word to be stored in memory or sent to the I/O unit, or is used to receive a word from memory or from the I/O unit.
- **Memory address register (MAR):** Specifies the address in memory of the word to be written from or read into the MBR.
- **Instruction register (IR):** Contains the 8-bit opcode instruction being executed.
- **Instruction buffer register (IBR):** Employed to hold temporarily the right-hand instruction from a word in memory.

- **Program counter (PC):** Contains the address of the next instruction pair to be fetched from memory.
- **Accumulator (AC) and multiplier quotient (MQ):** Employed to hold temporarily operands and results of ALU operations. For example, the result of multiplying two 40-bit numbers is an 80-bit number; the most significant 40 bits are stored in the AC and the least significant in the MQ.

The IAS operates by repetitively performing an *instruction cycle*, as shown in **Figure 1.8**. Each instruction cycle consists of two subcycles. During the *fetch cycle*, the opcode of the next instruction is loaded into the IR and the address portion is loaded into the MAR. This instruction may be taken from the IBR, or it can be obtained from memory by loading a word into the MBR, and then down to the IBR, IR, and MAR.

$M(X) = \text{contents of memory location whose address is } X$
 $(i:j) = \text{bits } i \text{ through } j$

Figure 1.8 Partial Flowchart of IAS Operation

Why the indirection? These operations are controlled by electronic circuitry and result in the use of data paths. To simplify the electronics, there is only one register that is used to specify the address in memory for a read or write and only one register used for the source or destination.

Once the opcode is in the IR, the *execute cycle* is performed. Control circuitry interprets the opcode and executes the instruction by sending out the appropriate control signals to cause data to be moved or an operation to be performed by the ALU.

The IAS computer had a total of 21 instructions, which are listed in **Table 1.1**. These can be grouped as follows:

Table 1.1 The IAS Instruction Set

Instruction Type	Opcode	Symbolic Representation	Description
Data transfer	00001010	LOAD MQ	Transfer contents of register MQ to the accumulator AC
	00001001	LOAD MQ,M(X)	Transfer contents of memory location X to MQ
	00100001	STOR M(X)	Transfer contents of accumulator to memory location X
	00000001	LOAD M(X)	Transfer M(X) to the accumulator
	00000010	LOAD -M(X)	Transfer -M(X) to the accumulator
	00000011	LOAD M(X)	Transfer absolute value of M(X) to the accumulator
	00000100	LOAD - M(X)	Transfer - M(X) to the accumulator
Unconditional branch	00001101	JUMP M(X,0:19)	Take next instruction from left half of M(X)
	00001110	JUMP M(X,20:39)	Take next instruction from right half of M(X)
Conditional branch	00001111	JUMP + M(X,0:19)	If number in the accumulator is nonnegative, take next instruction from left half of M(X)
	00010000	JUMP + M(X,20:39)	If number in the accumulator is nonnegative, take next instruction from right half of M(X)
Arithmetic	00000101	ADD M(X)	Add M(X) to AC; put the result in AC
	00000111	ADD M(X)	Add M(X) to AC; put the result in AC

	00000110	SUB M(X)	Subtract M(X) from AC; put the result in AC
	00001000	SUB M(X)	Subtract M(X) from AC; put the remainder in AC
	00001011	MUL M(X)	Multiply M(X) by MQ; put most significant bits of result in AC, put least significant bits in MQ
	00001100	DIV M(X)	Divide AC by M(X); put the quotient in MQ and the remainder in AC
	00010100	LSH	Multiply accumulator by 2; that is, shift left one bit position
	00010101	RSH	Divide accumulator by 2; that is, shift right one position
Address modify	00010010	STOR M(X,8:19)	Replace left address field at M(X) by 12 rightmost bits of AC
	00010011	STOR M(X,28:39)	Replace right address field at M(X) by 12 rightmost bits of AC

- **Data transfer:** Move data between memory and ALU registers or between two ALU registers.
- **Unconditional branch:** Normally, the control unit executes instructions in sequence from memory. This sequence can be changed by a branch instruction, which facilitates repetitive operations.
- **Conditional branch:** The branch can be made dependent on a condition, thus allowing decision points.
- **Arithmetic:** Operations performed by the ALU.
- **Address modify:** Permits addresses to be computed in the ALU and then inserted into instructions stored in memory. This allows a program considerable addressing flexibility.

Table 1.1 presents instructions (excluding I/O instructions) in a symbolic, easy-to-read form. In binary form, each instruction must conform to the format of **Figure 1.7b**. The opcode portion (first 8 bits) specifies which of the 21 instructions is to be executed. The address portion (remaining 12 bits) specifies which of the 4,096 memory locations is to be involved in the execution of the instruction.

Figure 1.8 shows several examples of instruction execution by the control unit. Note that each operation requires several steps, some of which are quite elaborate. The multiplication operation requires 39 suboperations, one for each bit position except that of the sign bit.

1.4 Gates, Memory Cells, Chips, and Multichip Modules

Gates and Memory Cells

The basic elements of a digital computer, as we know, must perform data storage, movement, processing, and control functions. Only two fundamental types of components are required (**Figure 1.9**): gates and memory cells. A **gate** is a device that implements a simple Boolean or logical function. For example, an AND gate with inputs *A* and *B* and output *C* implements the expression IF *A* AND *B* ARE TRUE THEN *C* IS TRUE. Such devices are called gates because they control data flow in much the same way that canal gates control the flow of water. The **memory cell** is a device that can store one bit of data; that is, the device can be in one of two stable states at any time. By interconnecting large numbers of these fundamental devices, we can construct a computer. We can relate this to our four basic functions as follows:

- **Data storage:** Provided by memory cells.
- **Data processing:** Provided by gates.
- **Data movement:** The paths among components are used to move data from memory to memory and from memory through gates to memory.
- **Control:** The paths among components can carry control signals. For example, a gate will have one or two data inputs plus a control signal input that activates the gate. When the control signal is ON, the gate performs its function on the data inputs and produces a data output. Conversely, when the control signal is OFF, the output line is null, such as is produced by a high impedance state. Similarly, the memory cell will store the bit that is on its input lead when the WRITE control signal is ON and will place the bit that is in the cell on its output lead when the READ control signal is ON.

Thus, a computer consists of gates, memory cells, and interconnections among these elements. The gates and memory cells are, in turn, constructed of simple electronic components, such as transistors and capacitors.

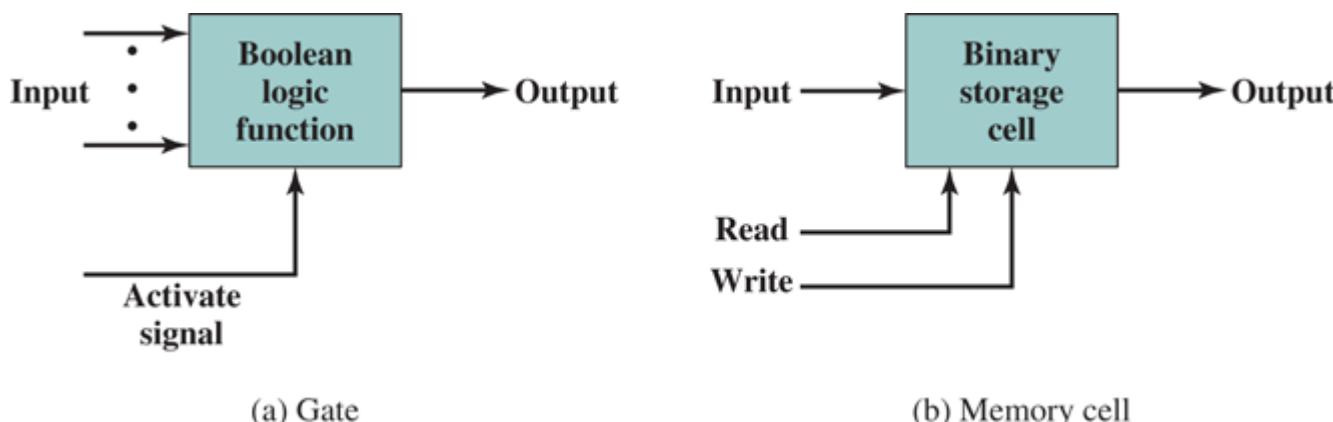

Figure 1.9 Fundamental Computer Elements

Transistors

The fundamental building block of digital circuits used to construct processors, memories, and other digital logic devices is the transistor. The active part of the transistor is made of silicon or some other semiconductor material that can change its electrical state when pulsed. In its normal state, the material may be nonconductive or conductive, either impeding or allowing current flow. When voltage is applied to the gate, the transistor changes its state.

A single, self-contained transistor is called a *discrete component*. Throughout the 1950s and early 1960s, electronic equipment was composed largely of discrete components—transistors, resistors, capacitors, and so on. Discrete components were manufactured separately, packaged in their own containers, and soldered or wired together onto Masonite-like circuit boards, which were then installed in computers, oscilloscopes, and other electronic equipment. Whenever an electronic device called for a transistor, a little tube of metal containing a pinhead-sized piece of silicon had to be soldered to a circuit board. The entire manufacturing process, from transistor to circuit board, was expensive and cumbersome.

These facts of life were beginning to create problems in the computer industry. Early second-generation computers contained about 10,000 transistors. This figure grew to the hundreds of thousands, making the manufacture of newer, more powerful machines increasingly difficult.

Microelectronic Chips

Microelectronics means, literally, “small electronics.” Since the beginning of digital electronics and the computer industry, there has been a consistent trend toward the reduction in size of digital electronic circuits. Before examining the implications and benefits of this trend, we need to say something about the nature of digital electronics. A more detailed discussion is found in [Chapter 12](#).

The integrated circuit exploits the fact that such components as transistors, resistors, and conductors can be fabricated from a semiconductor such as silicon. It is merely an extension of the solid-state art to fabricate an entire circuit in a tiny piece of silicon rather than assemble discrete components made from separate pieces of silicon into the same circuit. Many transistors can be produced at the same time on a single wafer of silicon. Equally important, these transistors can be connected with a process of metallization to form circuits.

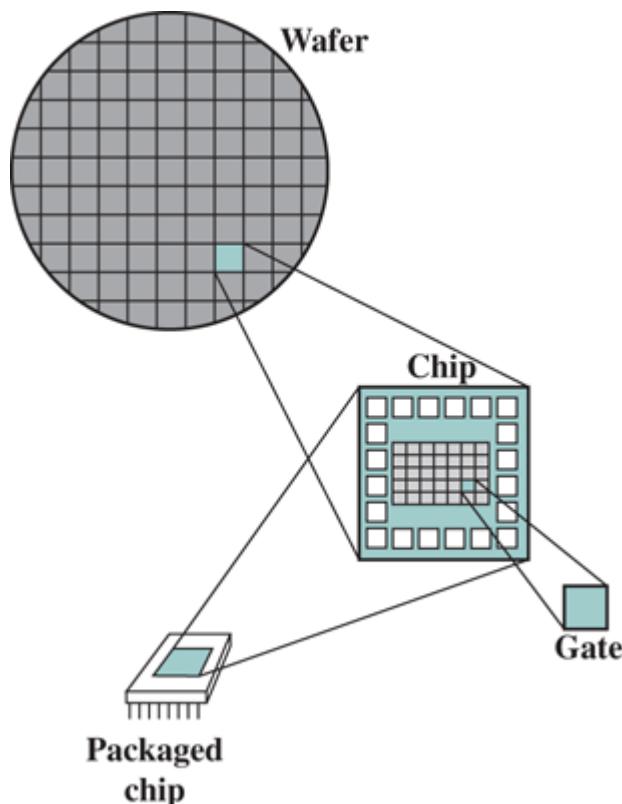

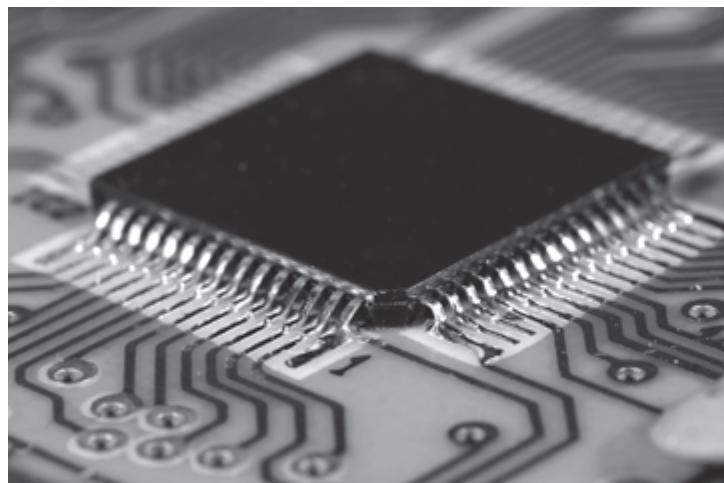

Figure 1.10 Relationship among Wafer, Chip, and Gate

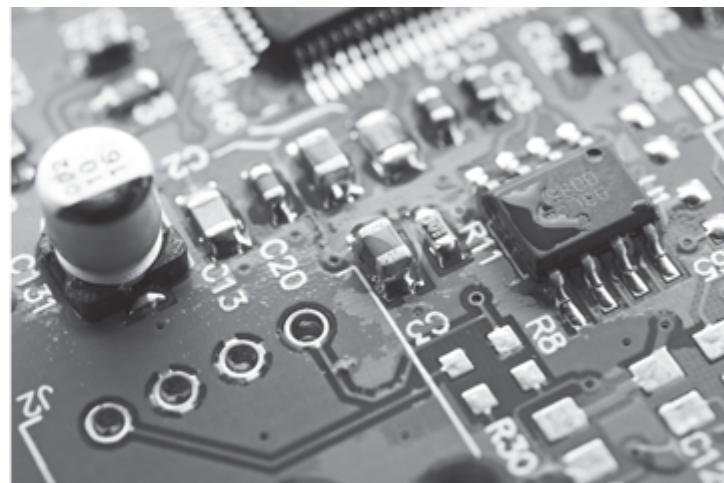

[Figure 1.10](#) depicts the key concepts in an integrated circuit. A thin *wafer* of silicon is divided into a

matrix of small areas, each a few millimeters square. The identical circuit pattern is fabricated in each area, and the wafer is broken up into chips. Each chip consists of many gates and/or memory cells plus a number of input and output attachment points. This chip is then packaged in housing that protects it and provides pins for attachment to devices beyond the chip. A number of these packages can then be interconnected on a printed circuit board to produce larger and more complex circuits.

Figure 1.11a indicates what a packaged processor or memory chip looks like, and **Figure 1.11b** shows a packaged chip wired onto a motherboard.

(a) Close-up of packaged chip

(b) Chip on motherboard

Figure 1.11 Processor or Memory Chip on Motherboard

Krzysztof Gorski/Shutterstock

Nikolich/Shutterstock

Initially, only a few gates or memory cells could be reliably manufactured and packaged together. These early integrated circuits are referred to as *small-scale integration* (SSI). As time went on, it became possible to pack more and more components on the same chip. This growth in density is illustrated in [Figure 1.12](#); it is one of the most remarkable technological trends ever recorded.⁶ This figure reflects the famous Moore's law, which was propounded by Gordon Moore, cofounder of Intel, in 1965 [MOOR65]. Moore observed that the number of transistors that could be put on a single chip was doubling every year, and correctly predicted that this pace would continue into the near future. To the surprise of many, including Moore, the pace continued year after year and decade after decade. The pace slowed to a doubling every 18 months in the 1970s, but has sustained that rate ever since.

⁶ Note that the vertical axis uses a log scale. A basic review of log scales is in the math refresher document at the Computer Science Student Resource Site at ComputerScienceStudent.com.

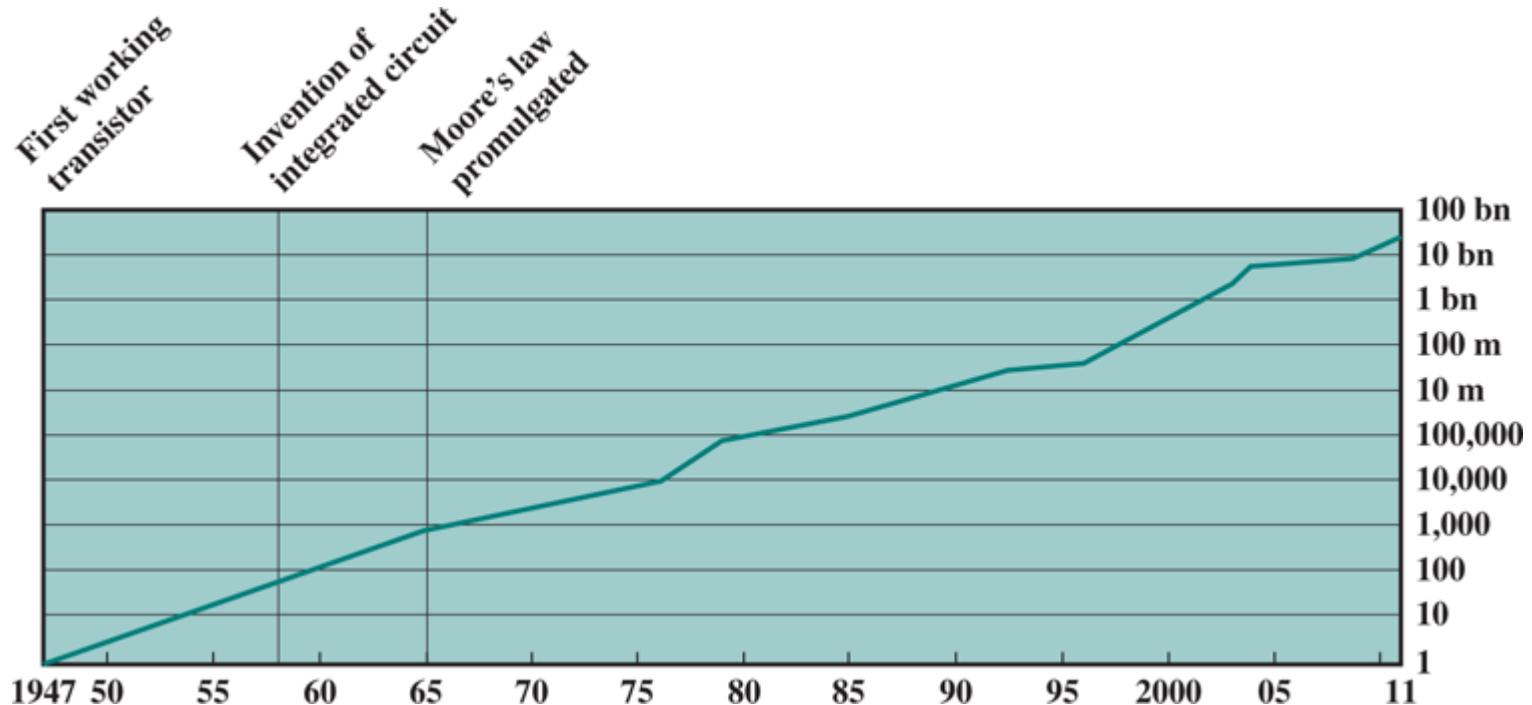

Figure 1.12 Growth in Transistor Count on Integrated Circuits

The consequences of Moore's law are profound:

1. The cost of a chip has remained virtually unchanged during this period of rapid growth in density. This means that the cost of computer logic and memory circuitry has fallen at a dramatic rate.
2. Because logic and memory elements are placed closer together on more densely packed chips, the electrical path length is shortened, increasing operating speed.
3. The computer becomes smaller, making it more convenient to place in a variety of environments.
4. There is a reduction in power requirements.
5. The interconnections on the integrated circuit are much more reliable than solder connections. With more circuitry on each chip, there are fewer interchip connections.

Multichip Module

The increasing requirements for denser and faster memories have led to efforts to further compact standard packaging approaches, with one of the most important and widely used being the multichip module. In traditional system design, each individual process or memory chip is packaged and then wired to a motherboard (see [Figure 1.11](#)).

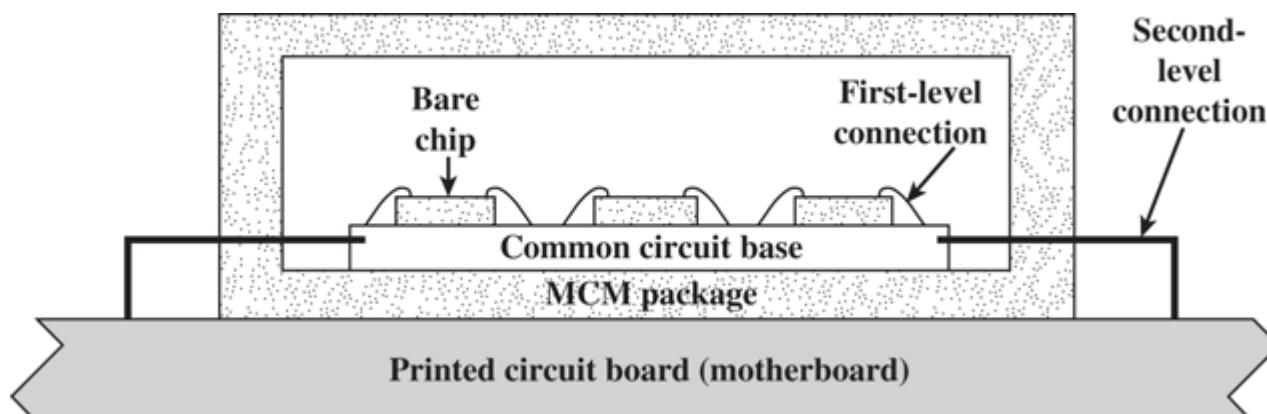

Figure 1.13 Multichip Module

The basic idea behind developing MCM technology is to decrease the average spacing between ICs in an electronic system. An MCM is a chip package that contains several bare chips mounted close together on a substrate (base) of some kind and interconnected by conductors in that base. The short tracks between the chips increase performance and eliminate much of the noise that external tracks between individual chip packages can pick up.

MCMs are classified by substrate, which include the following types [BLUM99]:

- **MCM-L:** composed of metal traces on stacked organic laminate sheets.
- **MCM-C:** metal patterned and interconnected on co-fired ceramic layers.
- **MCM-D:** vapor-deposited, patterned metal layers alternating sequentially with spun-on or vapor-deposited dielectric thin films.

The basic architecture of an MCM is composed of ([Figure 1.13](#)):

- **Integrated circuits:** Bare chips mounted on/in the surface of the substrate.
- **Level-1 interconnections:** Connections between chips through paths in the substrate.
- **Substrate:** The common base that provides all the signal interconnections and the mechanical support for all chips
- **MCM package:** Provides a degree of protection to the circuits in addition to heat removal and interconnections.
- **Level-2 interconnections:** Provides the necessary interface to the printed circuit board on which the MCM is mounted.

1.5 The Evolution of the Intel x86 Architecture

Throughout this book, we rely on many concrete examples of computer design and implementation to illustrate concepts and to illuminate trade-offs. Numerous systems, both contemporary and historical, provide examples of important computer architecture design features. But the book relies principally on examples from two processor families: the Intel x86 and the ARM architectures. The current x86 offerings represent the results of decades of design effort on **complex instruction set computers (CISCs)**. The x86 incorporates the sophisticated design principles once found only on mainframes and supercomputers and serves as an excellent example of CISC design. An alternative approach to processor design is the **reduced instruction set computer (RISC)** . The ARM architecture is used in a wide variety of embedded systems and is one of the most powerful and best-designed RISC-based systems on the market. In this section and the next, we provide a brief overview of these two systems.

In terms of market share, Intel has ranked as the number one maker of microprocessors for non-embedded systems for decades, a position it seems unlikely to yield. The evolution of its flagship microprocessor product serves as a good indicator of the evolution of computer technology in general.

Table 1.3 shows that evolution. Interestingly, as microprocessors have grown faster and much more complex, Intel has actually picked up the pace. Intel used to develop microprocessors one after another, every four years. But Intel hopes to keep rivals at bay by trimming a year or two off this development time, and has done so with the most recent x86 generations.⁷

⁷ Intel refers to this as the *tick-tock model*. Using this model, Intel has successfully delivered next-generation silicon technology as well as new processor microarchitecture on alternating years for the past several years. See <http://www.intel.com/content/www/us/en/silicon-innovations/intel-tick-tock-model-general.html>.

Table 1.3 Evolution of Intel Microprocessors (page 1 of 2)

	(a) 1970s Processors				
	4004	8008	8080	8086	8088
Introduced	1971	1972	1974	1978	1979
Clock speeds	108 kHz	108 kHz	2 MHz	5 MHz, 8 MHz, 10 MHz	5 MHz, 8 MHz
Bus width	4 bits	8 bits	8 bits	16 bits	8 bits
Number of transistors	2,300	3,500	6,000	29,000	29,000
Feature size (μm)	10	8	6	3	6
Addressable memory	640 bytes	16 KB	64 KB	1 MB	1 MB

(b) 1980s Processors

	80286	386TM DX	386TM SX	486TM DX CPU
Introduced	1982	1985	1988	1989
Clock speeds	6–12.5 MHz	16–33 MHz	16–33 MHz	25–50 MHz
Bus width	16 bits	32 bits	16 bits	32 bits
Number of transistors	134,000	275,000	275,000	1.2 million
Feature size (μm)	1.5	1	1	0.8–1
Addressable memory	16 MB	4 GB	16 MB	4 GB
Virtual memory	1 GB	64 TB	64 TB	64 TB
Cache	—	—	—	8 kB

	(c) 1990s Processors			
	486TM SX	Pentium	Pentium Pro	Pentium II
Introduced	1991	1993	1995	1997
Clock speeds	16–33 MHz	60–166 MHz,	150–200 MHz	200–300 MHz
Bus width	32 bits	32 bits	64 bits	64 bits
Number of transistors	1.185 million	3.1 million	5.5 million	7.5 million
Feature size (μm)	1	0.8	0.6	0.35
Addressable memory	4 GB	4 GB	64 GB	64 GB
Virtual memory	64 TB	64 TB	64 TB	64 TB
Cache	8 kB	8 kB	512 kB L1 and 1 MB L2	512 kB L2

	(d) Recent Processors				
	Pentium III	Pentium 4	Core 2 Duo	Core i7 EE 4960X	Core i9-7900X
Introduced	1999	2000	2006	2013	2017

Clock speeds	450–660 MHz	1.3–1.8 GHz	1.06–1.2 GHz	4 GHz	4.3 GHz
Bus width	64 bits	64 bits	64 bits	64 bits	64 bits
Number of transistors	9.5 million	42 million	167 million	1.86 billion	7.2 billion
Feature size (nm)	250	180	65	22	14
Addressable memory	64 GB	64 GB	64 GB	64 GB	128 GB
Virtual memory	64 TB	64 TB	64 TB	64 TB	64 TB
Cache	512 kB L2	256 kB L2	2 MB L2	1.5 MB L2/ 15 MB L3	14 MB L3
Number of cores	1	1	2	6	10

It is worthwhile to list some of the highlights of the evolution of the Intel product line:

- **8080:** The world's first general-purpose microprocessor. This was an 8-bit machine, with an 8-bit data path to memory. The 8080 was used in the first personal computer, the Altair.
- **8086:** A far more powerful, 16-bit machine. In addition to a wider data path and larger registers, the 8086 sported an instruction cache, or queue, that prefetches a few instructions before they are executed. A variant of this processor, the 8088, was used in IBM's first personal computer, securing the success of Intel. The 8086 is the first appearance of the x86 architecture.
- **80286:** This extension of the 8086 enabled addressing a 16-MB memory instead of just 1 MB.
- **80386:** Intel's first 32-bit machine, and a major overhaul of the product. With a 32-bit architecture, the 80386 rivaled the complexity and power of minicomputers and mainframes introduced just a few years earlier. This was the first Intel processor to support multitasking, meaning it could run multiple programs at the same time.
- **80486:** The 80486 introduced the use of much more sophisticated and powerful cache technology and sophisticated instruction pipelining. The 80486 also offered a built-in math coprocessor, offloading complex math operations from the main CPU.
- **Pentium:** With the Pentium, Intel introduced the use of superscalar techniques, which allow multiple instructions to execute in parallel.
- **Pentium Pro:** The Pentium Pro continued the move into superscalar organization begun with the Pentium, with aggressive use of register renaming, branch prediction, data flow analysis, and speculative execution.
- **Pentium II:** The Pentium II incorporated Intel MMX technology, which is designed specifically to process video, audio, and graphics data efficiently.
- **Pentium III:** The Pentium III incorporates additional floating-point instructions: The Streaming SIMD Extensions (SSE) instruction set extension added 70 new instructions designed to increase performance when exactly the same operations are to be performed on multiple data objects. Typical applications are digital signal processing and graphics processing.
- **Pentium 4:** The Pentium 4 includes additional floating-point and other enhancements for

multimedia.

- **Core:** This is the first Intel x86 microprocessor with a dual core, referring to the implementation of two cores on a single chip.
- **Core 2:** The Core 2 extends the Core architecture to 64 bits. The Core 2 Quad provides four cores on a single chip. More recent Core offerings have up to 10 cores per chip. An important addition to the architecture was the Advanced Vector Extensions instruction set that provided a set of 256-bit, and then 512-bit, instructions for efficient processing of vector data.

Almost 40 years after its introduction in 1978, the x86 architecture continues to dominate the processor market outside of embedded systems. Although the organization and technology of the x86 machines have changed dramatically over the decades, the instruction set architecture has evolved to remain backward compatible with earlier versions. Thus, any program written on an older version of the x86 architecture can execute on newer versions. All changes to the instruction set architecture have involved additions to the instruction set, with no subtractions. The rate of change has been the addition of roughly one instruction per month added to the architecture [ANTH08], so that there are now thousands of instructions in the instruction set.

The x86 provides an excellent illustration of the advances in computer hardware over the past 35 years. The 1978 8086 was introduced with a clock speed of 5 MHz and had 29,000 transistors. A six-core Core i7 EE 4960X introduced in 2013 operates at 4 GHz, a speedup of a factor of 800, and has 1.86 billion transistors, about 64,000 times as many as the 8086. Yet the Core i7 EE 4960X is in only a slightly larger package than the 8086 and has a comparable cost.

1.6 Embedded Systems

The term *embedded system* refers to the use of electronics and software within a product, as opposed to a general-purpose computer, such as a laptop or desktop system. Millions of computers are sold every year, including laptops, personal computers, workstations, servers, mainframes, and supercomputers. In contrast, billions of computer systems are produced each year that are embedded within larger devices. Today many, perhaps most, devices that use electric power have an embedded computing system. It is likely that in the near future virtually all such devices will have embedded computing systems.

Types of devices with embedded systems are almost too numerous to list. Examples include cell phones, digital cameras, video cameras, calculators, microwave ovens, home security systems, washing machines, lighting systems, thermostats, printers, various automotive systems (e.g., transmission control, cruise control, fuel injection, anti-lock brakes, and suspension systems), tennis rackets, toothbrushes, and numerous types of sensors and actuators in automated systems.

Often, embedded systems are tightly coupled to their environment. This can give rise to real-time constraints imposed by the need to interact with the environment. Constraints, such as required speeds of motion, required precision of measurement, and required time durations, dictate the timing of software operations. If multiple activities must be managed simultaneously, this imposes more complex real-time constraints.

Figure 1.14 shows in general terms an embedded system organization. In addition to the processor and memory, there are a number of elements that differ from the typical desktop or laptop computer:

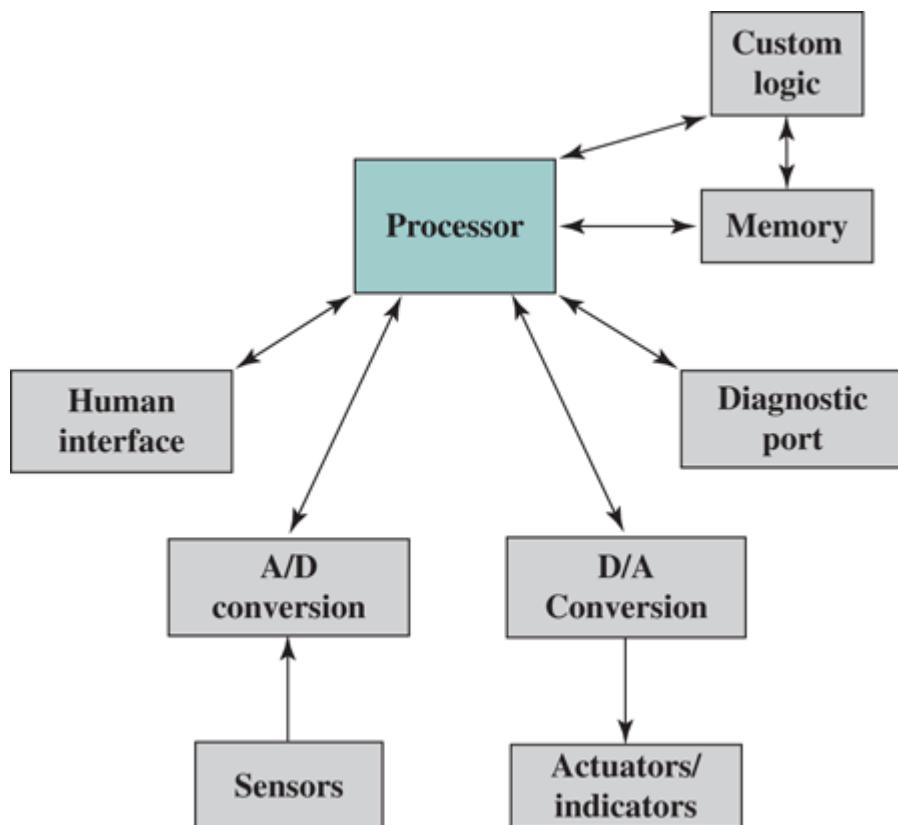

Figure 1.14 Possible Organization of an Embedded System

- There may be a variety of interfaces that enable the system to measure, manipulate, and otherwise interact with the external environment. Embedded systems often interact (sense, manipulate, and

communicate) with the external world through sensors and actuators, and hence are typically reactive systems; a reactive system is in continual interaction with the environment and executes at a pace determined by that environment.

- The human interface may be as simple as a flashing light or as complicated as real-time robotic vision. In many cases, there is no human interface.
- The diagnostic port may be used for diagnosing the system that is being controlled—not just for diagnosing the computer.
- Special-purpose field programmable (FPGA), application-specific (ASIC), or even nondigital hardware may be used to increase performance or reliability.
- Software often has a fixed function and is specific to the application.
- Efficiency is of paramount importance for embedded systems. They are optimized for energy, code size, execution time, weight and dimensions, and cost.

There are several noteworthy areas of similarity to general-purpose computer systems as well:

- Even with nominally fixed function software, the ability to field upgrade to fix bugs, to improve security, and to add functionality, has become very important for embedded systems, and not just in consumer devices.
- One comparatively recent development has been of embedded system platforms that support a wide variety of apps. Good examples of this are smartphones and audio/visual devices, such as smart TVs.

The Internet of Things

It is worthwhile to separately call out one of the major drivers in the proliferation of embedded systems. The **Internet of things (IoT)** is a term that refers to the expanding interconnection of smart devices, ranging from appliances to tiny sensors. A dominant theme is the embedding of short-range mobile transceivers into a wide array of gadgets and everyday items, enabling new forms of communication between people and things, and between things themselves. The Internet now supports the interconnection of billions of industrial and personal objects, usually through cloud systems. The objects deliver sensor information, act on their environment, and, in some cases, modify themselves to create overall management of a larger system, like a factory or city.

The IoT is primarily driven by deeply embedded devices (defined below). These devices are low-bandwidth, low-repetition data-capture, and low-bandwidth data-usage appliances that communicate with each other and provide data via user interfaces. Embedded appliances, such as high-resolution video security cameras, video VoIP phones, and a handful of others, require high-bandwidth streaming capabilities. Yet countless products simply require packets of data to be intermittently delivered.

With reference to the end systems supported, the Internet has gone through roughly four generations of deployment culminating in the IoT:

1. **Information technology (IT):** PCs, servers, routers, firewalls, and so on, bought as IT devices by enterprise IT people and primarily using wired connectivity.
2. **Operational technology (OT):** Machines/appliances with embedded IT built by non-IT companies, such as medical machinery, SCADA (supervisory control and data acquisition), process control, and kiosks, bought as appliances by enterprise OT people and primarily using wired connectivity.
3. **Personal technology:** Smartphones, tablets, and eBook readers bought as IT devices by consumers (employees) exclusively using wireless connectivity and often multiple forms of wireless connectivity.
4. **Sensor/actuator technology:** Single-purpose devices bought by consumers, IT, and OT

people exclusively using wireless connectivity, generally of a single form, as part of larger systems.

It is the fourth generation that is usually thought of as the IoT, and it is marked by the use of billions of embedded devices.

Embedded Operating Systems

There are two general approaches to developing an embedded operating system (OS). The first approach is to take an existing OS and adapt it for the embedded application. For example, there are embedded versions of Linux, Windows, and Mac, as well as other commercial and proprietary operating systems specialized for embedded systems. The other approach is to design and implement an OS intended solely for embedded use. An example of the latter is TinyOS, widely used in wireless sensor networks. This topic is explored in depth in [STAL18].

Application Processors versus Dedicated Processors

In this subsection, and the next two, we briefly introduce some terms commonly found in the literature on embedded systems. **Application processors** are defined by the processor's ability to execute complex operating systems, such as Linux, Android, and Chrome. Thus, the application processor is general-purpose in nature. A good example of the use of an embedded application processor is the smartphone. The embedded system is designed to support numerous apps and perform a wide variety of functions.

Most embedded systems employ a **dedicated processor**, which, as the name implies, is dedicated to one or a small number of specific tasks required by the host device. Because such an embedded system is dedicated to a specific task or tasks, the processor and associated components can be engineered to reduce size and cost.

Microprocessors versus Microcontrollers

As we have seen, early **microprocessor** chips included registers, an ALU, and some sort of control unit or instruction processing logic. As transistor density increased, it became possible to increase the complexity of the instruction set architecture, and ultimately to add memory and more than one processor. Contemporary microprocessor chips, as shown in [Figure 1.2](#), include multiple cores and a substantial amount of cache memory.

A **microcontroller** chip makes a substantially different use of the logic space available. [Figure 1.15](#) shows in general terms the elements typically found on a microcontroller chip. As shown, a microcontroller is a single chip that contains the processor, non-volatile memory for the program (ROM), volatile memory for input and output (RAM), a clock, and an I/O control unit. The processor portion of the microcontroller has a much lower silicon area than other microprocessors and much higher energy efficiency. We examine microcontroller organization in more detail in [Section 1.7](#).

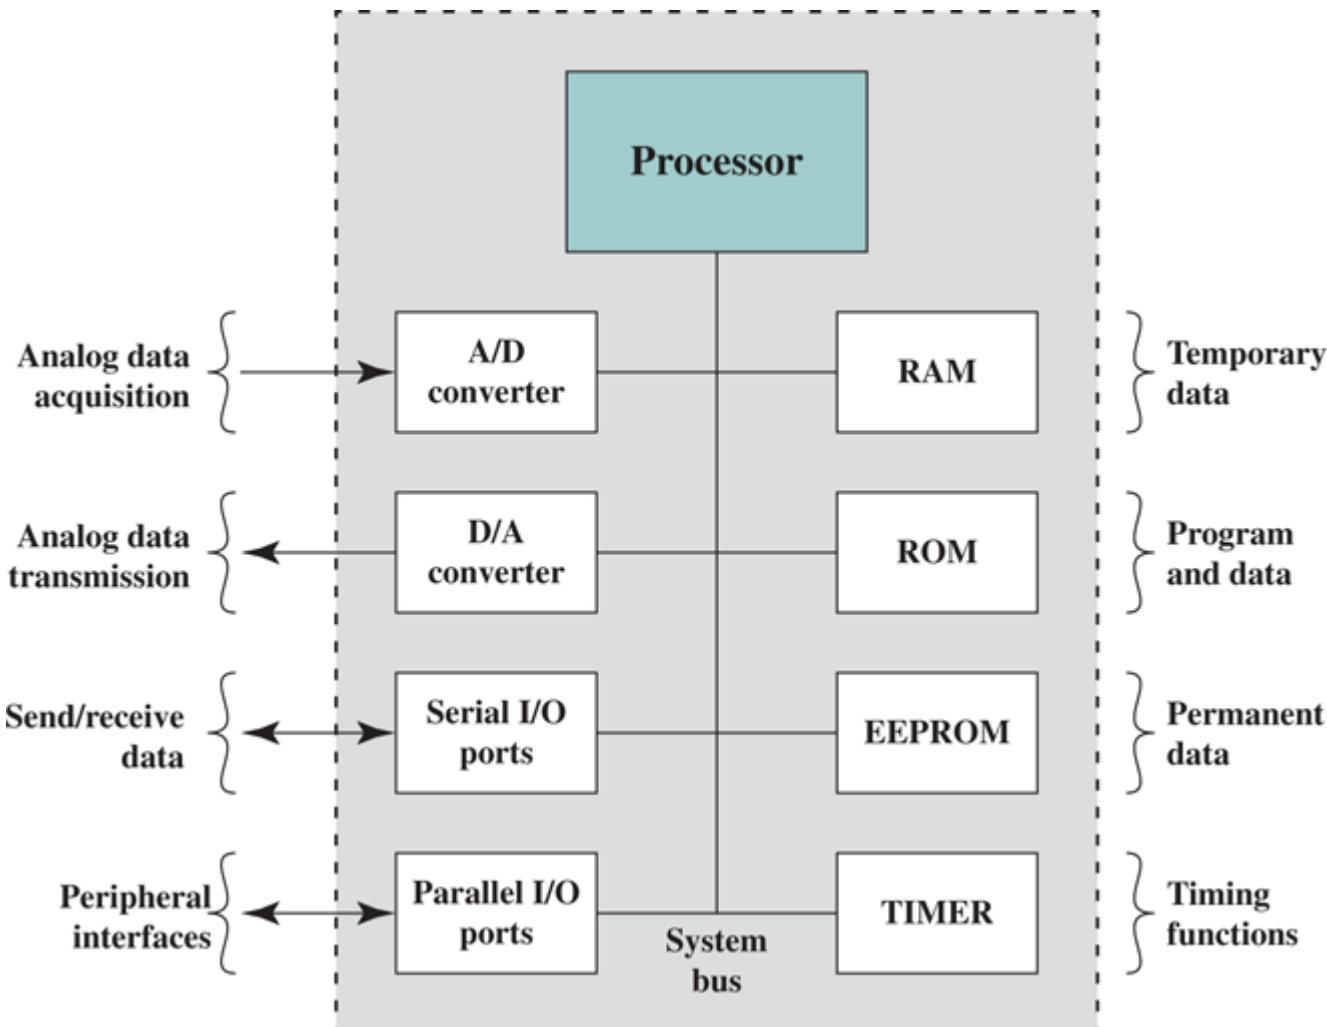

Figure 1.15 Typical Microcontroller Chip Elements

Also called a “computer on a chip,” billions of microcontroller units are embedded each year in myriad products from toys to appliances to automobiles. For example, a single vehicle can use 70 or more microcontrollers. Typically, especially for the smaller, less expensive microcontrollers, they are used as dedicated processors for specific tasks. For example, microcontrollers are heavily utilized in automation processes. By providing simple reactions to input, they can control machinery, turn fans on and off, open and close valves, and so forth. They are integral parts of modern industrial technology and are among the most inexpensive ways to produce machinery that can handle extremely complex functionalities.

Microcontrollers come in a range of physical sizes and processing power. Processors range from 4-bit to 32-bit architectures. Microcontrollers tend to be much slower than microprocessors, typically operating in the MHz range rather than the GHz speeds of microprocessors. Another typical feature of a microcontroller is that it does not provide for human interaction. The microcontroller is programmed for a specific task, embedded in its device, and executes as and when required.

Embedded versus Deeply Embedded Systems

We have, in this section, defined the concept of an embedded system. A subset of embedded systems, and a quite numerous subset, is referred to as **deeply embedded systems**. Although this term is widely used in the technical and commercial literature, you will search the Internet in vain (or at least I did) for a straightforward definition. Generally, we can say that a deeply embedded system has a processor whose behavior is difficult to observe both by the programmer and the user. A deeply embedded system uses a microcontroller rather than a microprocessor, is not programmable once the

program logic for the device has been burned into ROM (read-only memory), and has no interaction with a user.

Deeply embedded systems are dedicated, single-purpose devices that detect something in the environment, perform a basic level of processing, and then do something with the results. Deeply embedded systems often have wireless capability and appear in networked configurations, such as networks of sensors deployed over a large area (e.g., factory, agricultural field). The Internet of things depends heavily on deeply embedded systems. Typically, deeply embedded systems have extreme resource constraints in terms of memory, processor size, time, and power consumption.

1.7 ARM Architecture

The ARM architecture refers to a processor architecture that has evolved from RISC design principles and is used in embedded systems. [Chapter 7](#) examines RISC design principles in detail. In this section, we give a brief overview of the ARM architecture.

ARM Evolution

ARM is a family of RISC-based microprocessors and microcontrollers designed by ARM Holdings, Cambridge, England. The company doesn't make processors but instead designs microprocessor and multicore architectures and licenses them to manufacturers. ARM Holdings has two types of licensable products: processors and processor architectures. For processors, the customer buys the rights to use ARM-supplied design in their own chips. For a processor architecture, the customer buys the rights to design their own processor compliant with ARM's architecture.

ARM chips are high-speed processors that are known for their small die size and low power requirements. They are widely used in smartphones and other handheld devices, including game systems, as well as a large variety of consumer products. ARM chips are the processors in Apple's popular iPod and iPhone devices, and are used in virtually all Android smartphones as well. ARM's partners shipped 16.7 billion ARM-based chips in 2016. ARM is probably the most widely used embedded processor architecture and indeed the most widely used processor architecture of any kind in the world [VANC14].

The origins of ARM technology can be traced back to the British-based Acorn Computers company. In the early 1980s, Acorn was awarded a contract by the British Broadcasting Corporation (BBC) to develop a new microcomputer architecture for the BBC Computer Literacy Project. The success of this contract enabled Acorn to go on to develop the first commercial RISC processor, the Acorn RISC Machine (ARM). The first version, ARM1, became operational in 1985 and was used for internal research and development as well as being used as a coprocessor in the BBC machine.

In this early stage, Acorn used the company VLSI Technology to do the actual fabrication of the processor chips. VLSI was licensed to market the chip on its own and had some success in getting other companies to use the ARM in their products, particularly as an embedded processor.

The ARM design matched a growing commercial need for a high-performance, low-power-consumption, small-size, and low-cost processor for embedded applications. But further development was beyond the scope of Acorn's capabilities. Accordingly, a new company was organized, with Acorn, VLSI, and Apple Computer as founding partners, known as ARM Ltd. The Acorn RISC Machine became Advanced RISC Machines.⁸ ARM was acquired by Japanese telecommunications company SoftBank Group in 2016.

⁸ The company dropped the designation *Advanced RISC Machines* in the late 1990s. It is now simply known as the ARM architecture.

Instruction Set Architecture

The ARM instruction set is highly regular, designed for efficient implementation of the processor and efficient execution. All instructions are 32 bits long and follow a regular format. This makes the ARM ISA suitable for implementation over a wide range of products.

Augmenting the basic ARM ISA is the Thumb instruction set, which is a re-encoded subset of the ARM instruction set. Thumb is designed to increase the performance of ARM implementations that use a 16-bit or narrower memory data bus, and to allow better code density than provided by the ARM instruction set. The Thumb instruction set contains a subset of the ARM 32-bit instruction set recoded into 16-bit instructions. The current defined version is Thumb-2.

The ARM and Thumb-2 ISAs are discussed in [Chapters 12](#) and [13](#).

ARM Products

ARM Holdings licenses a number of specialized microprocessors and related technologies, but the bulk of their product line is the Cortex family of microprocessor architectures. There are three Cortex architectures, conveniently labeled with the initials A, R, and M.

CORTEX-A

The Cortex-A series of processors are application processors, intended for mobile devices such as smartphones and eBook readers, as well as consumer devices such as digital TV and home gateways (e.g., DSL and cable Internet modems). These processors run at higher clock frequency (over 1 GHz), and support a memory management unit (MMU), which is required for full feature OSs such as Linux, Android, MS Windows, and mobile OSs. An MMU is a hardware module that supports virtual memory and paging by translating virtual addresses into physical addresses; this topic is explored in [Chapter 8](#).

The two architectures use both the ARM and Thumb-2 instruction. Some of the processors in this series are 32-bit machines and others are 64-bit machines.

CORTEX-R

The Cortex-R is designed to support real-time applications, in which the timing of events needs to be controlled with rapid response to events. They can run at a fairly high clock frequency (e.g., 2 MHz to 4 MHz) and have very low response latency. The Cortex-R includes enhancements both to the instruction set and to the processor organization to support deeply embedded real-time devices. Most of these processors do not have MMU; the limited data requirements and the limited number of simultaneous processes eliminates the need for elaborate hardware and software support for virtual memory. The Cortex-R does have a Memory Protection Unit (MPU), cache, and other memory features designed for industrial applications. An MPU is a hardware module that prohibits one program in memory from accidentally accessing memory assigned to another active program. Using various methods, a protective boundary is created around the program, and instructions within the program are prohibited from referencing data outside of that boundary.

Examples of embedded systems that would use the Cortex-R are automotive braking systems, mass storage controllers, and networking and printing devices.

CORTEX-M

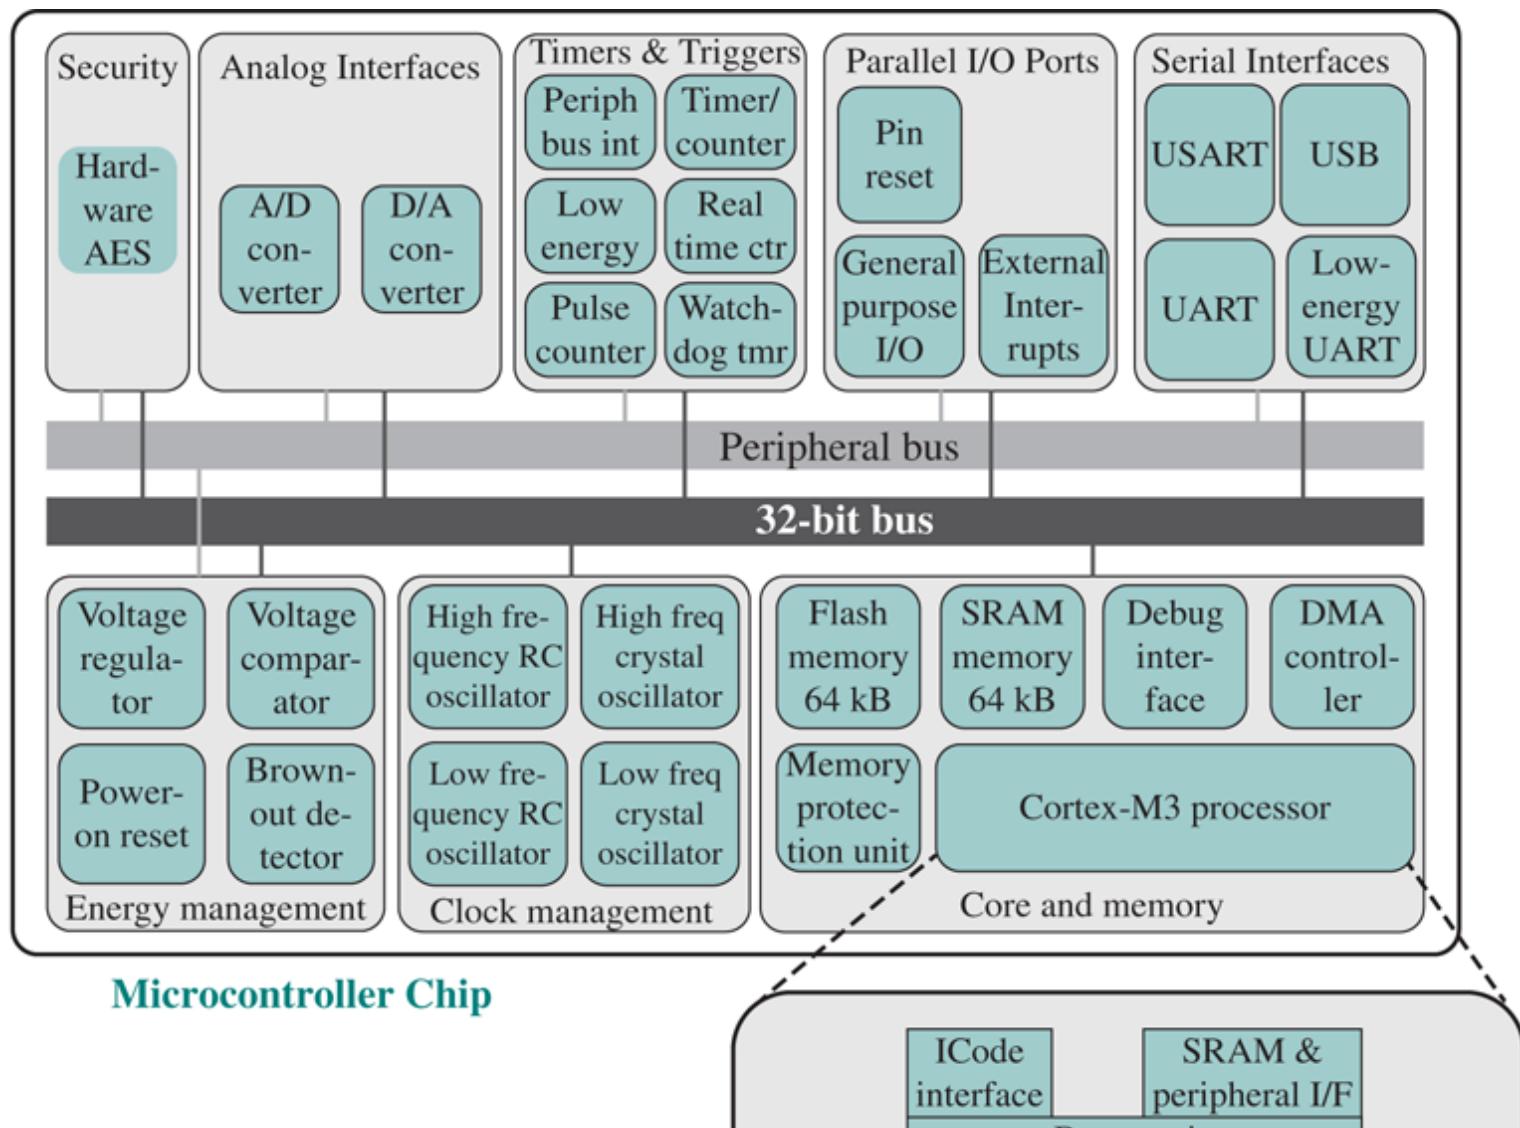

Cortex-M series processors have been developed primarily for the microcontroller domain where the need for fast, highly deterministic interrupt management is coupled with the desire for extremely low gate count and lowest possible power consumption. As with the Cortex-R series, the Cortex-M architecture has an MPU but no MMU. The Cortex-M uses only the Thumb-2 instruction set. The market for the Cortex-M includes IoT devices, wireless sensor/actuator networks used in factories and other enterprises, automotive body electronics, and so on.

There are currently seven versions of the Cortex-M series:

- **Cortex-M0:** Designed for 8- and 16-bit applications, this model emphasizes low cost, ultra low power, and simplicity. It is optimized for small silicon die size (starting from 12k gates) and use in the lowest cost chips.
- **Cortex-M0+:** An enhanced version of the M0 that is more energy efficient.
- **Cortex-M3:** Designed for 16- and 32-bit applications, this model emphasizes performance and energy efficiency. It also has comprehensive debug and trace features to enable software developers to develop their applications quickly.
- **Cortex-M4:** This model provides all the features of the Cortex-M3, with additional instructions to support digital signal processing tasks.
- **Cortex-M7:** Provides higher performance than the M4. It is still primarily a 32-bit machine but uses 64-bit wide instruction and data buses.
- **Cortex-M23:** This model is similar to the M0+, and adds integer divide instructions and some security features.
- **Cortex-M33:** This model is similar to the M4, and adds some security features.

In this text, we will primarily use the ARM Cortex-M3 as our example embedded system processor. It is the best suited of all ARM models for general-purpose microcontroller use. The Cortex-M3 is used by a variety of manufacturers of microcontroller products. Initial microcontroller devices from lead partners already combine the Cortex-M3 processor with flash, SRAM, and multiple peripherals to provide a competitive offering at the price of just \$1.

Figure 1.16 provides a block diagram of the EFM32 microcontroller from Silicon Labs. The figure also shows detail of the Cortex-M3 processor and core components. We examine each level in turn.

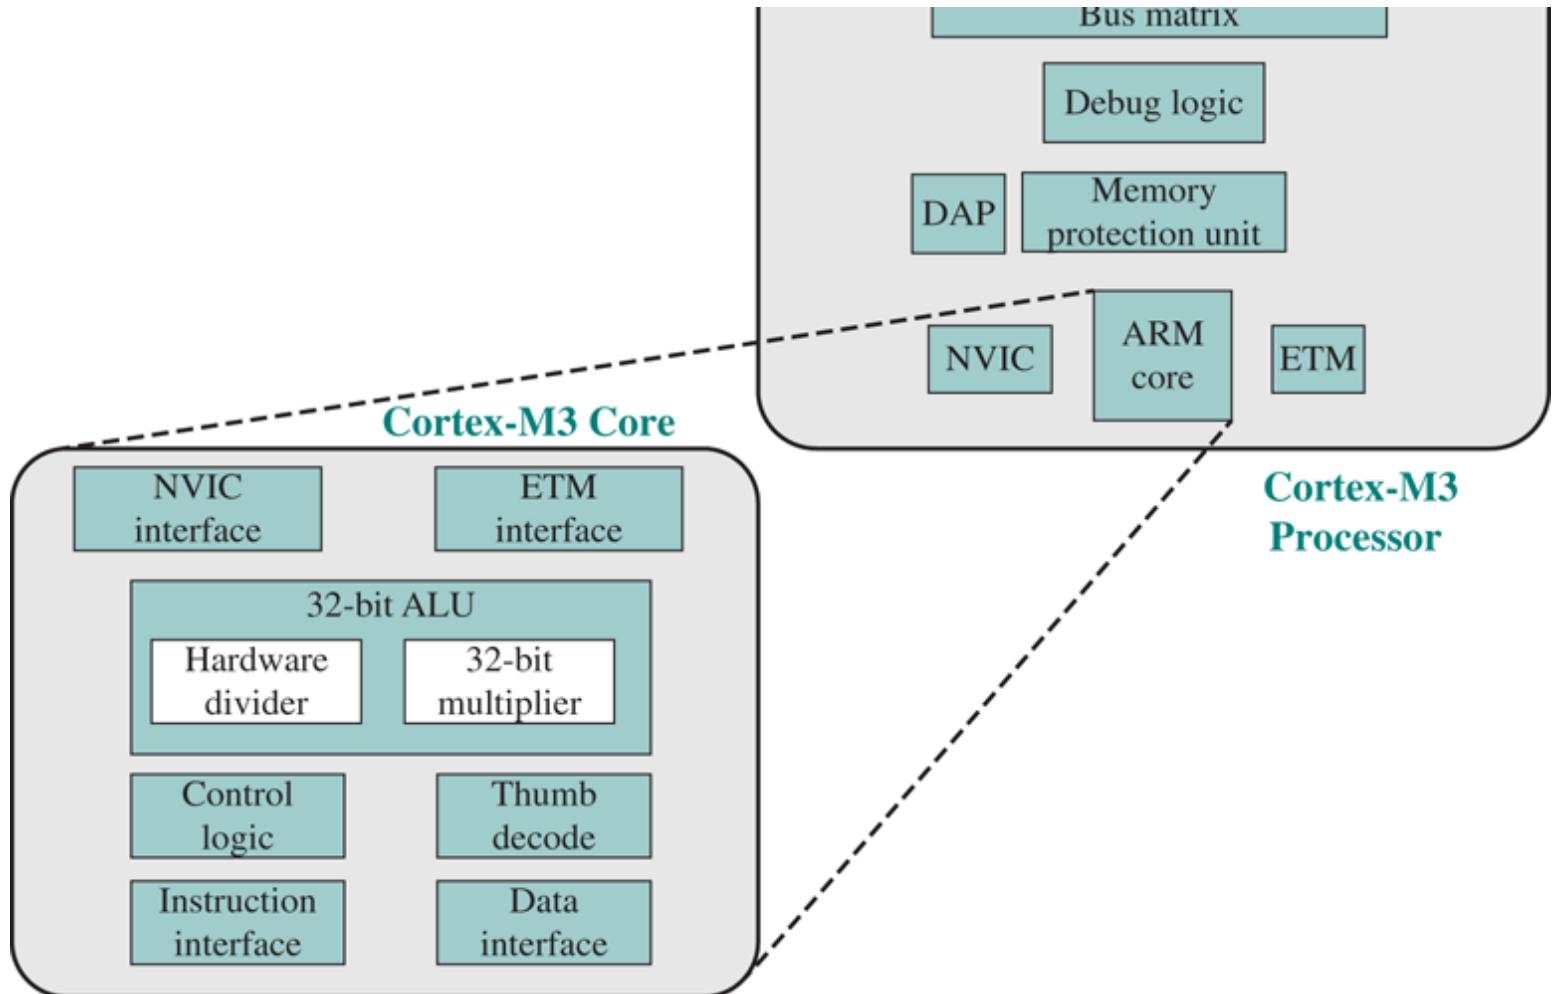

Figure 1.16 Typical Microcontroller Chip Based on Cortex-M3

The **Cortex-M3 core** makes use of separate buses for instructions and data. This arrangement is sometimes referred to as a Harvard architecture, in contrast with the von Neumann architecture, which uses the same signal buses and memory for both instructions and data. By being able to read both an instruction and data from memory at the same time, the Cortex-M3 processor can perform many operations in parallel, speeding application execution. The core contains a decoder for Thumb instructions, an advanced ALU with support for hardware multiply and divide, control logic, and interfaces to the other components of the processor. In particular, there is an interface to the nested vector interrupt controller (NVIC) and the embedded trace macrocell (ETM) module.

The core is part of a module called the **Cortex-M3 processor**. This term is somewhat misleading, because typically in the literature, the terms core and processor are viewed as equivalent. In addition to the core, the processor includes the following elements:

- **NVIC:** Provides configurable interrupt handling abilities to the processor. It facilitates low-latency exception and interrupt handling, and controls power management.
- **ETM:** An optional debug component that enables reconstruction of program execution. The ETM is designed to be a high-speed, low-power debug tool that only supports instruction trace.
- **Debug access port (DAP):** This provides an interface for external debug access to the processor.
- **Debug logic:** Basic debug functionality includes processor halt, single-step, processor core register access, unlimited software breakpoints, and full system memory access.
- **ICode interface:** Fetches instructions from the code memory space.
- **SRAM & peripheral interface:** Read/write interface to data memory and peripheral devices.
- **Bus matrix:** Connects the core and debug interfaces to external buses on the microcontroller.
- **Memory protection unit:** Protects critical data used by the operating system from user

applications, separating processing tasks by disallowing access to each other's data, disabling access to memory regions, allowing memory regions to be defined as read-only, and detecting unexpected memory accesses that could potentially break the system.

The upper part of [Figure 1.16](#) shows the block diagram of a typical microcontroller built with the Cortex-M3, in this case the EFM32 microcontroller. This microcontroller is marketed for use in a wide variety of devices, including energy, gas, and water metering; alarm and security systems; industrial automation devices; home automation devices; smart accessories; and health and fitness devices. The silicon chip consists of 10 main areas:

- **Core and memory:** This region includes the Cortex-M3 processor, static RAM (SRAM) data memory,⁹ and flash memory¹⁰ for storing program instructions and nonvarying application data. Flash memory is nonvolatile (data is not lost when power is shut off) and so is ideal for this purpose. The SRAM stores variable data. This area also includes a debug interface, which makes it easy to reprogram and update the system in the field.

⁹ Static RAM (SRAM) is a form of random-access memory used for cache memory; see [Chapter 6](#).

¹⁰ Flash memory is a versatile form of memory used both in microcontrollers and as external memory; it is discussed in [Chapter 7](#).

- **Parallel I/O ports:** Configurable for a variety of parallel I/O schemes.
- **Serial interfaces:** Supports various serial I/O schemes.
- **Analog interfaces:** Analog-to-digital and digital-to-analog logic to support sensors and actuators.
- **Timers and triggers:** Keeps track of timing and counts events, generates output waveforms, and triggers timed actions in other peripherals.
- **Clock management:** Controls the clocks and oscillators on the chip. Multiple clocks and oscillators are used to minimize power consumption and provide short startup times.
- **Energy management:** Manages the various low-energy modes of operation of the processor and peripherals to provide real-time management of the energy needs so as to minimize energy consumption.
- **Security:** The chip includes a hardware implementation of the Advanced Encryption Standard (AES).
- **32-bit bus:** Connects all of the components on the chip.
- **Peripheral bus:** A network which lets the different peripheral modules communicate directly with each other without involving the processor. This supports timing-critical operation and reduces software overhead.

Comparing [Figure 1.16](#) with [Figure 1.2](#), you will see many similarities and the same general hierarchical structure. Note, however, that the top level of a microcontroller computer system is a single chip, whereas for a multicore computer, the top level is a motherboard containing a number of chips. Another noteworthy difference is that there is no cache, either in the Cortex-M3 processor or in the microcontroller as a whole, which plays an important role if the code or data resides in external memory. Though the number of cycles to read the instruction or data varies depending on cache hit or miss, the cache greatly improves the performance when external memory is used. Such overhead is not needed for a microcontroller.

Review Questions

- 1.1 What, in general terms, is the distinction between computer organization and computer architecture?
- 1.2 What, in general terms, is the distinction between computer structure and computer function?
- 1.3 What are the four main functions of a computer?
- 1.4 List and briefly define the main structural components of a computer.
- 1.5 List and briefly define the main structural components of a processor.
- 1.6 What is a stored program computer?
- 1.7 Explain Moore's law.
- 1.8 What is the key distinguishing feature of a microprocessor?

Problems

- 1.1 You are to write an IAS program to compute the results of the following equation.

$$Y = \sum_{X=1}^{N(N+1)} X$$

Assume that the computation does not result in an arithmetic overflow and that X , Y , and N are positive integers with $N \geq 1$. Note: The IAS did not have assembly language, only machine language.

- a. Use the equation $\text{Sum}(Y) = \frac{N(N+1)}{2}$ when writing the IAS program.
- b. Do it the "hard way," without using the equation from part (a).

- 1.2

- a. On the IAS, what would the machine code instruction look like to load the contents of memory address 2 to the accumulator?
- b. How many trips to memory does the CPU need to make to complete this instruction during the instruction cycle?

- 1.3 On the IAS, describe in English the process that the CPU must undertake to read a value from memory and to write a value to memory in terms of what is put into the MAR, MBR, address bus, data bus, and control bus.

- 1.4 Given the memory contents of the IAS computer shown below,

Address	Contents
0000	10101010

08A	010FA210FB
08B	010FA0F08D
08C	020FA210FB

show the assembly language code for the program, starting at address 08A. Explain what this program does.

1.5 In **Figure 1.6**, indicate the width, in bits, of each data path (e.g., between AC and ALU).

1.6 In the IBM 360 Models 65 and 75, addresses are staggered in two separate main memory units (e.g., all even-numbered words in one unit and all odd-numbered words in another). What might be the purpose of this technique?

1.7 The relative performance of the IBM 360 Model 75 is 50 times that of the 360 Model 30, yet the instruction cycle time is only 5 times as fast. How do you account for this discrepancy?

1.8 While browsing at Billy Bob's computer store, you overhear a customer asking Billy Bob what is the fastest computer in the store that he can buy. Billy Bob replies, "You're looking at our Macintoshes. The fastest Mac we have runs at a clock speed of 1.2 GHz. If you really want the fastest machine, you should buy our 2.4-GHz Intel Pentium IV instead." Is Billy Bob correct? What would you say to help this customer?

1.9 The ENIAC, a precursor to the ISA machine, was a decimal machine, in which each register was represented by a ring of 10 vacuum tubes. At any time, only one vacuum tube was in the ON state, representing one of the 10 decimal digits. Assuming that ENIAC had the capability to have multiple vacuum tubes in the ON and OFF state simultaneously, why is this representation "wasteful" and what range of integer values could we represent using the 10 vacuum tubes?

1.10 For each of the following examples, determine whether this is an embedded system, explaining why or why not.

- a. Are programs that understand physics and/or hardware embedded? For example, one that uses finite-element methods to predict fluid flow over airplane wings?
- b. Is the internal microprocessor controlling a disk drive an example of an embedded system?
- c. I/O drivers control hardware, so does the presence of an I/O driver imply that the computer executing the driver is embedded?
- d. Is a PDA (Personal Digital Assistant) an embedded system?
- e. Is the microprocessor controlling a cell phone an embedded system?
- f. Are the computers in a big phased-array radar considered embedded? These radars are 10-story buildings with one to three 100-foot diameter radiating patches on the sloped sides of the building.
- g. Is a traditional flight management system (FMS) built into an airplane cockpit considered embedded?
- h. Are the computers in a hardware-in-the-loop (HIL) simulator embedded?
 - i. Is the computer controlling a pacemaker in a person's chest an embedded computer?
 - j. Is the computer controlling fuel injection in an automobile engine embedded?

Learning Objectives

After studying this chapter, you should be able to:

- Understand the key performance issues that relate to computer design.
- Explain the reasons for the move to multicore organization, and understand the trade-off between cache and processor resources on a single chip.
- Distinguish among multicore, MIC, and GPGPU organizations.
- Summarize some of the issues in computer performance assessment.
- Discuss the SPEC benchmarks.
- Explain the differences among arithmetic, harmonic, and geometric means.

This chapter addresses the issue of computer system performance. We begin with a consideration of the need for balanced utilization of computer resources, which provides a perspective that is useful throughout the book. Next we look at contemporary computer organization designs intended to provide performance to meet current and projected demand. Finally, we look at tools and models that have

been developed to provide a means of assessing comparative computer system performance.

2.1 Designing for Performance

Year by year, the cost of computer systems continues to drop dramatically, while the performance and capacity of those systems continue to rise equally dramatically. Today's laptops have the computing power of an IBM mainframe from 10 or 15 years ago. Thus, we have virtually "free" computer power. Processors are so inexpensive that we now have microprocessors we throw away. The digital pregnancy test is an example (used once and then thrown away). And this continuing technological revolution has enabled the development of applications of astounding complexity and power. For example, desktop applications that require the great power of today's microprocessor-based systems include:

- Image processing
- Three-dimensional rendering
- Speech recognition
- Videoconferencing
- Multimedia authoring
- Voice and video annotation of files
- Simulation modeling

Workstation systems now support highly sophisticated engineering and scientific applications and have the capacity to support image and video applications. In addition, businesses are relying on increasingly powerful servers to handle transaction and database processing and to support massive client/server networks that have replaced the huge mainframe computer centers of yesteryear. As well, cloud service providers use massive high-performance banks of servers to satisfy high-volume, high-transaction-rate applications for a broad spectrum of clients.

What is fascinating about all this from the perspective of computer organization and architecture is that, on the one hand, the basic building blocks for today's computer miracles are virtually the same as those of the IAS computer from over 50 years ago, while on the other hand, the techniques for squeezing the maximum performance out of the materials at hand have become increasingly sophisticated.

This observation serves as a guiding principle for the presentation in this book. As we progress through the various elements and components of a computer, two objectives are pursued. First, the book explains the fundamental functionality in each area under consideration, and second, the book explores those techniques required to achieve maximum performance. In the remainder of this section, we highlight some of the driving factors behind the need to design for performance.

Microprocessor Speed

What gives Intel x86 processors or IBM mainframe computers such mind-boggling power is the relentless pursuit of speed by processor chip manufacturers. The evolution of these machines continues to bear out Moore's law, described in [Chapter 1](#). So long as this law holds, chipmakers can unleash a new generation of chips every three years—with four times as many transistors. In memory chips, this has quadrupled the capacity of **dynamic random-access memory (DRAM)**, still the basic technology for computer main memory, every three years. In microprocessors, the addition of new circuits, and the speed boost that comes from reducing the distances between them, has improved performance four- or fivefold every three years or so since Intel launched its x86 family in 1978.

But the raw speed of the microprocessor will not achieve its potential unless it is fed a constant stream of work to do in the form of computer instructions. Anything that gets in the way of that smooth flow undermines the power of the processor. Accordingly, while the chipmakers have been busy learning

how to fabricate chips of greater and greater density, the processor designers must come up with ever more elaborate techniques for feeding the monster. Among the techniques built into contemporary processors are the following:

- **Pipelining:** The execution of an instruction involves multiple stages of operation, including fetching the instruction, decoding the opcode, fetching operands, performing a calculation, and so on. Pipelining enables a processor to work simultaneously on multiple instructions by performing a different phase for each of the multiple instructions at the same time. The processor overlaps operations by moving data or instructions into a conceptual pipe with all stages of the pipe processing simultaneously. For example, while one instruction is being executed, the computer is decoding the next instruction. This is the same principle as seen in an assembly line.
- **Branch prediction:** The processor looks ahead in the instruction code fetched from memory and predicts which branches, or groups of instructions, are likely to be processed next. If the processor guesses right most of the time, it can prefetch the correct instructions and buffer them so that the processor is kept busy. The more sophisticated examples of this strategy predict not just the next branch but multiple branches ahead. Thus, branch prediction potentially increases the amount of work available for the processor to execute.
- **Superscalar execution:** This is the ability to issue more than one instruction in every processor clock cycle. In effect, multiple parallel pipelines are used.
- **Data flow analysis:** The processor analyzes which instructions are dependent on each other's results, or data, to create an optimized schedule of instructions. In fact, instructions are scheduled to be executed when ready, independent of the original program order. This prevents unnecessary delay.
- **Speculative execution:** Using branch prediction and data flow analysis, some processors speculatively execute instructions ahead of their actual appearance in the program execution, holding the results in temporary locations. This enables the processor to keep its execution engines as busy as possible by executing instructions that are likely to be needed.

These and other sophisticated techniques are made necessary by the sheer power of the processor. Collectively they make it possible to execute many instructions per processor cycle, rather than to take many cycles per instruction.

Performance Balance

While processor power has raced ahead at breakneck speed, other critical components of the computer have not kept up. The result is a need to look for performance balance: an adjustment/tuning of the organization and architecture to compensate for the mismatch among the capabilities of the various components.

The problem created by such mismatches is particularly critical at the interface between processor and main memory. While processor speed has grown rapidly, the speed with which data can be transferred between main memory and the processor has lagged badly. The interface between processor and main memory is the most crucial pathway in the entire computer because it is responsible for carrying a constant flow of program instructions and data between memory chips and the processor. If memory or the pathway fails to keep pace with the processor's insistent demands, the processor stalls in a wait state, and valuable processing time is lost.

A system architect can attack this problem in a number of ways, all of which are reflected in contemporary computer designs. Consider the following examples:

- Increase the number of bits that are retrieved at one time by making DRAMs "wider" rather than "deeper" and by using wide bus data paths.
- Change the DRAM interface to make it more efficient by including a cache¹ or other buffering

scheme on the DRAM chip.

¹ A cache is a relatively small fast memory interposed between a larger, slower memory and the logic that accesses the larger memory. The cache holds recently accessed data and is designed to speed up subsequent access to the same data. Caches are discussed in [Chapter 4](#).

- Reduce the frequency of memory access by incorporating increasingly complex and efficient cache structures between the processor and main memory. This includes the incorporation of one or more caches on the processor chip as well as on an off-chip cache close to the processor chip.
- Increase the interconnect bandwidth between processors and memory by using higher-speed buses and a hierarchy of buses to buffer and structure data flow.

Another area of design focus is the handling of I/O devices. As computers become faster and more capable, more sophisticated applications are developed that support the use of peripherals with intensive I/O demands. [Figure 2.1](#) gives some examples of typical peripheral devices in use on personal computers and workstations. These devices create tremendous data throughput demands. While the current generation of processors can handle the data pumped out by these devices, there remains the problem of getting that data moved between processor and peripheral. Strategies here include caching and buffering schemes plus the use of higher-speed interconnection buses and more elaborate interconnection structures. In addition, the use of multiple-processor configurations can aid in satisfying I/O demands.

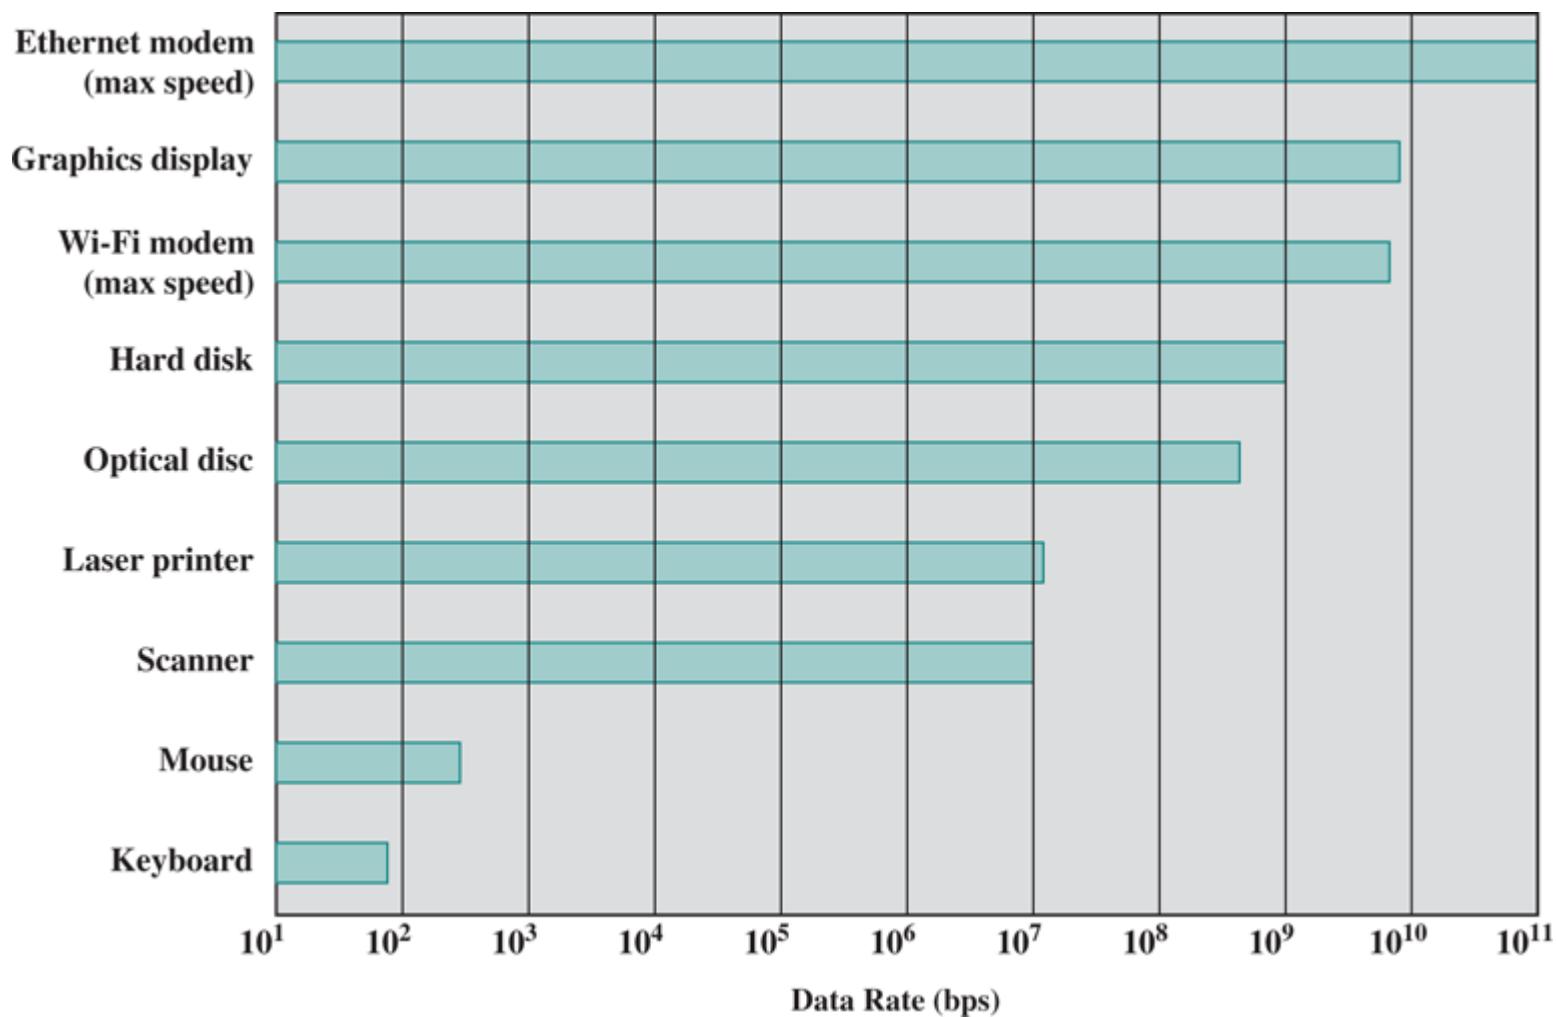

Figure 2.1 Typical I/O Device Data Rates

The key in all this is balance. Designers constantly strive to balance the throughput and processing demands of the processor components, main memory, I/O devices, and the interconnection

structures. This design must constantly be rethought to cope with two constantly evolving factors:

- The rate at which performance is changing in the various technology areas (processor, buses, memory, peripherals) differs greatly from one type of element to another.
- New applications and new peripheral devices constantly change the nature of the demand on the system in terms of typical instruction profile and the data access patterns.

Thus, computer design is a constantly evolving art form. This book attempts to present the fundamentals on which this art form is based and to present a survey of the current state of that art.

Improvements in Chip Organization and Architecture

As designers wrestle with the challenge of balancing processor performance with that of main memory and other computer components, the need to increase processor speed remains. There are three approaches to achieving increased processor speed:

- Increase the hardware speed of the processor. This increase is fundamentally due to shrinking the size of the logic gates on the processor chip so that more gates can be packed together more tightly and to increasing the clock rate. With gates closer together, the propagation time for signals is significantly reduced, enabling a speeding up of the processor. An increase in clock rate means that individual operations are executed more rapidly.
- Increase the size and speed of caches that are interposed between the processor and main memory. In particular, by dedicating a portion of the processor chip itself to the cache, cache access times drop significantly.
- Make changes to the processor organization and architecture that increase the effective speed of instruction execution. Typically, this involves using parallelism in one form or another.

Traditionally, the dominant factor in performance gains has been increases in clock speed and logic density. However, as clock speed and logic density increase, a number of obstacles become more significant [INTE04]:

- **Power:** As the density of logic and the clock speed on a chip increase, so does the power density ($\text{Watts} / \text{cm}^2$). The difficulty of dissipating the heat generated on high-density, high-speed chips is becoming a serious design issue [GIBB04, BORK03].
- **RC delay:** The speed at which electrons can flow on a chip between transistors is limited by the resistance and capacitance of the metal wires connecting them; specifically, delay increases as the RC product increases. As components on the chip decrease in size, the wire interconnects become thinner, increasing resistance. Also, the wires are closer together, increasing capacitance.
- **Memory latency and throughput:** Memory access speed (latency) and transfer speed (throughput) lag processor speeds, as previously discussed.

Thus, there will be more emphasis on organization and architectural approaches to improving performance. These techniques are discussed in later chapters of the text.

Beginning in the late 1980s, and continuing for about 15 years, two main strategies have been used to increase performance beyond what can be achieved simply by increasing clock speed. First, there has been an increase in cache capacity. There are now typically two or three levels of cache between the processor and main memory. As chip density has increased, more of the cache memory has been incorporated on the chip, enabling faster cache access. For example, the original Pentium chip devoted about 10% of on-chip area to a cache. Contemporary chips devote over half of the chip area to caches. And, typically, about three-quarters of the other half is for pipeline-related control and buffering.

Second, the instruction execution logic within a processor has become increasingly complex to enable parallel execution of instructions within the processor. Two noteworthy design approaches have been

pipelining and superscalar. A pipeline works much like an assembly line in a manufacturing plant, enabling different stages of execution of different instructions to occur at the same time along the pipeline. A superscalar approach, in essence, allows multiple pipelines within a single processor, so that instructions that do not depend on one another can be executed in parallel.

By the mid to late 90s, both of these approaches were reaching a point of diminishing returns. The internal organization of contemporary processors is exceedingly complex and is able to squeeze a great deal of parallelism out of the instruction stream. It seems likely that further significant increases in this direction will be relatively modest [GIBB04]. With three levels of cache on the processor chip, each level providing substantial capacity, it also seems that the benefits from the cache are reaching a limit.

However, simply relying on increasing clock rate for increased performance runs into the power dissipation problem already referred to. The faster the clock rate, the greater the amount of power to be dissipated, and some fundamental physical limits are being reached.

Figure 2.2 illustrates the concepts we have been discussing.² The top line shows that, as per Moore's Law, the number of transistors on a single chip continues to grow exponentially.³ Meanwhile, the clock speed has leveled off, in order to prevent a further rise in power. To continue increasing performance, designers have had to find ways of exploiting the growing number of transistors other than simply building a more complex processor. The response in recent years has been the development of the multicore computer chip.

² I am grateful to Professor Kathy Yellick of UC Berkeley, who provided this graph.

³ The observant reader will note that the transistor count values in this figure are significantly less than those of **Figure 1.12**. That latter figure shows the transistor count for a form of main memory known as DRAM (discussed in **Chapter 5**), which supports higher transistor density than processor chips.

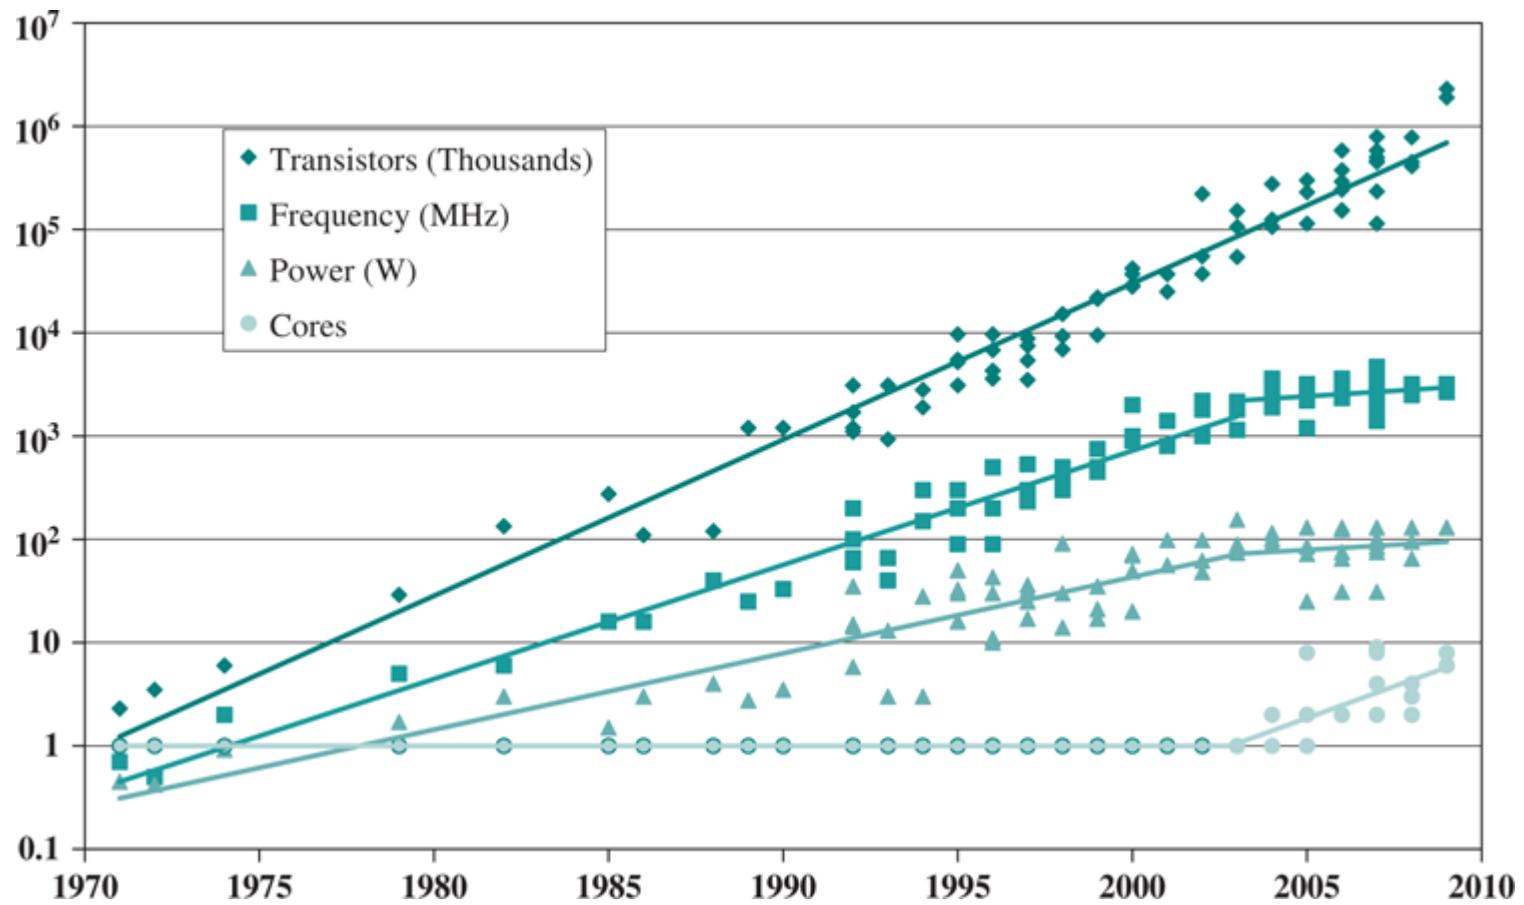

Figure 2.2 Processor Trends

Source: Graph provided by: Professor Kathy Yelick, Associate Laboratory Director for Computing Sciences Lawrence Berkeley National Laboratory, Computer Science Division University of California at Berkeley.

2.2 Multicore, Mics, and GPGPUs

With all of the difficulties cited in the preceding section in mind, designers have turned to a fundamentally new approach to improving performance: placing multiple processors on the same chip, with a large shared cache. The use of multiple processors on the same chip, also referred to as multiple cores, or **multicore**, provides the potential to increase performance without increasing the clock rate. Studies indicate that, within a processor, the increase in performance is roughly proportional to the square root of the increase in complexity [BORK03]. But if the software can support the effective use of multiple processors, then doubling the number of processors almost doubles performance. Thus, the strategy is to use two simpler processors on the chip, rather than one more complex processor.

In addition, with two processors larger caches are justified. This is important because the power consumption of memory logic on a chip is much less than that of processing logic.

As the logic density on chips continues to rise, the trend for both more cores and more cache on a single chip continues. Two-core chips were quickly followed by four-core chips, then 8, then 16, and so on. As the caches became larger, it made performance sense to create two and then three levels of cache on a chip, with the first-level cache initially dedicated to an individual processor, and levels two and three being shared by all the processors. It is now common for the second-level cache to also be private to each core.

Chip manufacturers are now in the process of making a huge leap forward in the number of cores per chip, with more than 50 cores per chip. The leap in performance as well as the challenges in developing software to exploit such a large number of cores has led to the introduction of a new term: **many integrated core (MIC)**.

The multicore and MIC strategy involves a homogeneous collection of general-purpose processors on a single chip. At the same time, chip manufacturers are pursuing another design option: a chip with multiple general-purpose processors plus **graphics processing units (GPUs)** and specialized cores for video processing and other tasks. In broad terms, a GPU is a core designed to perform parallel operations on graphics data. Traditionally found on a plug-in graphics card (display adapter), it is used to encode and render 2D and 3D graphics as well as process video.

Since GPUs perform parallel operations on multiple sets of data, they are increasingly being used as vector processors for a variety of applications that require repetitive computations. This blurs the line between the GPU and the CPU [AROR12, FATA08, PROP11]. When a broad range of applications are supported by such a processor, the term **general-purpose computing on GPUs (GPGPU)** is used.

We explore design characteristics of multicore computers in [Chapter 18](#) and GPGPUs in [Chapter 19](#).

2.3 Two Laws that Provide Insight: Ahmdahl's Law and Little's Law

In this section, we look at two equations, called “laws.” The two laws are unrelated, but both provide insight into the performance of parallel systems and multicore systems.

Amdahl's Law

Computer system designers look for ways to improve system performance by advances in technology or change in design. Examples include the use of parallel processors, the use of a memory cache hierarchy, and speedup in memory access time and I/O transfer rate due to technology improvements. In all of these cases, it is important to note that a speedup in one aspect of the technology or design does not result in a corresponding improvement in performance. This limitation is succinctly expressed by Amdahl's law.

Amdahl's law was first proposed by Gene Amdahl in 1967 ([AMDA67], [AMDA13]) and deals with the potential speedup of a program using multiple processors compared to a single processor. Consider a program running on a single processor such that a fraction $(1 - f)$ of the execution time involves code that is inherently sequential, and a fraction f that involves code that is infinitely parallelizable with no scheduling overhead. Let T be the total execution time of the program using a single processor. Then the speedup using a parallel processor with N processors that fully exploits the parallel portion of the program is as follows:

$$\begin{aligned}\text{Speedup} &= \frac{\text{Time to execute program on a single processor}}{\text{Time to execute program on } N \text{ parallel processors}} \\ &= \frac{T(1-f) + Tf}{T(1-f) + \frac{fT}{N}} = \frac{1}{(1-f) + \frac{f}{N}}\end{aligned}$$

This equation is illustrated in [Figures 2.3](#) and [2.4](#). Two important conclusions can be drawn:

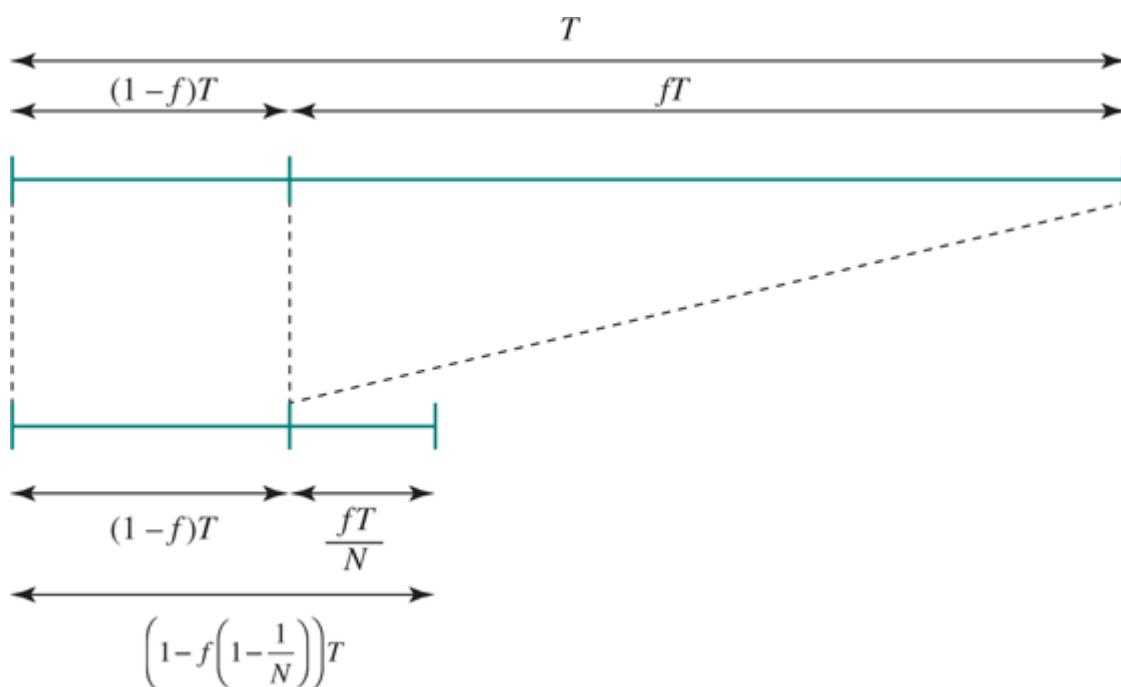

Figure 2.3 Illustration of Amdahl's Law

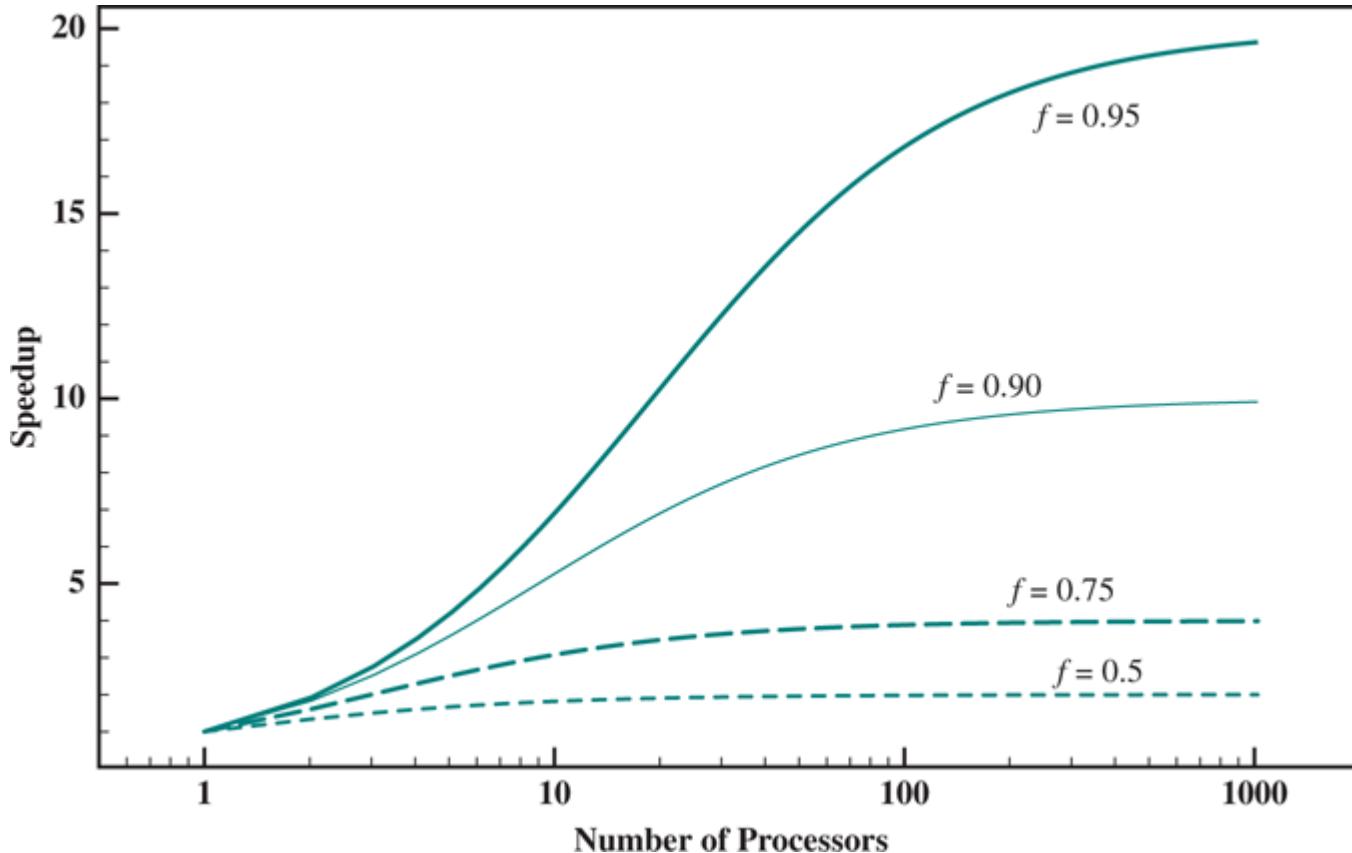

Figure 2.4 Amdahl's Law for Multiprocessors

1. When f is small, the use of parallel processors has little effect.
2. As N approaches infinity, speedup is bound by $1 / (1 - f)$, so that there are diminishing returns for using more processors.

These conclusions are too pessimistic, an assertion first put forward in [GUST88]. For example, a server can maintain multiple threads or multiple tasks to handle multiple clients and execute the threads or tasks in parallel up to the limit of the number of processors. Many database applications involve computations on massive amounts of data that can be split up into multiple parallel tasks. Nevertheless, Amdahl's law illustrates the problems facing industry in the development of multicore machines with an ever-growing number of cores: The software that runs on such machines must be adapted to a highly parallel execution environment to exploit the power of parallel processing.

Amdahl's law can be generalized to evaluate any design or technical improvement in a computer system. Consider any enhancement to a feature of a system that results in a speedup. The speedup can be expressed as

$$\text{Speedup} = \frac{\text{Performance after enhancement}}{\text{Performance before enhancement}} = \frac{\text{Execution time before enhancement}}{\text{Execution time after enhancement}} \quad (2.1)$$

Suppose that a feature of the system is used during execution a fraction of the time f , before enhancement, and that the speedup of that feature after enhancement is SU_f . Then the overall speedup of the system is

$$\text{Speedup} = \frac{1}{(1-f) + \frac{f}{SU_f}}$$

Example 2.1

Suppose that a task makes extensive use of floating-point operations, with 40% of the time consumed by floating-point operations. With a new hardware design, the floating-point module is sped up by a factor of K . Then the overall speedup is as follows:

$$\text{Speedup} = \frac{1}{\frac{0.4}{0.6 + K}}$$

Thus, independent of K , the maximum speedup is 1.67.

Little's Law

A fundamental and simple relation with broad applications is Little's Law [LITT61, LITT11].⁴ We can apply it to almost any system that is statistically in steady state, and in which there is no leakage. Specifically, we have a steady state system to which items arrive at an average rate of λ items per unit time. The items stay in the system an average of W units of time. Finally, there is an average of L units in the system at any one time. Little's Law relates these three variables as $L = \lambda W$.

⁴ The second reference is a retrospective article on his law that Little wrote 50 years after his original paper. That must be unique in the history of the technical literature, although Amdahl comes close, with a 46-year gap between [AMDA67] and [AMDA13].

Using queuing theory terminology, Little's Law applies to a queuing system. The central element of the system is a server, which provides some service to items. Items from some population of items arrive at the system to be served. If the server is idle, an item is served immediately. Otherwise, an arriving item joins a waiting line, or queue. There can be a single queue for a single server, a single queue for multiple servers, or multiples queues, one for each of multiple servers. When a server has completed serving an item, the item departs. If there are items waiting in the queue, one is immediately dispatched to the server. The server in this model can represent anything that performs some function or service for a collection of items. Examples: A processor provides service to processes; a transmission line provides a transmission service to packets or frames of data; and an I/O device provides a read or write service for I/O requests.

To understand Little's formula, consider the following argument, which focuses on the experience of a single item. When the item arrives, it will find on average L items ahead of it, one being serviced and the rest in the queue. When the item leaves the system after being serviced, it will leave behind on average the same number of items in the system, namely L , because L is defined as the average number of items waiting. Further, the average time that the item was in the system was W . Since items arrive at a rate of λ , we can reason that in the time W , a total of λW items must have arrived.

Thus $L = \lambda W$.

To summarize, under steady state conditions, the average number of items in a queuing system equals the average rate at which items arrive multiplied by the average time that an item spends in the system. This relationship requires very few assumptions. We do not need to know what the service time distribution is, what the distribution of arrival times is, or the order or priority in which items are served. Because of its simplicity and generality, Little's Law is extremely useful and has experienced somewhat of a revival due to the interest in performance problems related to multicore computers.

A very simple example, from [LITT11], illustrates how Little's Law might be applied. Consider a multicore system, with each core supporting multiple threads of execution. At some level, the cores share a common memory. The cores share a common main memory and typically share a common cache memory as well. In any case, when a thread is executing, it may arrive at a point at which it must retrieve a piece of data from the common memory. The thread stops and sends out a request for that data. All such stopped threads are in a queue. If the system is being used as a server, an analyst can determine the demand on the system in terms of the rate of user requests, and then translate that into the rate of requests for data from the threads generated to respond to an individual user request. For this purpose, each user request is broken down into subtasks that are implemented as threads. We then have λ =the average rate of total thread processing required after all members' requests have been broken down into whatever detailed subtasks are required. Define L as the average number of stopped threads waiting during some relevant time. Then W =average response time. This simple model can serve as a guide to designers as to whether user requirements are being met and, if not, provide a quantitative measure of the amount of improvement needed.

2.4 Basic Measures of Computer Performance

In evaluating processor hardware and setting requirements for new systems, performance is one of the key parameters to consider, along with cost, size, security, reliability, and, in some cases, power consumption.

It is difficult to make meaningful performance comparisons among different processors, even among processors in the same family. Raw speed is far less important than how a processor performs when executing a given application. Unfortunately, application performance depends not just on the raw speed of the processor but also on the instruction set, choice of implementation language, efficiency of the compiler, and skill of the programming done to implement the application.

In this section, we look at some traditional measures of processor speed. In the next section, we examine benchmarking, which is the most common approach to assessing processor and computer system performance. The following section discusses how to average results from multiple tests.

Clock Speed

Operations performed by a processor, such as fetching an instruction, decoding the instruction, performing an arithmetic operation, and so on, are governed by a system clock. Typically, all operations begin with the pulse of the clock. Thus, at the most fundamental level, the speed of a processor is dictated by the pulse frequency produced by the clock, measured in cycles per second, or Hertz (Hz).

Typically, clock signals are generated by a quartz crystal, which generates a constant sine wave while power is applied. This wave is converted into a digital voltage pulse stream that is provided in a constant flow to the processor circuitry (**Figure 2.5**). For example, a 1-GHz processor receives 1 billion pulses per second. The rate of pulses is known as the **clock rate**, or **clock speed**. One increment, or pulse, of the clock is referred to as a **clock cycle**, or a **clock tick**. The time between pulses is the **cycle time**.

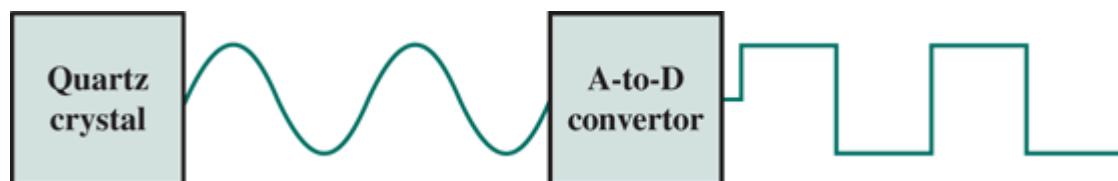

Figure 2.5 System Clock

The clock rate is not arbitrary, but must be appropriate for the physical layout of the processor. Actions in the processor require signals to be sent from one processor element to another. When a signal is placed on a line inside the processor, it takes some finite amount of time for the voltage levels to settle down so that an accurate value (logical 1 or 0) is available. Furthermore, depending on the physical layout of the processor circuits, some signals may change more rapidly than others. Thus, operations must be synchronized and paced so that the proper electrical signal (voltage) values are available for each operation.

The execution of an instruction involves a number of discrete steps, such as fetching the instruction from memory, decoding the various portions of the instruction, loading and storing data, and performing arithmetic and logical operations. Thus, most instructions on most processors require multiple clock cycles to complete. Some instructions may take only a few cycles, while others require

dozens. In addition, when pipelining is used, multiple instructions are being executed simultaneously. Thus, a straight comparison of clock speeds on different processors does not tell the whole story about performance.

Instruction Execution Rate

A processor is driven by a clock with a constant frequency f or, equivalently, a constant cycle time τ , where $\tau = 1/f$. Define the instruction count, I_c , for a program as the number of machine instructions executed for that program until it runs to completion or for some defined time interval. Note that this is the number of instruction executions, not the number of instructions in the object code of the program. An important parameter is the average cycles per instruction (CPI) for a program. If all instructions required the same number of clock cycles, then CPI would be a constant value for a processor. However, on any given processor, the number of clock cycles required varies for different types of instructions, such as load, store, branch, and so on. Let CPI_i be the number of cycles required for instruction type i , and I_i be the number of executed instructions of type i for a given program. Then we can calculate an overall CPI as follows:

$$CPI = \frac{\sum_{i=1}^n (CPI_i \times I_i)}{I_c} \quad (2.2)$$

The processor time T needed to execute a given program can be expressed as

$$T = I_c \times CPI \times \tau$$

We can refine this formulation by recognizing that during the execution of an instruction, part of the work is done by the processor, and part of the time a word is being transferred to or from memory. In this latter case, the time to transfer depends on the memory cycle time, which may be greater than the processor cycle time. We can rewrite the preceding equation as

$$T = I_c \times [p + (m \times k)] \times \tau$$

where p is the number of processor cycles needed to decode and execute the instruction, m is the number of memory references needed, and k is the ratio between memory cycle time and processor cycle time. The five performance factors in the preceding equation (I_c, p, m, k, τ) are influenced by four system attributes: the design of the instruction set (known as *instruction set architecture*); compiler technology (how effective the compiler is in producing an efficient machine language program from a high-level language program); processor implementation; and cache and memory hierarchy. **Table 2.1** is a matrix in which one dimension shows the five performance factors and the other dimension shows the four system attributes. An X in a cell indicates a system attribute that affects a performance factor.

Table 2.1 Performance Factors and System Attributes

	I_c	p	m	k	τ
Instruction set architecture	X	X			
Compiler technology	X	X	X		
Processor implementation			X		X

A common measure of performance for a processor is the rate at which instructions are executed, expressed as millions of instructions per second (MIPS), referred to as the **MIPS rate**. We can express the MIPS rate in terms of the clock rate and *CPI* as follows:

$$\text{MIPS rate} = \frac{I_c}{T \times 10^6} = \frac{f}{CPI \times 10^6} \quad (2.3)$$

Example 2.2

Consider the execution of a program that results in the execution of 2 million instructions on a 400-MHz processor. The program consists of four major types of instructions. The instruction mix and the CPI for each instruction type are given below, based on the result of a program trace experiment:

Instruction Type	CPI	Instruction Mix (%)
Arithmetic and logic	1	60
Load/store with cache hit	2	18
Branch	4	12
Memory reference with cache miss	8	10

The average CPI when the program is executed on a uniprocessor with the above trace results is $CPI = 0.6 + (2 \times 0.18) + (4 \times 0.12) + (8 \times 0.1) = 2.24$. The corresponding MIPS rate is $(400 \times 10^6) / (2.24 \times 10^6) \approx 178$.

Another common performance measure deals only with floating-point instructions. These are common in many scientific and game applications. Floating-point performance is expressed as millions of floating-point operations per second (MFLOPS), defined as follows:

$$\text{MFLOPS rate} = \frac{\text{Number of executed floating - point operations in a program}}{\text{Execution time} \times 10^6}$$

2.5 Calculating the Mean

In evaluating some aspect of computer system performance, it is often the case that a single number, such as execution time or memory consumed, is used to characterize performance and to compare systems. Clearly, a single number can provide only a very simplified view of a system's capability. Nevertheless, and especially in the field of benchmarking, single numbers are typically used for performance comparison [SMIT88].

As is discussed in [Section 2.6](#), the use of benchmarks to compare systems involves calculating the mean value of a set of data points related to execution time. It turns out that there are multiple alternative algorithms that can be used for calculating a mean value, and this has been the source of some controversy in the benchmarking field. In this section, we define these alternative algorithms and comment on some of their properties. This prepares us for a discussion in the next section of mean calculation in benchmarking.

The three common formulas used for calculating a mean are arithmetic, geometric, and harmonic. Given a set of n real numbers (x_1, x_2, \dots, x_n) , the three means are defined as follows:

Arithmetic mean

$$AM = \frac{x_1 + \dots + x_n}{n} = \frac{1}{n} \sum_{i=1}^n x_i \quad (2.4)$$

Geometric mean

$$GM = \sqrt[n]{x_1 \times \dots \times x_n} = \prod_{i=1}^n x_i^{1/n} = e^{\frac{1}{n} \sum_{i=1}^n \ln(x_i)} \quad (2.5)$$

Harmonic mean

$$HM = \frac{n}{\frac{1}{x_1} + \dots + \frac{1}{x_n}} = \frac{n}{\sum_{i=1}^n \frac{1}{x_i}} \quad x_i > 0 \quad (2.6)$$

It can be shown that the following inequality holds:

$$AM \geq GM \geq HM$$

The values are equal only if $x_1 = x_2 = \dots = x_n$.

We can get a useful insight into these alternative calculations by defining the functional mean. Let $f(x)$ be a continuous monotonic function defined in the interval $0 \leq y < \infty$. The functional mean with respect to the function $f(x)$ for n positive real numbers x_1, x_2, \dots, x_n is defined as

Functional mean

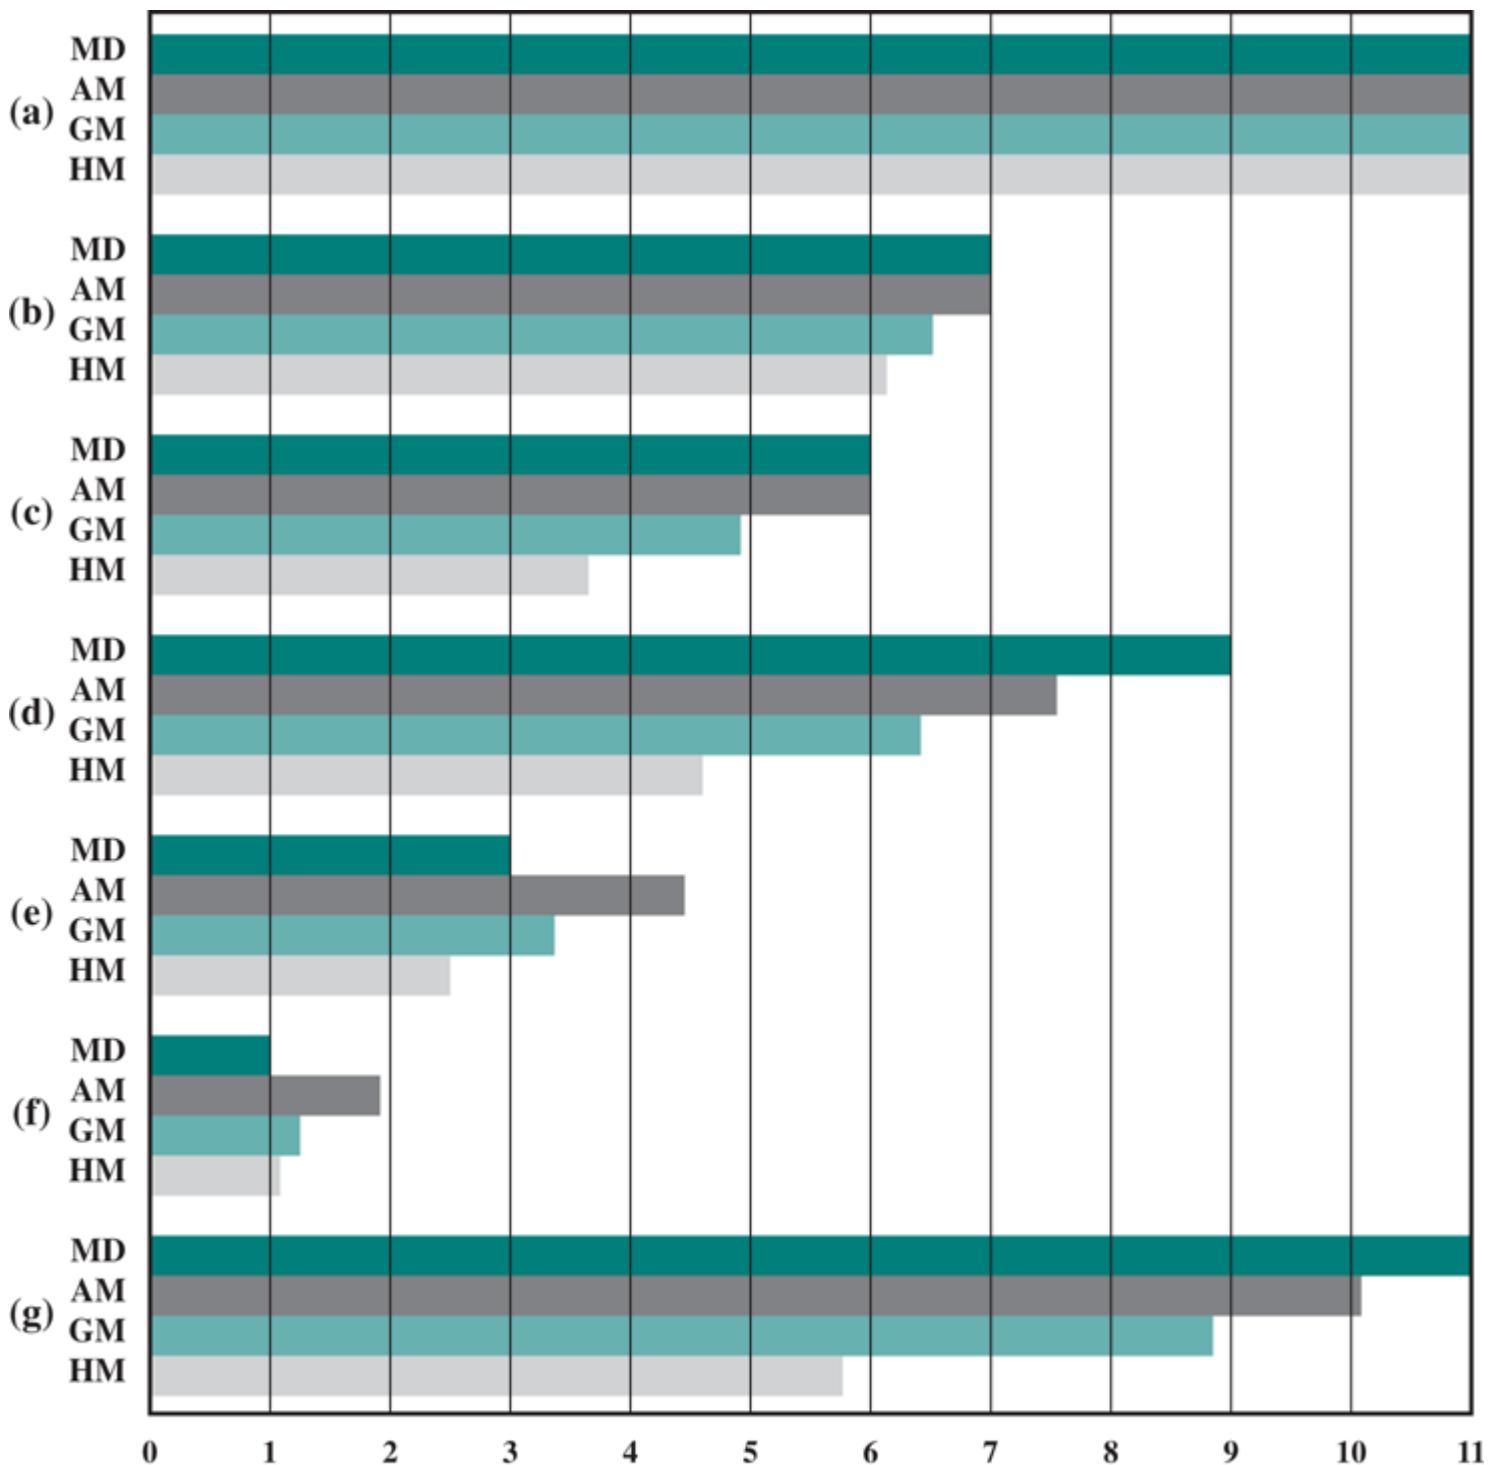

$$FM = f^{-1} \left(\frac{f(x_1) + \dots + f(x_n)}{n} \right) = f^{-1} \left(\frac{1}{n} \sum_{i=1}^n f(x_i) \right)$$

where $f^{-1}(x)$ is the inverse of $f(x)$. The mean values defined in **Equations (2.1)** through **(2.3)** are special cases of the functional mean, as follows:

- AM is the FM with respect to $f(x)=x$
- GM is the FM with respect to $f(x)=\ln x$
- HM is the FM with respect to $f(x)=1/x$

Example 2.3

Figure 2.6 illustrates the three means applied to various data sets, each of which has eleven data points and a maximum data point value of 11. The median value is also included in the chart. Perhaps what stands out the most in this figure is that the HM has a tendency to produce a misleading result when the data is skewed to larger values or when there is a small-value outlier.

- (a) Constant (11, 11, 11, 11, 11, 11, 11, 11, 11, 11, 11, 11)
- (b) Clustered around a central value (3, 5, 6, 6, 7, 7, 7, 8, 8, 9, 11)
- (c) Uniform distribution (1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11)
- (d) Large-number bias (1, 4, 4, 7, 7, 9, 9, 10, 10, 11, 11)
- (e) Small-number bias (1, 1, 2, 2, 3, 3, 5, 5, 8, 8, 11)
- (f) Upper outlier (11, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1)
- (g) Lower outlier (1, 11, 11, 11, 11, 11, 11, 11, 11, 11, 11, 11)

MD = median
 AM = arithmetic mean
 GM = geometric mean
 HM = harmonic mean

Figure 2.6 Comparison of Means on Various Data Sets (each set has a maximum data point value of 11)

Let us now consider which of these means are appropriate for a given performance measure. As a preface to these remarks, it should be noted that a number of papers ([CITR06], [FLEM86], [GILA95], [JACO95], [JOHN04], [MASH04], [SMIT88]) and books ([HENN12], [HWAN93], [JAIN91], [LILJ00])

over the years have argued the pros and cons of the three means for performance analysis and come to conflicting conclusions. To simplify a complex controversy, we just note that the conclusions reached depend very much on the examples chosen and the way in which the objectives are stated.

Arithmetic Mean

An AM is an appropriate measure if the sum of all the measurements is a meaningful and interesting value. The AM is a good candidate for comparing the execution time performance of several systems. For example, suppose we were interested in using a system for large-scale simulation studies and wanted to evaluate several alternative products. On each system we could run the simulation multiple times with different input values for each run, and then take the average execution time across all runs. The use of multiple runs with different inputs should ensure that the results are not heavily biased by some unusual feature of a given input set. The AM of all the runs is a good measure of the system's performance on simulations, and a good number to use for system comparison.

The AM used for a time-based variable (e.g., seconds), such as program execution time, has the important property that it is directly proportional to the total time. So, if the total time doubles, the mean value doubles.

Harmonic Mean

For some situations, a system's execution rate may be viewed as a more useful measure of the value of the system. This could be either the instruction execution rate, measured in MIPS or MFLOPS, or a program execution rate, which measures the rate at which a given type of program can be executed. Consider how we wish the calculated mean to behave. It makes no sense to say that we would like the mean rate to be proportional to the total rate, where the total rate is defined as the sum of the individual rates. The sum of the rates would be a meaningless statistic. Rather, we would like the mean to be inversely proportional to the total execution time. For example, if the total time to execute all the benchmark programs in a suite of programs is twice as much for system C as for system D, we would want the mean value of the execution rate to be half as much for system C as for system D.

Let us look at a basic example and first examine how the AM performs. Suppose we have a set of n benchmark programs and record the execution times of each program on a given system as t_1, t_2, \dots, t_n . For simplicity, let us assume that each program executes the same number of

operations Z ; we could weight the individual programs and calculate accordingly, but this would not change the conclusion of our argument. The execution rate for each individual program is $R_i = Z / t_i$.

We use the AM to calculate the average execution rate.

$$AM = \frac{1}{n} \sum_{i=1}^n R_i = \frac{1}{n} \sum_{i=1}^n \frac{Z}{t_i} = \frac{Z}{n} \sum_{i=1}^n \frac{1}{t_i}$$

We see that the AM execution rate is proportional to the sum of the inverse execution times, which is not the same as being inversely proportional to the sum of the execution times. Thus, the AM does not have the desired property.

The HM yields the following result.

$$HM = \frac{n}{\sum_{i=1}^n \frac{1}{R_i}} = \frac{n}{\sum_{i=1}^n \frac{1}{Z/t_i}} = \frac{nZ}{\sum_{i=1}^n t_i}$$

The HM is inversely proportional to the total execution time, which is the desired property.

Example 2.4

A simple numerical example will illustrate the difference between the two means in calculating a mean value of the rates, shown in **Table 2.2**. The table compares the performance of three computers on the execution of two programs. For simplicity, we assume that the execution of each program results in the execution of 10^8 floating-point operations. The left half of the table shows the execution times for each computer running each program, the total execution time, and the AM of the execution times. Computer A executes in less total time than B, which executes in less total time than C, and this is reflected accurately in the AM.

Table 2.2 A Comparison of Arithmetic and Harmonic Means for Rates

	Computer A time (secs)	Computer B time (secs)	Computer C time (secs)	Computer A rate (MFLOPS)	Computer B rate (MFLOPS)	Computer C rate (MFLOPS)
Program 1 (108 FP ops)	2.0	1.0	0.75	50	100	133.33
Program 2 (108 FP ops)	0.75	2.0	4.0	133.33	50	25
Total execution time	2.75	3.0	4.75	—	—	—
Arithmetic mean of times	1.38	1.5	2.38	—	—	—
Inverse of total execution time (1/sec)	0.36	0.33	0.21	—	—	—
Arithmetic mean of rates	—	—	—	91.67	75.00	79.17
Harmonic mean of rates	—	—	—	72.72	66.67	42.11

The right half of the table provides a comparison in terms of rates, expressed in MFLOPS. The rate calculation is straightforward. For example, program 1 executes 100 million floating-point operations. Computer A takes 2 seconds to execute the program for a MFLOPS rate of $100 / 2 = 50$.

Next, consider the AM of the rates. The greatest value is for computer A, which suggests that A is the fastest computer. In terms of total execution time, A has the minimum time, so it is the fastest computer of the three. But the AM of rates shows B as slower than C, whereas in fact B is faster

than C. Looking at the HM values, we see that they correctly reflect the speed ordering of the computers. This confirms that the HM is preferred when calculating rates.

The reader may wonder why go through all this effort. If we want to compare execution times, we could simply compare the total execution times of the three systems. If we want to compare rates, we could simply take the inverse of the total execution time, as shown in the table. There are two reasons for doing the individual calculations rather than only looking at the aggregate numbers:

1. A customer or researcher may be interested not only in the overall average performance but also performance against different types of benchmark programs, such as business applications, scientific modeling, multimedia applications, and systems programs. Thus, a breakdown by type of benchmark is needed, as well as a total.
2. Usually, the different programs used for evaluation are weighted differently. In **Table 2.2**, it is assumed that the two test programs execute the same number of operations. If that is not the case, we may want to weight accordingly. Or different programs could be weighted differently to reflect importance or priority.

Let us see what the result is if test programs are weighted proportional to the number of operations. Following the preceding notation, each program i executes Z_i instructions in a time t_i . Each rate is weighted by the instructions count. The weighted HM is therefore:

$$WHM = \frac{1}{\sum_{i=1}^n \frac{Z_i}{\sum_{j=1}^n Z_j} \frac{1}{R_i}} = \frac{n}{\sum_{i=1}^n \frac{Z_i}{\sum_{j=1}^n Z_j} \frac{t_i}{Z_i}} = \frac{\sum_{j=1}^n Z_j}{\sum_{i=1}^n t_i} \quad (2.7)$$

We see that the weighted HM is the quotient of the sum of the operation count divided by the sum of the execution times.

Geometric Mean

Looking at the equations for the three types of means, it is easier to get an intuitive sense of the behavior of the AM and the HM than that of the GM. Several observations from [FEIT15] may be helpful in this regard. First, we note that with respect to changes in values, the GM gives equal weight to all of the values in the data set. For example, suppose the set of data values to be averaged includes a few large values and more small values. Here, the AM is dominated by the large values. A change of 10% in the largest value will have a noticeable effect, while a change in the smallest value by the same factor will have a negligible effect. In contrast, a change in value by 10% of any of the data values results in the same change in the GM: $\sqrt[n]{1.1}$.

Example 2.5

This point is illustrated by data set (e) in **Figure 2.6**. Here are the effects of increasing either the maximum or the minimum value in the data set by 10%:

	Geometric Mean	Arithmetic Mean
Original value	3.37	4.45
	3.40 (+ 0.87%)	4.55 (+ 2.24%)

Increase max value from 11 to 12.1 (+ 10%)		
Increase min value from 1 to 1.1 (+ 10%)	3.40 (+ 0.87%)	4.46 (+ 0.20%)

A second observation is that for the GM of a ratio, the GM of the ratios equals the ratio of the GMs:

$$GM = \left(\prod_{i=1}^n \frac{Z_i}{t_i} \right)^{1/n} = \frac{\prod_{i=1}^n Z_i}{\prod_{i=1}^n t_i} \quad (2.8)$$

Compare this with [Equation 2.4](#).

For use with execution times, as opposed to rates, one drawback of the GM is that it may be non-monotonic relative to the more intuitive AM. In other words there may be cases where the AM of one data set is larger than that of another set, but the GM is smaller.

Example 2.6

In [Figure 2.6](#), the AM for data set d is larger than the AM for data set c, but the opposite is true for the GM.

	Data set c	Data set d
Arithmetic mean	7.00	7.55
Geometric mean	6.68	6.42

One property of the GM that has made it appealing for benchmark analysis is that it provides consistent results when measuring the relative performance of machines. This is in fact what benchmarks are primarily used for: to compare one machine with another in terms of performance metrics. The results, as we have seen, are expressed in terms of values that are normalized to a reference machine.

Example 2.7

A simple example will illustrate the way in which the GM exhibits consistency for normalized results. In [Table 2.3](#), we use the same performance results as were used in [Table 2.2](#). In [Table 2.3a](#), all results are normalized to Computer A, and the means are calculated on the normalized values. Based on total execution time, A is faster than B, which is faster than C. Both the AMs and GMs of the normalized times reflect this. In [Table 2.3b](#), the systems are now normalized to B. Again the GMs correctly reflect the relative speeds of the three computers, but now the AM produces a different ordering.

Table 2.3 A Comparison of Arithmetic and Geometric Means for Normalized Results

(a) Results normalized to Computer A			

	Computer A time	Computer B time	Computer C time
Program 1	2.0 (1.0)	1.0 (0.5)	0.75 (0.38)
Program 2	0.75 (1.0)	2.0 (2.67)	4.0 (5.33)
Total execution time	2.75	3.0	4.75
Arithmetic mean of normalized times	1.00	1.58	2.85
Geometric mean of normalized times	1.00	1.15	1.41

(b) Results normalized to Computer B			
	Computer A time	Computer B time	Computer C time
Program 1	2.0 (2.0)	1.0 (1.0)	0.75 (0.75)
Program 2	0.75 (0.38)	2.0 (1.0)	4.0 (2.0)
Total execution time	2.75	3.0	4.75
Arithmetic mean of normalized times	1.19	1.00	1.38
Geometric mean of normalized times	0.87	1.00	1.22

Sadly, consistency does not always produce correct results. In [Table 2.4](#), some of the execution times are altered. Once again, the AM reports conflicting results for the two normalizations. The GM reports consistent results, but the result is that B is faster than A and C, which are equal.

Table 2.4 Another Comparison of Arithmetic and Geometric Means for Normalized Results

(a) Results normalized to Computer A			
	Computer A time	Computer B time	Computer C time
Program 1	2.0 (1.0)	1.0 (0.5)	0.20 (0.1)

Program 2	0.4 (1.0)	2.0 (5.0)	4.0 (10.0)
Total execution time	2.4	3.00	4.2
Arithmetic mean of normalized times	1.00	2.75	5.05
Geometric mean of normalized times	1.00	1.58	1.00

	(b) Results normalized to Computer B		
	Computer A time	Computer B time	Computer C time
Program 1	2.0 (2.0)	1.0 (1.0)	0.20 (0.2)
Program 2	0.4 (0.2)	2.0 (1.0)	4.0 (2.0)
Total execution time	2.4	3.00	4.2
Arithmetic mean of normalized times	1.10	1.00	1.10
Geometric mean of normalized times	0.63	1.00	0.63

It is examples like this that have fueled the “benchmark means wars” in the citations listed earlier. It is safe to say that no single number can provide all the information that one needs for comparing performance across systems. However, despite the conflicting opinions in the literature, SPEC has chosen to use the GM, for several reasons:

1. As mentioned, the GM gives consistent results regardless of which system is used as a reference. Because benchmarking is primarily a comparison analysis, this is an important feature.
2. As documented in [MCMA93], and confirmed in subsequent analyses by SPEC analysts [MASH04], the GM is less biased by outliers than the HM or AM.
3. [MASH04] demonstrates that distributions of performance ratios are better modeled by lognormal distributions than by normal ones, because of the generally skewed distribution of the normalized numbers. This is confirmed in [CITR06]. And, as shown in [Equation \(2.5\)](#), the GM can be described as the back-transformed average of a lognormal distribution.

2.6 Benchmarks and Spec

Benchmark Principles

Measures such as MIPS and MFLOPS have proven inadequate to evaluating the performance of processors. Because of differences in instruction sets, the instruction execution rate is not a valid means of comparing the performance of different architectures.

Example 2.8

Consider this high-level language statement:

```
A = B + C /* assume all quantities in main memory */
```

With a traditional instruction set architecture, referred to as a complex instruction set computer (CISC), this instruction can be compiled into one processor instruction:

```
add mem(B), mem(C), mem(A)
```

On a typical RISC machine, the compilation would look something like this:

```
load mem(B), reg(1);
load mem(C), reg(2);
add reg(1), reg(2), reg(3);
store reg(3), mem(A)
```

Because of the nature of the RISC architecture (discussed in [Chapter 15](#)), both machines may execute the original high-level language instruction in about the same time. If this example is representative of the two machines, then if the CISC machine is rated at 1 MIPS, the RISC machine would be rated at 4 MIPS. But both do the same amount of high-level language work in the same amount of time.

Another consideration is that the performance of a given processor on a given program may not be useful in determining how that processor will perform on a very different type of application. Accordingly, beginning in the late 1980s and early 1990s, industry and academic interest shifted to measuring the performance of systems using a set of benchmark programs. The same set of programs can be run on different machines and the execution times compared. Benchmarks provide guidance to customers trying to decide which system to buy, and can be useful to vendors and designers in determining how to design systems to meet benchmark goals.

[WEIC90] lists the following as desirable characteristics of a benchmark program:

1. It is written in a high-level language, making it portable across different machines.
2. It is representative of a particular kind of programming domain or paradigm, such as systems programming, numerical programming, or commercial programming.
3. It can be measured easily.

4. It has wide distribution.

SPEC Benchmarks

The common need in industry and academic and research communities for generally accepted computer performance measurements has led to the development of standardized benchmark suites. A benchmark suite is a collection of programs, defined in a high-level language, that together attempt to provide a representative test of a computer in a particular application or system programming area. The best known such collection of benchmark suites is defined and maintained by the Standard Performance Evaluation Corporation (SPEC), an industry consortium. This organization defines several benchmark suites aimed at evaluating computer systems. SPEC performance measurements are widely used for comparison and research purposes.

The best known of the SPEC benchmark suites is SPEC CPU2017. This is the industry standard suite for processor-intensive applications. That is, SPEC CPU2017 is appropriate for measuring performance for applications that spend most of their time doing computation rather than I/O.

Other SPEC suites include the following:

- **SPEC Cloud_IaaS:** Benchmark addresses the performance of infrastructure-as-a-service (IaaS) public or private cloud platforms.
- **SPECviewperf:** Standard for measuring 3D graphics performance based on professional applications.
- **SPECwpc:** benchmark to measure all key aspects of workstation performance based on diverse professional applications, including media and entertainment, product development, life sciences, financial services, and energy.
- **SPECjvm2008:** Intended to evaluate performance of the combined hardware and software aspects of the Java Virtual Machine (JVM) client platform.
- **SPECjbb2015 (Java Business Benchmark):** A benchmark for evaluating server-side Java-based electronic commerce applications.
- **SPECsfs2014:** Designed to evaluate the speed and request-handling capabilities of file servers.
- **SPECvirt_sc2013:** Performance evaluation of datacenter servers used in virtualized server consolidation. Measures the end-to-end performance of all system components including the hardware, virtualization platform, and the virtualized guest operating system and application software. The benchmark supports hardware virtualization, operating system virtualization, and hardware partitioning schemes.

The CPU2017 suite is based on existing applications that have already been ported to a wide variety of platforms by SPEC industry members. In order to make the benchmark results reliable and realistic, the CPU2017 benchmarks are drawn from real-life applications, rather than using artificial loop programs or synthetic benchmarks. The suite consists of 20 integer benchmarks and 23 floating-point benchmarks written in C, C++, and Fortran ([Table 2.5](#)). For all of the integer benchmarks and most of the floating-point benchmarks, there are both rate and speed benchmark programs. The differences between corresponding rate and speed benchmarks include workload sizes, compile flags, and run rules. The suite contains over 11 million lines of code. This is the sixth generation of processor-intensive suites from SPEC; the fifth generation was CPU2006. CPU2017 is designed to provide a contemporary set of benchmarks that reflect the dramatic changes in workload and performance requirements in the 11 years since CPU2006 [MOOR17].

Table 2.5 SPEC CPU2017 Benchmarks

Kloc = line count (including comments/whitespace) for source files used in a build/1000

(a) Integer

Rate	Speed	Language	Kloc	Application Area
500.perlbench_r	600.perlbench_s	C	363	Perl interpreter
502.gcc_r	602.gcc_s	C	1304	GNU C compiler
505.mcf_r	605.mcf_s	C	3	Route planning
520.omnetpp_r	620.omnetpp_s	C++	134	Discrete event simulation - computer network
523.xalancbmk_r	623.xalancbmk_s	C++	520	XML to HTML conversion via XSLT
525.x264_r	625.x264_s	C	96	Video compression
531.deepsjeng_r	631.deepsjeng_s	C++	10	AI: alpha-beta tree search (chess)
541.leela_r	641.leela_s	C++	21	AI: Monte Carlo tree search (Go)
548.exchange2_r	648.exchange2_s	Fortran	1	AI: recursive solution generator (Sudoku)
557.xz_r	657.xz_s	C	33	General data compression

(b) Floating Point

503.bwaves_r	603.bwaves_s	Fortran	1	Explosion modeling
507.cactuBSSN_r	607.cactuBSSN_s	C++, C, Fortran	257	Physics; relativity
508.namd_r		C++, C	8	Molecular dynamics
510.parest_r		C++	427	Biomedical imaging; optical tomography with finite elements
511.povray_r		C++	170	Ray tracing
519.ibm_r	619.ibm_s	C	1	Fluid dynamics
521.wrf_r	621.wrf_s	Fortran, C	991	Weather forecasting
526.blender_r		C++	1577	3D rendering and animation

527.cam4_r	627.cam4_s	Fortran, C	407	Atmosphere modeling
	628.pop2_s	Fortran, C	338	Wide-scale ocean modeling (climate level)
538.imagick_r	638.imagick_s	C	259	Image manipulation
544.nab_r	644.nab_s	C	24	Molecular dynamics
549.fotonik3d_r	649.fotonik3d_s	Fortran	14	Computational electromagnetics
554.roms_r	654.roms_s	Fortran	210	Regional ocean modeling.

To better understand published results of a system using CPU2017, we define the following terms used in the SPEC documentation:

- **Benchmark:** A program written in a high-level language that can be compiled and executed on any computer that implements the compiler.
- **System under test:** This is the system to be evaluated.
- **Reference machine:** This is a system used by SPEC to establish a baseline performance for all benchmarks. Each benchmark is run and measured on this machine to establish a reference time for that benchmark. A system under test is evaluated by running the CPU2017 benchmarks and comparing the results for running the same programs on the reference machine.
- **Base metric:** These are required for all reported results and have strict guidelines for compilation. In essence, the standard compiler with more or less default settings should be used on each system under test to achieve comparable results.
- **Peak metric:** This enables users to attempt to optimize system performance by optimizing the compiler output. For example, different compiler options may be used on each benchmark, and feedback-directed optimization is allowed.
- **Speed metric:** This is simply a measurement of the time it takes to execute a compiled benchmark. The speed metric is used for comparing the ability of a computer to complete single tasks.
- **Rate metric:** This is a measurement of how many tasks a computer can accomplish in a certain amount of time; this is called a **throughput**, capacity, or rate measure. The rate metric allows the system under test to execute simultaneous tasks to take advantage of multiple processors.

SPEC uses a historical Sun system, the “Ultra Enterprise 2,” which was introduced in 1997, as the reference machine. The reference machine uses a 296-MHz UltraSPARC II processor. It takes about 12 days to do a rule-conforming run of the base metrics for CINT2017 and CFP2017 on the CPU2017 reference machine. [Tables 2.5](#) and [2.6](#) show the amount of time to run each benchmark using the reference machine. The tables also show the dynamic instruction counts on the reference machine, as reported in [PHAN07]. These values are the actual number of instructions executed during the run of each program.

Table 2.6 SPEC CPU2017 Integer Benchmarks for HP Integrity Superdome X

(a) Rate Result (768 copies)		
	Base	Peak

Benchmark	Seconds	Rate	Seconds	Rate
500.perlbench_r	1141	1070	933	1310
502.gcc_r	1303	835	1276	852
505.mcf_r	1433	866	1378	901
520.omnetpp_r	1664	606	1634	617
523.xalancbmk_r	722	1120	713	1140
525.x264_r	655	2053	661	2030
531.deepsjeng_r	604	1460	597	1470
541.leela_r	892	1410	896	1420
548.exchange2_r	833	2420	770	2610
557.xz_r	870	953	863	961

(b) Speed Result (384 threads)

Benchmark	Base		Peak	
	Seconds	Ratio	Seconds	Ratio
600.perlbench_s	358	4.96	295	6.01
602.gcc_s	546	7.29	535	7.45
605.mcf_s	866	5.45	700	6.75
620.omnetpp_s	276	5.90	247	6.61
623.xalancbmk_s	188	7.52	179	7.91
625.x264_s	283	6.23	271	6.51
631.deepsjeng_s	407	3.52	343	4.18
641.leela_s	469	3.63	439	3.88
648.exchange2_s	329	8.93	299	9.82

We now consider the specific calculations that are done to assess a system. We consider the integer benchmarks; the same procedures are used to create a floating-point benchmark value. For the integer benchmarks, there are 12 programs in the test suite. Calculation is a three-step process ([Figure 2.7](#)):

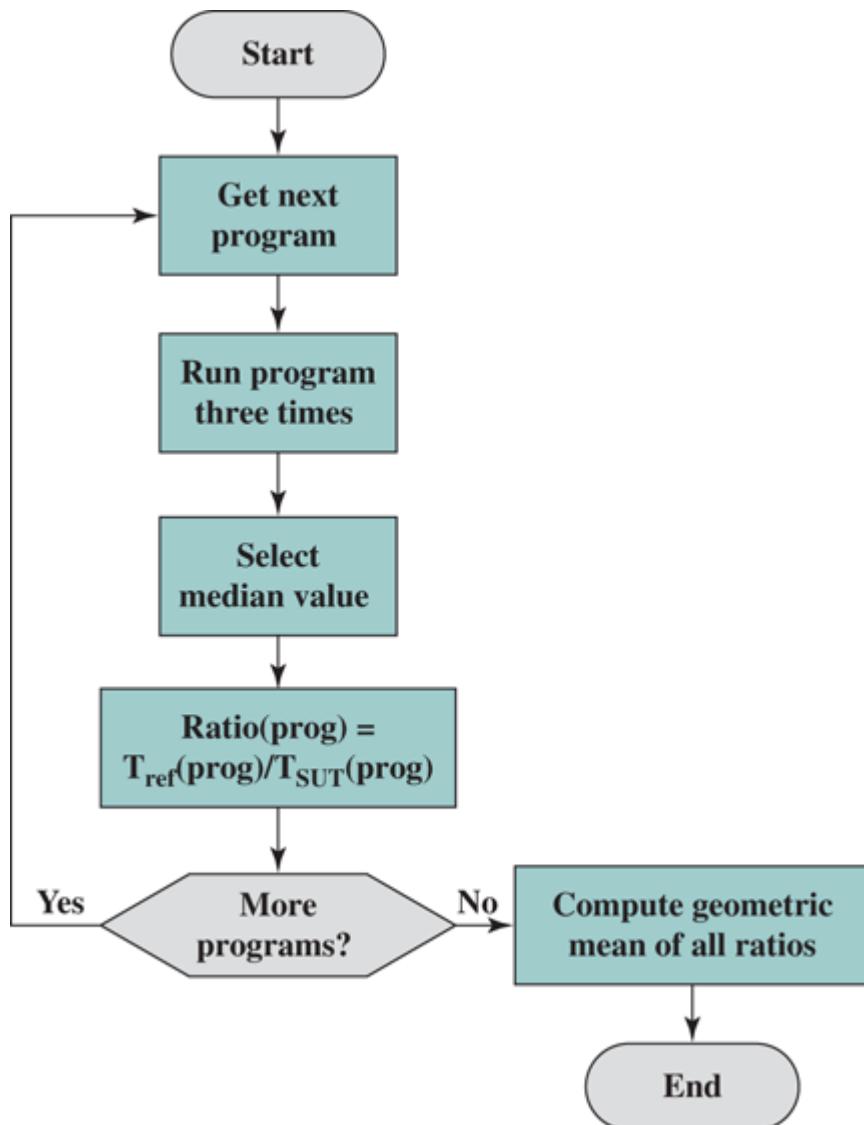

Figure 2.7 SPEC Evaluation Flowchart

1. The first step in evaluating a system under test is to compile and run each program on the system three times. For each program, the runtime is measured and the median value is selected. The reason to use three runs and take the median value is to account for variations in execution time that are not intrinsic to the program, such as disk access time variations, and OS kernel execution variations from one run to another.
2. Next, each of the 12 results is normalized by calculating the runtime ratio of the reference run time to the system run time. The ratio is calculated as follows:

$$r_i = \frac{T_{ref_i}}{T_{sut_i}} \quad (2.9)$$

where T_{ref_i} is the execution time of benchmark program i on the reference system and T_{sut_i} is the execution time of benchmark program i on the system under test. Thus, ratios are higher for faster machines.

3. Finally, the geometric mean of the 12 runtime ratios is calculated to yield the overall metric:

$$r_G = \prod_{i=1}^{12} r_i$$

For the integer benchmarks, four separate metrics can be calculated:

- **SPECspeed2017_int_base:** The geometric mean of 12 normalized ratios when the benchmarks are compiled with base tuning.
- **SPECspeed2017_int_peak:** The geometric mean of 12 normalized ratios when the benchmarks are compiled with peak tuning.
- **SPECrate2017_int_base:** The geometric mean of 12 normalized throughput ratios when the benchmarks are compiled with base tuning.
- **SPECrate2017_int_peak:** The geometric mean of 12 normalized throughput ratios when the benchmarks are compiled with peak tuning.

Table 2.6 shows the CPU2017 integer benchmarks reported for the HP Integrity Superdome X.

Example 2.9

One of the SPEC CPU2017 integer speed benchmarks is 625.x264_s. This is an implementation of H.264/AVC (Advanced Video Coding), the commonly used video compression standard. The reference machine Sun Fire V490 executes this program in a median time of 1764 seconds for the base speed metric. The HP Integrity Superdome X requires 283 seconds. The ratio is calculated as: $1764 / 283 = 6.23$. Similar calculations are done to determine the ratios for the other benchmark programs. The SPECspeed2017_int_base speed metric is calculated by taking the tenth root of the product of the ratios:

$$(4.96 \times 7.29 \times 5.45 \times 5.90 \times 7.52 \times 6.23 \times 3.52 \times 3.63 \times 8.93 \times 2.86)^{1/10} = 5.31$$

The rate metrics take into account a system with multiple processors. To test a machine, a number of copies N is selected—usually this is equal to the number of processors or the number of simultaneous threads of execution on the test system. Each individual test program's rate is determined by taking the median of three runs. Each run consists of N copies of the program running simultaneously on the test system. The execution time is the time it takes for all the copies to finish (i.e., the time from when the first copy starts until the last copy finishes). The rate metric for that program is calculated by the following formula:

$$\text{rate}_i = N \times \frac{T_{ref_i}}{T_{sut_i}}$$

The rate score for the system under test is determined from a geometric mean of rates for each program in the test suite.

Example 2.10

The results for the HP Integrity Superdome X are shown in **Table 2.6a**. This system has 16 processor chips, with 24 cores per chip, for a total of 384 cores. Two threads are run per core so that a total of 768 copies of a program are run simultaneously. To get the rate metric, each benchmark program is executed simultaneously on all threads, with the execution time being the time from the start of all 768 copies to the end of the slowest run. The speed ratio is calculated as before, and the rate value is simply 384 times the speed ratio. For example, for the integer rate benchmark SPECrate2017_int_base, the reference machine report a speed of 1751 seconds, and

the system under test reports a speed of 655 seconds. The rate is calculated as $768 \times (1751 / 655) = 2053$. The final rate metric is found by taking the geometric mean of the rate values:

$$(1070 \times 835 \times 866 \times 606 \times 1120 \times 2053 \times 1460 \times 1410 \times 2420 \times 953)^{1/10} = 1223$$

SPEC CPU2017 introduces an additional, experimental, metric that enables measurement of power consumption while running the benchmark, giving users insight into the relationship between performance and power. A vendor can measure and report power statistics, including maximum power (W), average power (W), and total energy used (kJ) and compare these to the reference machine. The results for the reference machine are shown in [Table 2.7](#).

Table 2.7 SPECspeed2017_int_base Benchmark Results for Reference Machine (1 thread)

Benchmark	Seconds	Energy (kJ)	Average Power (W)	Maximum Power (W)
600.perlbench_s	1774	1920	1080	1090
602.gcc_s	3981	4330	1090	1110

Review Questions

- 2.1 List and briefly define some of the techniques used in contemporary processors to increase speed.
- 2.2 Explain the concept of performance balance.
- 2.3 Explain the differences among multicore systems, MICs, and GPGPUs.
- 2.4 Briefly characterize Amdahl's law.
- 2.5 Briefly characterize Little's law.
- 2.6 Define MIPS and FLOPS.
- 2.7 List and define three methods for calculating a mean value of a set of data values.
- 2.8 List the desirable characteristics of a benchmark program.
- 2.9 What are the SPEC benchmarks?
- 2.10 What are the differences among base metric, peak metric, speed metric, and rate metric?

Problems

2.1 A benchmark program is run on a 40 MHz processor. The executed program consists of 100,000 instruction executions, with the following instruction mix and clock cycle count:

Instruction Type	Instruction Count	Cycles per Instruction
Integer arithmetic	45,000	1
Data transfer	32,000	2
Floating point	15,000	2
Control transfer	8000	2

Determine the effective CPI, MIPS rate, and execution time for this program.

2.2 Consider two different machines, with two different instruction sets, both of which have a clock rate of 200 MHz. The following measurements are recorded on the two machines running a given set of benchmark programs:

Instruction Type	Instruction Count (millions)	Cycles per Instruction
Machine A		
Arithmetic and logic	8	1
Load and store	4	3
Branch	2	4
Others	4	3
Machine A		
Arithmetic and logic	10	1

Load and store	8	2
Branch	2	4
Others	4	3

- a. Determine the effective CPI, MIPS rate, and execution time for each machine.
- b. Comment on the results.

2.3 Early examples of CISC and RISC design are the VAX 11/780 and the IBM RS/6000, respectively. Using a typical benchmark program, the following machine characteristics result:

Processor	Clock Frequency (MHz)	Performance (MIPS)	CPU Time (secs)
VAX 11/780	5	1	12 x
IBM RS/6000	25	18	x

The final column shows that the VAX required 12 times longer than the IBM measured in CPU time.

- a. What is the relative size of the instruction count of the machine code for this benchmark program running on the two machines?
- b. What are the *CPI* values for the two machines?

2.4 Four benchmark programs are executed on three computers with the following results:

	Computer A	Computer B	Computer C
Program 1	1	10	20
Program 2	1000	100	20
Program 3	500	1000	50
Program 4	100	800	100

The table shows the execution time in seconds, with 100,000,000 instructions executed in each of the four programs. Calculate the MIPS values for each computer for each program. Then calculate the arithmetic and harmonic means assuming equal weights for the four programs, and rank the computers based on arithmetic mean and harmonic mean.

2.5 The following table, based on data reported in the literature [HEAT84], shows the execution times, in seconds, for five different benchmark programs on three machines.

Benchmark	Processor		
	R	M	Z
E	417	244	134

F	83	70	70
H	66	153	135
I	39,449	35,527	66,000
K	772	368	369

- a. Compute the speed metric for each processor for each benchmark, normalized to machine R. That is, the ratio values for R are all 1.0. Other ratios are calculated using **Equation (2.5)** with R treated as the reference system. Then compute the arithmetic mean value for each system using **Equation (2.3)**. This is the approach taken in [HEAT84].
- b. Repeat part (a) using M as the reference machine. This calculation was not tried in [HEAT84].
- c. Which machine is the slowest based on each of the preceding two calculations?
- d. Repeat the calculations of parts (a) and (b) using the geometric mean, defined in **Equation (2.6)**. Which machine is the slowest based on the two calculations?

2.6 To clarify the results of the preceding problem, we look at a simpler example.

Benchmark	Processor		
	X	Y	Z
1	20	10	40
2	40	80	20

- a. Compute the arithmetic mean value for each system using X as the reference machine and then using Y as the reference machine. Argue that intuitively, the three machines have roughly equivalent performance and that the arithmetic mean gives misleading results.
- b. Compute the geometric mean value for each system, using X as the reference machine and then using Y as the reference machine. Argue that the results are more realistic than with the arithmetic mean.

2.7 Consider the example in **Section 2.5** for the calculation of average CPI and MIPS rate, which yielded the result of $CPI=2.24$ and MIPS rate=178. Now assume that the program can be executed in eight parallel tasks or threads, with roughly equal number of instructions executed in each task. Execution is on an 8-core system, with each core (processor) having the same performance as the single processor originally used. Coordination and synchronization between the parts adds an extra 25,000 instruction executions to each task. Assume the same instruction mix as in the example for each task, but increase the CPI for memory reference with cache miss to 12 cycles due to contention for memory.

- a. Determine the average CPI.
- b. Determine the corresponding MIPS rate.

- c. Calculate the speedup factor.
- d. Compare the actual speedup factor with the theoretical speedup factor determined by Amdahl's law.

2.8 A processor accesses main memory with an average access time of T_2 . A smaller cache memory is interposed between the processor and main memory. The cache has a significantly faster access time of $T_1 < T_2$. The cache holds, at any time, copies of some main memory words and is designed so that the words more likely to be accessed in the near future are in the cache. Assume that the probability that the next word accessed by the processor is in the cache is H , known as the hit ratio.

- a. For any single memory access, what is the theoretical speedup of accessing the word in the cache rather than in main memory?
- b. Let T be the average access time. Express T as a function of T_1 , T_2 , and H . What is the overall speedup as a function of H ?
- c. In practice, a system may be designed so that the processor must first access the cache to determine if the word is in the cache and, if it is not, then access main memory, so that on a miss (opposite of a hit), memory access time is $T_1 + T_2$. Express T as a function of T_1 , T_2 , and H . Now calculate the speedup and compare to the result produced in part (b).

2.9 The owner of a shop observes that on average 18 customers per hour arrive, and there are typically 8 customers in the shop. What is the average length of time each customer spends in the shop?

2.10 We can gain more insight into Little's law by considering [Figure 2.8a](#). Over a period of time T , a total of C items arrive at a system, wait for service, and complete service. The upper solid line shows the time sequence of arrivals, and the lower solid line shows the time sequence of departures. The shaded area bounded by the two lines represents the total "work" done by the system in units of job-seconds; let A be the total work. We wish to derive the relationship among L , W , and λ .

- a. [Figure 2.8b](#) divides the total area into horizontal rectangles, each with a height of one job. Picture sliding all these rectangles to the left so that their left edges line up at $t = 0$. Develop an equation that relates A , C , and W .
- b. [Figure 2.8c](#) divides the total area into vertical rectangles, defined by the vertical transition boundaries indicated by the dashed lines. Picture sliding all these rectangles down so that their lower edges line up at $N(t) = 0$. Develop an equation that relates A , T , and L .
- c. Finally, derive $L = \lambda W$ from the results of (a) and (b).

2.11 In [Figure 2.8a](#), jobs arrive at times $t = 0, 1, 1.5, 3.25, 5.25$, and 7.75 . The corresponding completion times are $t = 2, 3, 3.5, 4.25, 8.25$, and 8.75 .

- a. Determine the area of each of the six rectangles in [Figure 2.8b](#) and sum to get the total area A . Show your work.
- b. Determine the area of each of the 10 rectangles in [Figure 2.8c](#) and sum to get the total area A . Show your work.

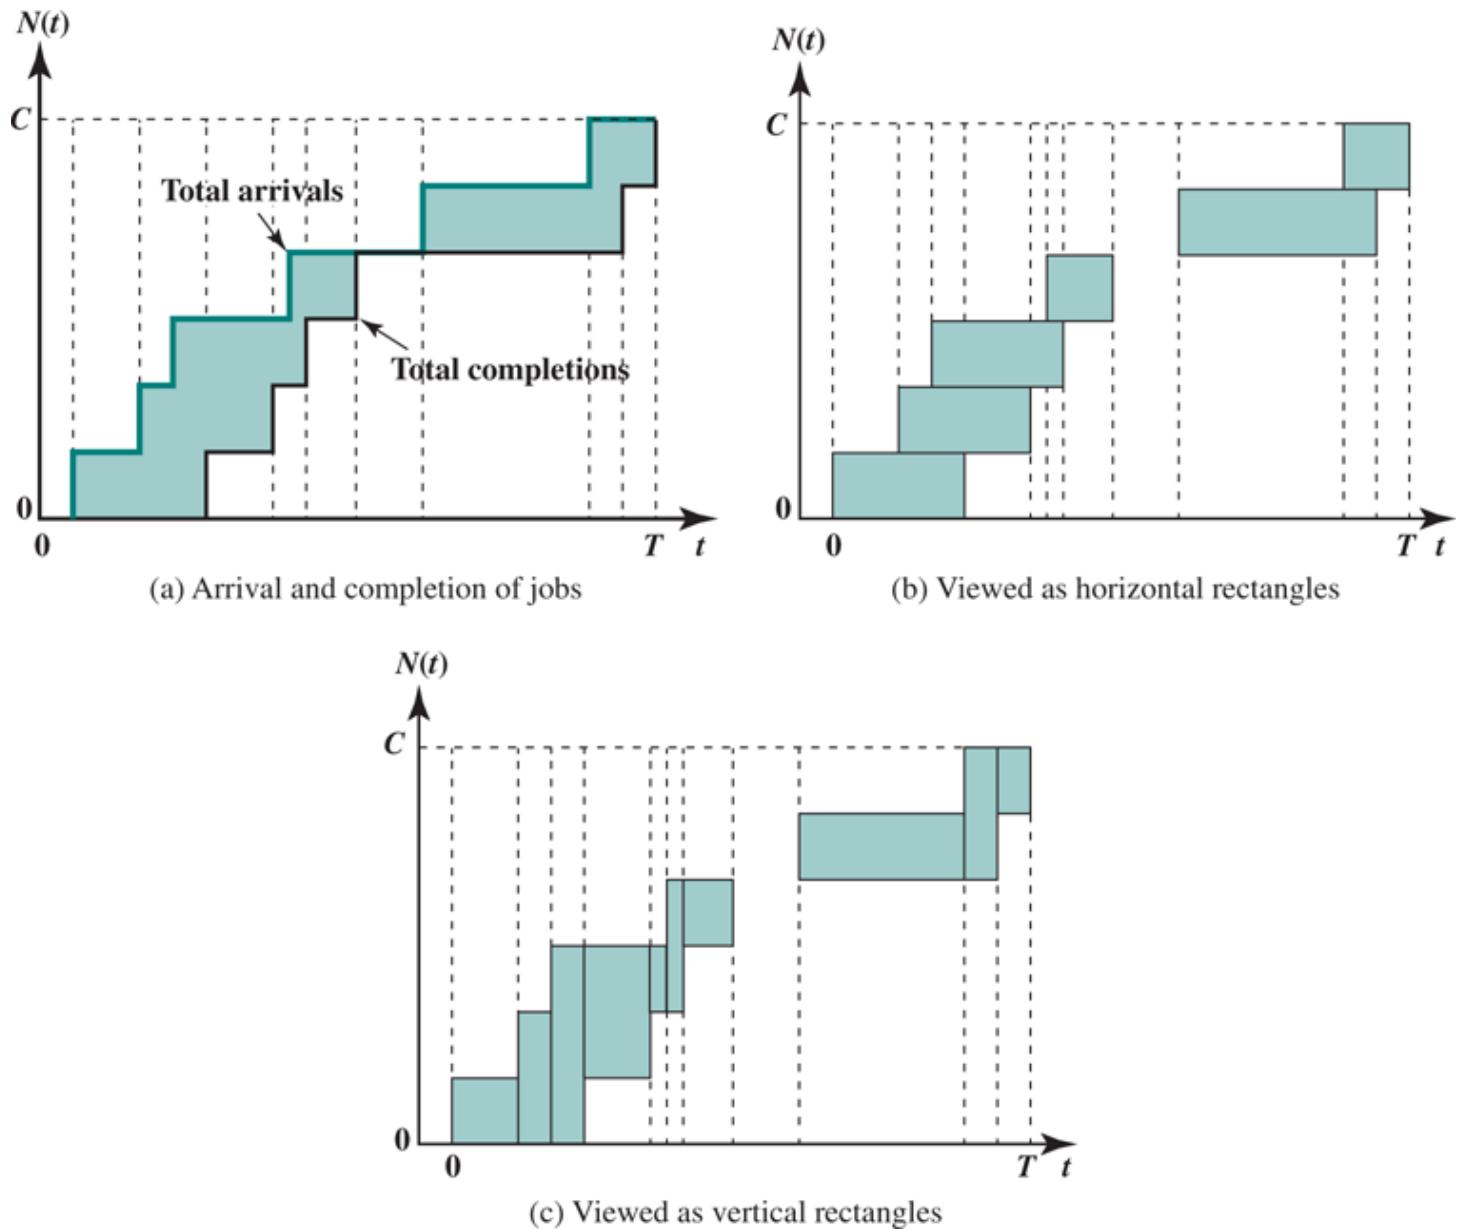

Figure 2.8 Illustration of Little's Law

2.12 In [Section 2.6](#), we specified that the base ratio used for comparing a system under test to a reference system is:

$$r_i = \frac{T_{ref_i}}{T_{sut_i}}$$

- The preceding equation provides a measure of the speedup of the system under test compared to the reference system. Assume that the number of floating-point operations executed in the test program is I_i . Now show the speedup as a function of the instruction execution rate $FLOPS_i$.
- Another technique for normalizing performance is to express the performance of a system as a percent change relative to the performance of another system. Express this relative change first as a function of instruction execution rate, and then as a function of execution times.

2.13 Assume that a benchmark program executes in 480 seconds on a reference machine A. The same program executes on systems B, C, and D in 360, 540, and 210 seconds, respectively.

- a. Show the speedup of each of the three systems under test relative to A.
- b. Now show the relative speedup of the three systems. Comment on the three ways of comparing machines (execution time, speedup, relative speedup).

2.14 Repeat the preceding problem using machine D as the reference machine. How does this affect the relative rankings of the four systems?

2.15 Recalculate the results in **Table 2.2** using the computer time data of **Table 2.4** and comment on the results.

2.16 **Equation 2.5** shows two different formulations of the geometric mean, one using a product operator and one using a summation operator.

- a. Show that the two formulas are equivalent.
- b. Why would the summation formulation be preferred for calculating the geometric mean?

2.17 **Project.** **Section 2.5** lists a number of references that document the “benchmark means wars.” All of the referenced papers are available at box.com/COA10e. Read these papers and summarize the case for and against the use of the geometric mean for SPEC calculations.

Learning Objectives

After studying this chapter, you should be able to:

- Understand the basic elements of an instruction cycle and the role of interrupts.
- Describe the concept of interconnection within a computer system.
- Assess the relative advantages of point-to-point interconnection compared to bus interconnection.
- Present an overview of QPI.
- Present an overview of PCIe.

At a top level, a computer consists of CPU (central processing unit), memory, and I/O components, with one or more modules of each type. These components are interconnected in some fashion to achieve the basic function of the computer, which is to execute programs. Thus, at a top level, we can characterize a computer system by describing (1) the external behavior of each component, that

is, the data and control signals that it exchanges with other components, and (2) the interconnection structure and the controls required to manage the use of the interconnection structure.

This top-level view of structure and function is important because of its explanatory power in understanding the nature of a computer. Equally important is its use to understand the increasingly complex issues of performance evaluation. A grasp of the top-level structure and function offers insight into system bottlenecks, alternate pathways, the magnitude of system failures if a component fails, and the ease of adding performance enhancements. In many cases, requirements for greater system power and fail-safe capabilities are being met by changing the design rather than merely increasing the speed and reliability of individual components.

This chapter focuses on the basic structures used for computer component interconnection. As background, the chapter begins with a brief examination of the basic components and their interface requirements. Then a functional overview is provided. We are then prepared to examine the use of buses to interconnect system components.

3.1 Computer Components

As discussed in [Chapter 1](#), virtually all contemporary computer designs are based on concepts developed by John von Neumann at the Institute for Advanced Studies, Princeton. Such a design is referred to as the *von Neumann architecture* and is based on three key concepts:

- Data and instructions are stored in a single read–write memory.
- The contents of this memory are addressable by location, without regard to the type of data contained there.
- Execution occurs in a sequential fashion (unless explicitly modified) from one instruction to the next.

The reasoning behind these concepts was discussed in [Chapter 2](#) but is worth summarizing here. There is a small set of basic logic components that can be combined in various ways to store binary data and perform arithmetic and logical operations on that data. If there is a particular computation to be performed, a configuration of logic components designed specifically for that computation could be constructed. We can think of the process of connecting the various components in the desired configuration as a form of programming. The resulting “program” is in the form of hardware and is termed a *hardwired program*.

Now consider this alternative. Suppose we construct a general-purpose configuration of arithmetic and logic functions. This set of hardware will perform various functions on data depending on control signals applied to the hardware. In the original case of customized hardware, the system accepts data and produces results ([Figure 3.1a](#)). With general-purpose hardware, the system accepts data and control signals and produces results. Thus, instead of rewiring the hardware for each new program, the programmer merely needs to supply a new set of control signals.

How shall control signals be supplied? The answer is simple but subtle. The entire program is actually a sequence of steps. At each step, some arithmetic or logical operation is performed on some data. For each step, a new set of control signals is needed. Let us provide a unique code for each possible set of control signals, and let us add to the general-purpose hardware a segment that can accept a code and generate control signals ([Figure 3.1b](#)).

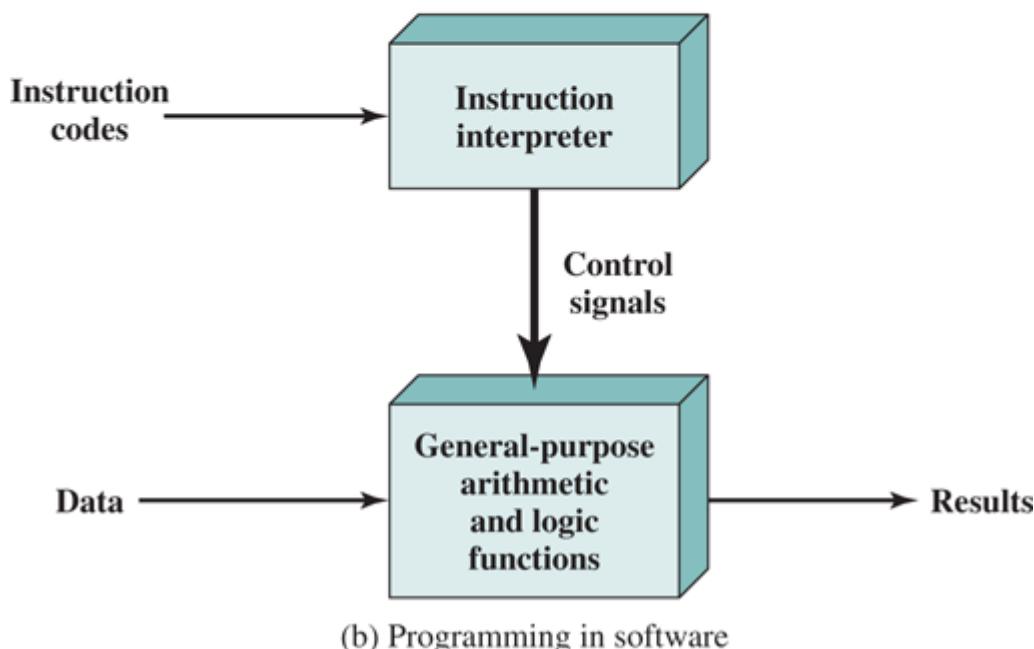

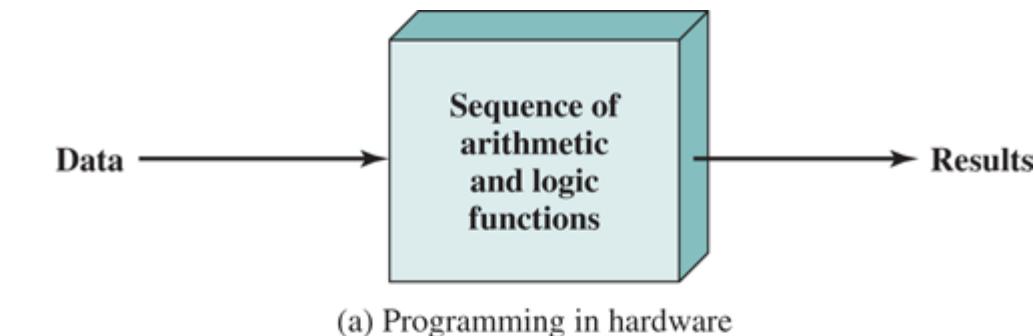

Figure 3.1 Hardware and Software Approaches

Programming is now much easier. Instead of rewiring the hardware for each new program, all we need to do is provide a new sequence of codes. Each code is, in effect, an instruction, and part of the hardware interprets each instruction and generates control signals. To distinguish this new method of programming, a sequence of codes or instructions is called *software*.

Figure 3.1b indicates two major components of the system: an instruction interpreter and a module of general-purpose arithmetic and logic functions. These two constitute the CPU. Several other components are needed to yield a functioning computer. Data and instructions must be put into the system. For this we need some sort of input module. This module contains basic components for accepting data and instructions in some form and converting them into an internal form of signals usable by the system. A means of reporting results is needed, and this is in the form of an output module. Taken together, these are referred to as *I/O components*.

One more component is needed. An input device will bring instructions and data in sequentially. But a program is not invariably executed sequentially; it may jump around (e.g., the IAS jump instruction). Similarly, operations on data may require access to more than just one element at a time in a predetermined sequence. Thus, there must be a place to temporarily store both instructions and data. That module is called *memory*, or *main memory*, to distinguish it from external storage or peripheral devices. Von Neumann pointed out that the same memory could be used to store both instructions and data.

Figure 3.2 illustrates these top-level components and suggests the interactions among them. The

CPU exchanges data with memory. For this purpose, it typically makes use of two internal (to the CPU) registers: a **memory address register (MAR)**, which specifies the address in memory for the next read or write, and a **memory buffer register (MBR)**, which contains the data to be written into memory or receives the data read from memory. Similarly, an I/O address register (I/OAR) specifies a particular I/O device. An I/O buffer register (I/OBR) is used for the exchange of data between an I/O module and the CPU.

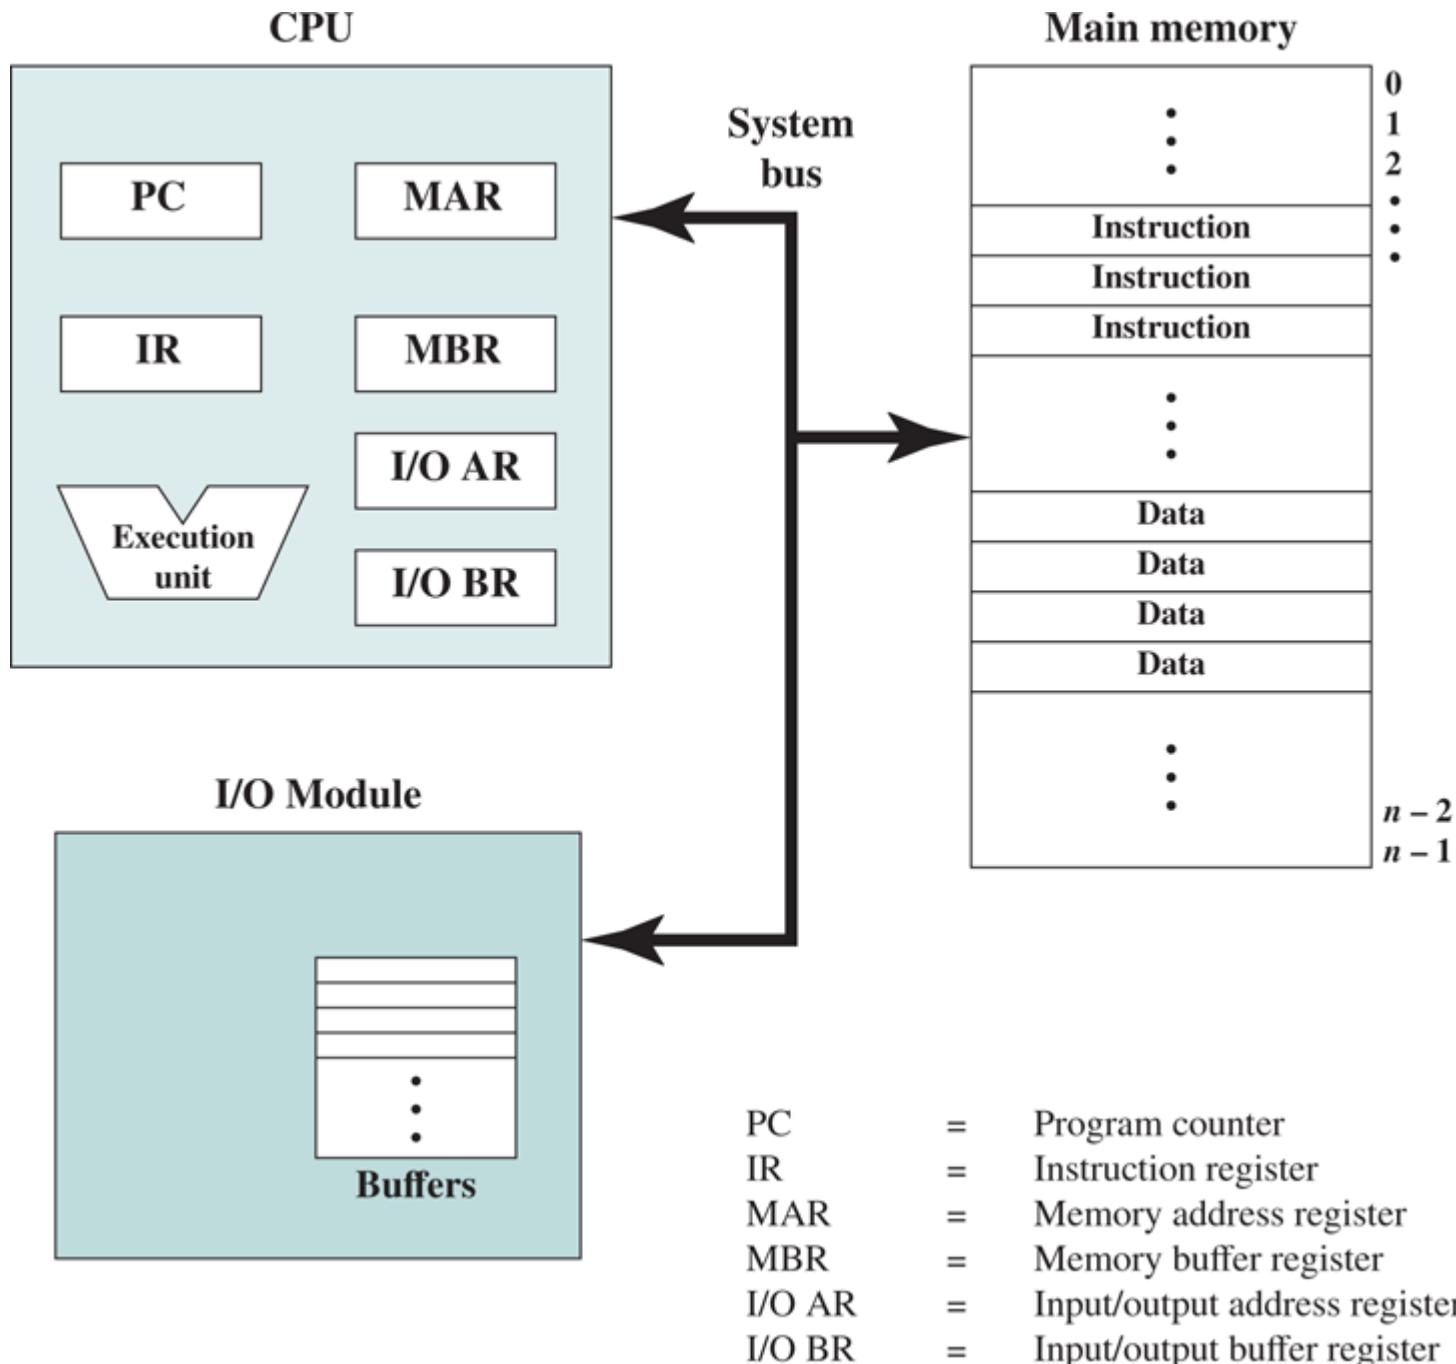

Figure 3.2 Computer Components: Top-Level View

A memory module consists of a set of locations, defined by sequentially numbered addresses. Each location contains a binary number that can be interpreted as either an instruction or data. An I/O module transfers data from external devices to CPU and memory, and vice versa. It contains internal buffers for temporarily holding these data until they can be sent on.

Having looked briefly at these major components, we now turn to an overview of how these components function together to execute programs.

3.2 Computer Function

The basic function performed by a computer is execution of a program, which consists of a set of instructions stored in memory. The processor does the actual work by executing instructions specified in the program. This section provides an overview of the key elements of program execution. In its simplest form, instruction processing consists of two steps. The processor reads (*fetches*) instructions from memory one at a time, then executes each instruction. Program execution consists of repeating the process of instruction fetch and instruction execution. The instruction execution may involve several operations and depends on the nature of the instruction (see, for example, the lower portion of [Figure 2.4](#)).

The processing required for a single instruction is called an **instruction cycle**. Using the simplified two-step description given previously, the instruction cycle is depicted in [Figure 3.3](#). The two steps are referred to as the **fetch cycle** and the **execute cycle**. Program execution halts only if the machine is turned off, some sort of unrecoverable error occurs, or a program instruction that halts the computer is encountered.

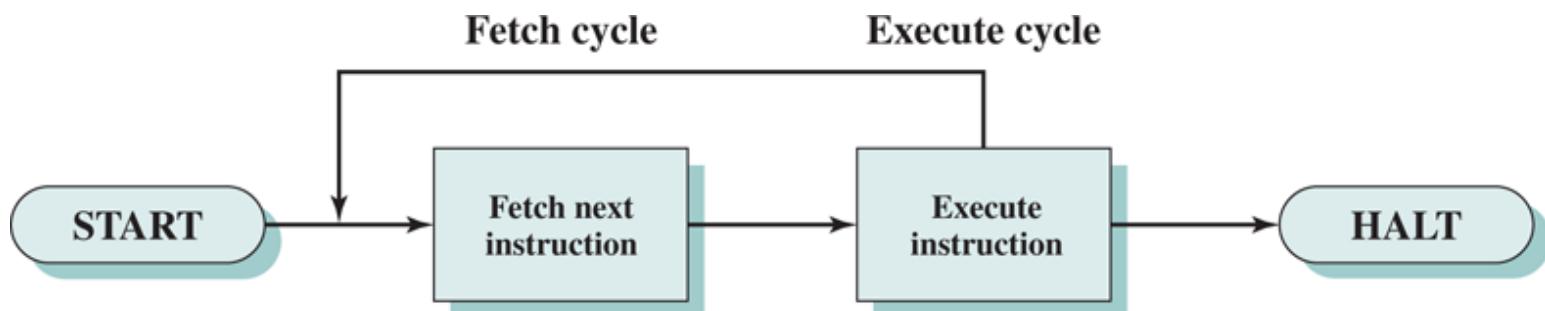

Figure 3.3 Basic Instruction Cycle

Instruction Fetch and Execute

At the beginning of each instruction cycle, the processor fetches an instruction from memory. In a typical processor, a register called the program counter (PC) holds the address of the instruction to be fetched next. Unless told otherwise, the processor always increments the PC after each instruction fetch so that it will fetch the next instruction in sequence (i.e., the instruction located at the next higher memory address). So, for example, consider a computer in which each instruction occupies one 16-bit word of memory. Assume that the program counter is set to memory location 300, where the location address refers to a 16-bit word. The processor will next fetch the instruction at location 300. On succeeding instruction cycles, it will fetch instructions from locations 301, 302, 303, and so on. This sequence may be altered, as explained presently.

The fetched instruction is loaded into a register in the processor known as the instruction register (IR). The instruction contains bits that specify the action the processor is to take. The processor interprets the instruction and performs the required action. In general, these actions fall into four categories:

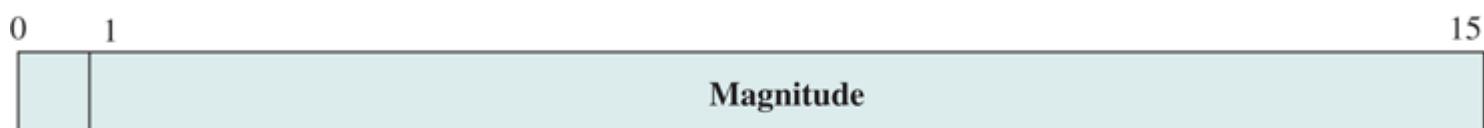

- **Processor-memory:** Data may be transferred from processor to memory or from memory to processor.
- **Processor-I/O:** Data may be transferred to or from a peripheral device by transferring between the processor and an I/O module.
- **Data processing:** The processor may perform some arithmetic or logic operation on data.
- **Control:** An instruction may specify that the sequence of execution be altered. For example, the processor may fetch an instruction from location 149, which specifies that the next instruction be

from location 182. The processor will remember this fact by setting the program counter to 182. Thus, on the next fetch cycle, the instruction will be fetched from location 182 rather than 150. An instruction's execution may involve a combination of these actions.

Consider a simple example using a hypothetical machine that includes the characteristics listed in **Figure 3.4**. The processor contains a single data register, called an accumulator (AC). Both instructions and data are 16 bits long. Thus, it is convenient to organize memory using 16-bit words. The instruction format provides 4 bits for the opcode, so that there can be as many as $2^4 = 16$ different opcodes, and up to $2^{12} = 4096$ (4K) words of memory can be directly addressed.

(a) Instruction format

(b) Integer format

Program counter (PC) = Address of instruction
 Instruction register (IR) = Instruction being executed
 Accumulator (AC) = Temporary storage

(c) Internal CPU registers

0001 = Load AC from memory
 0010 = Store AC to memory
 0101 = Add to AC from memory

(d) Partial list of opcodes

Figure 3.4 Characteristics of a Hypothetical Machine

Figure 3.5 illustrates a partial program execution, showing the relevant portions of memory and processor registers.¹ The program fragment shown adds the contents of the memory word at address 940 to the contents of the memory word at address 941 and stores the result in the latter location. Three instructions, which can be described as three fetch and three execute cycles, are required:

¹ Hexadecimal notation is used, in which each digit represents 4 bits. This is the most convenient notation for representing the contents of memory and registers when the word length is a multiple of 4. See **Chapter 9** for a basic refresher on number systems (decimal, binary, hexadecimal)

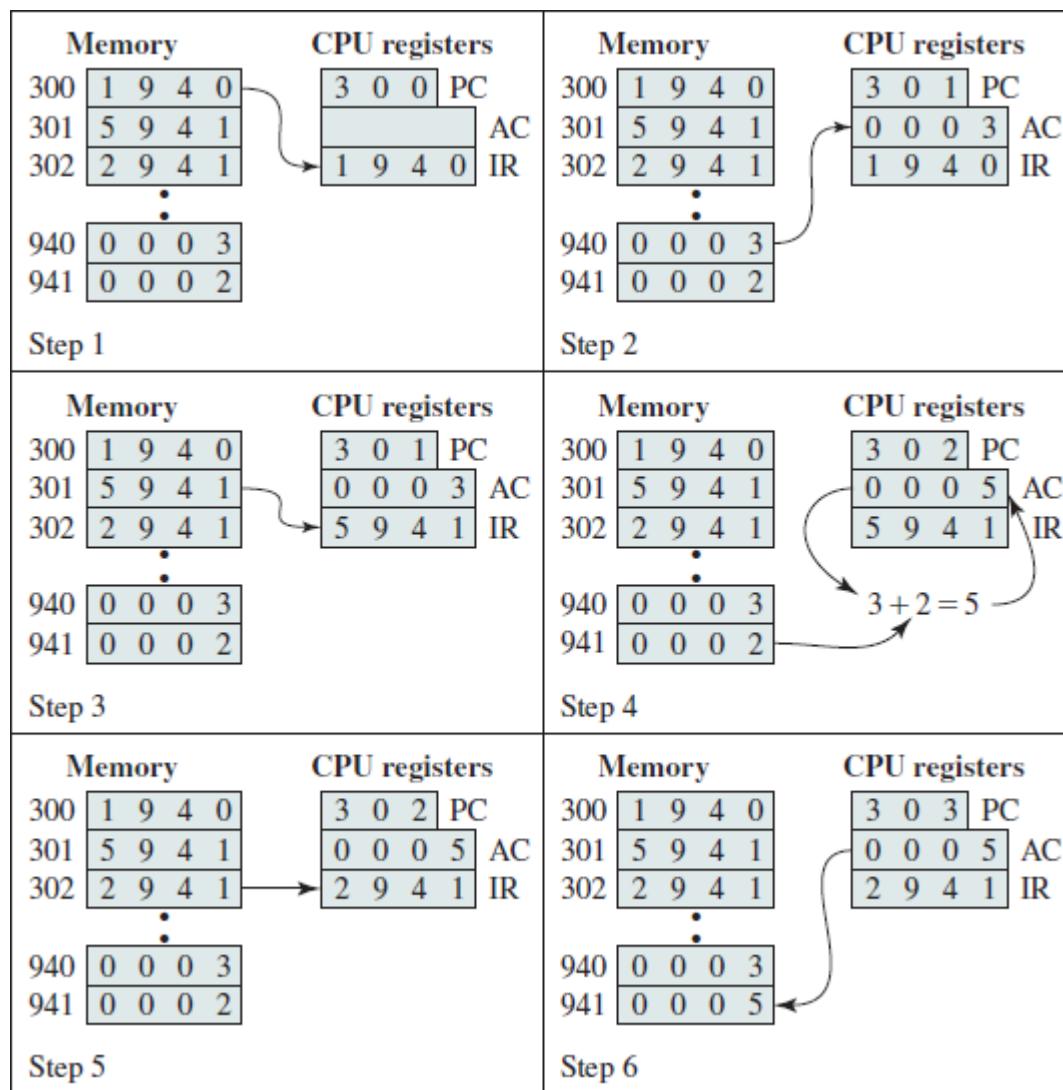

Figure 3.5 Example of Program Execution (contents of memory and registers in hexadecimal)

1. The PC contains 300, the address of the first instruction. This instruction (the value 1940 in hexadecimal) is loaded into the instruction register IR, and the PC is incremented. Note that this process involves the use of a memory address register and a memory buffer register. For simplicity, these intermediate registers are ignored.
2. The first 4 bits (first hexadecimal digit) in the IR indicate that the AC is to be loaded. The remaining 12 bits (three hexadecimal digits) specify the address (940) from which data are to be loaded.
3. The next instruction (5941) is fetched from location 301, and the PC is incremented.
4. The old contents of the AC and the contents of location 941 are added, and the result is stored in the AC.
5. The next instruction (2941) is fetched from location 302, and the PC is incremented.
6. The contents of the AC are stored in location 941.

In this example, three instruction cycles, each consisting of a fetch cycle and an execute cycle, are needed to add the contents of location 940 to the contents of 941. With a more complex set of instructions, fewer cycles would be needed. Some older processors, for example, included instructions that contain more than one memory address. Thus, the execution cycle for a particular instruction on such processors could involve more than one reference to memory. Also, instead of memory references, an instruction may specify an I/O operation.

For example, the PDP-11 processor includes an instruction, expressed symbolically as `ADD B,A`, that

stores the sum of the contents of memory locations B and A into memory location A. A single instruction cycle with the following steps occurs:

- Fetch the ADD instruction.
- Read the contents of memory location A into the processor.
- Read the contents of memory location B into the processor. In order that the contents of A are not lost, the processor must have at least two registers for storing memory values, rather than a single accumulator.
- Add the two values.
- Write the result from the processor to memory location A.

Thus, the execution cycle for a particular instruction may involve more than one reference to memory. Also, instead of memory references, an instruction may specify an I/O operation. With these additional considerations in mind, [Figure 3.6](#) provides a more detailed look at the basic instruction cycle of [Figure 3.3](#). The figure is in the form of a state diagram. For any given instruction cycle, some states may be null and others may be visited more than once. The states can be described as follows:

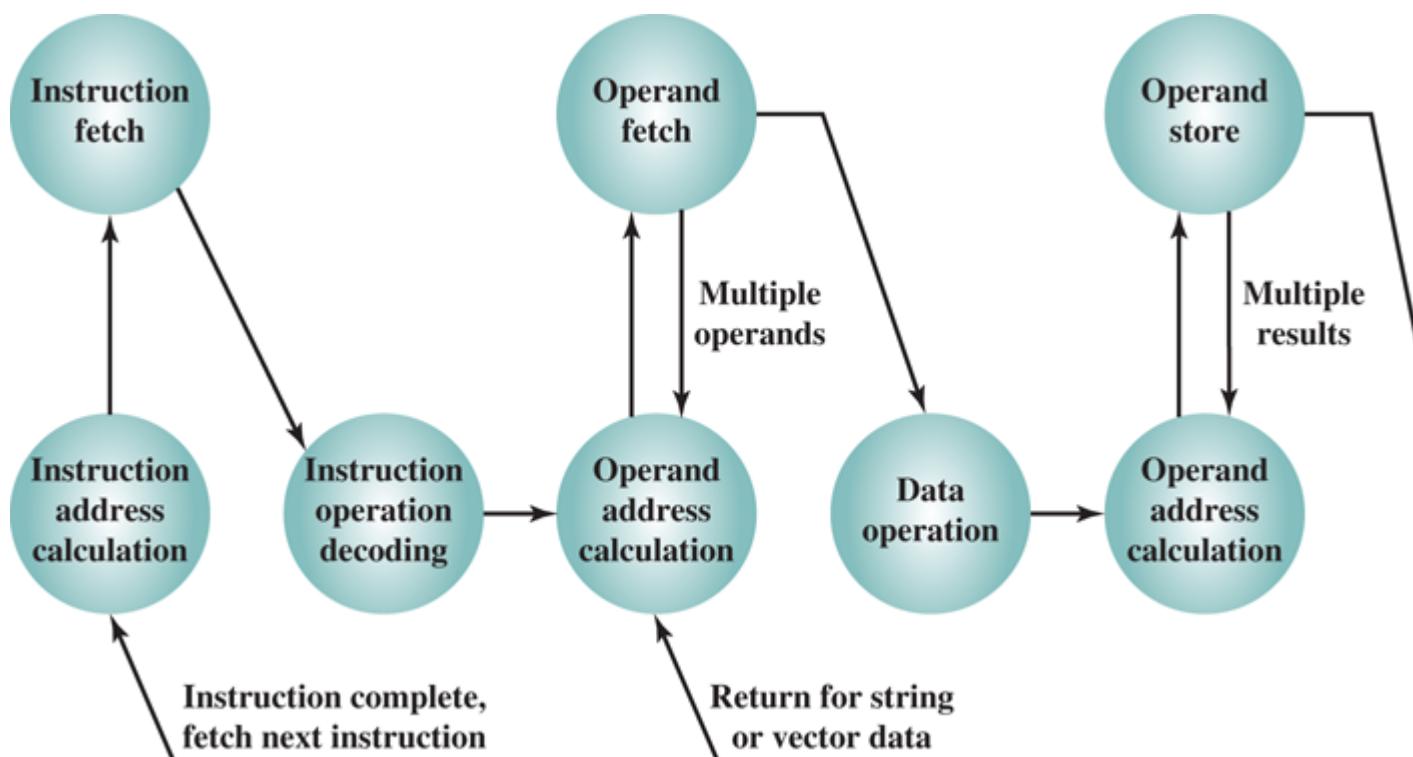

Figure 3.6 Instruction Cycle State Diagram

- **Instruction address calculation (iac):** Determine the address of the next instruction to be executed. Usually, this involves adding a fixed number to the address of the previous instruction. For example, if each instruction is 16 bits long and memory is organized into 16-bit words, then add 1 to the previous address. If instead memory is organized as individually addressable 8-bit bytes, then add 2 to the previous address.
- **Instruction fetch (if):** Read instruction from its memory location into the processor.
- **Instruction operation decoding (iod):** Analyze instruction to determine type of operation to be performed and operand(s) to be used.
- **Operand address calculation (oac):** If the operation involves reference to an operand in memory or available via I/O, then determine the address of the operand.
- **Operand fetch (of):** Fetch the operand from memory or read it in from I/O.
- **Data operation (do):** Perform the operation indicated in the instruction.
- **Operand store (os):** Write the result into memory or out to I/O.

States in the upper part of [Figure 3.6](#) involve an exchange between the processor and either memory

or an I/O module. States in the lower part of the diagram involve only internal processor operations. The oac state appears twice, because an instruction may involve a read, a write, or both. However, the action performed during that state is fundamentally the same in both cases, and so only a single state identifier is needed.

Also note that the diagram allows for multiple operands and multiple results, because some instructions on some machines require this. For example, the PDP-11 instruction ADD A,B results in the following sequence of states: iac, if, iod, oac, of, oac, of, do, oac, os.

Finally, on some machines, a single instruction can specify an operation to be performed on a vector (one-dimensional array) of numbers or a string (one-dimensional array) of characters. As [Figure 3.6](#) indicates, this would involve repetitive operand fetch and/or store operations.

Interrupts

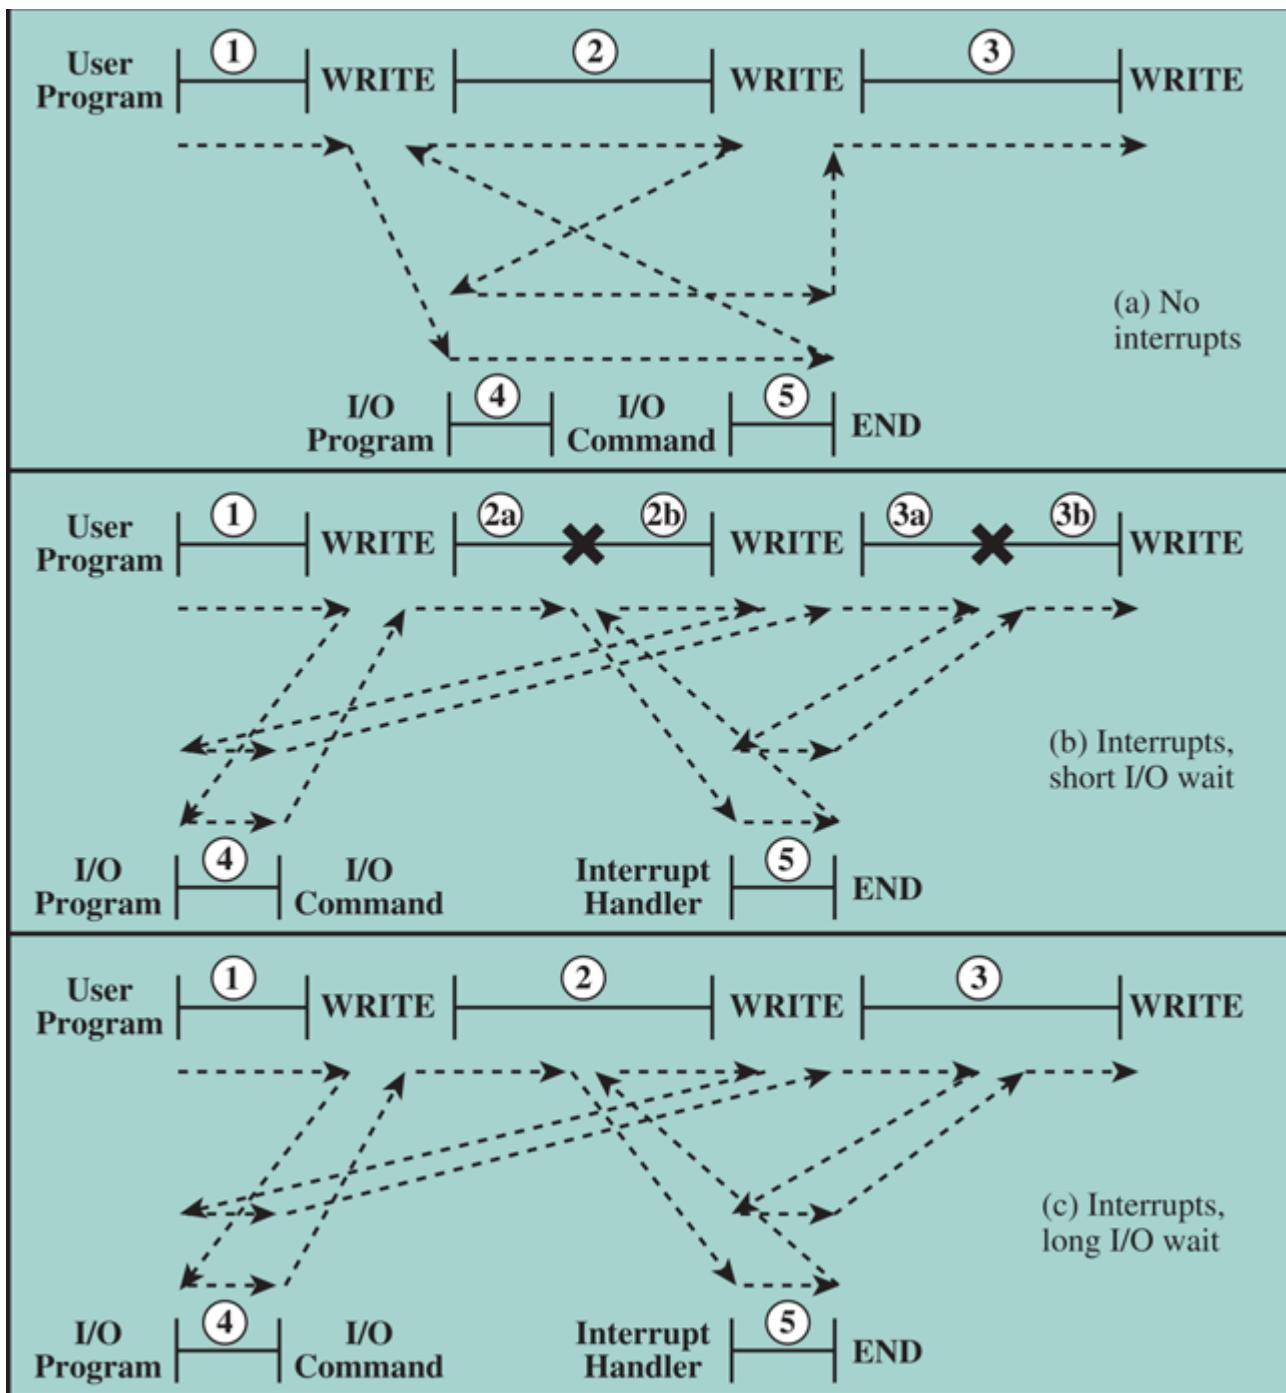

Virtually all computers provide a mechanism by which other modules (I/O, memory) may [interrupt](#) the normal processing of the processor. [Table 3.1](#) lists the most common classes of interrupts. The specific nature of these interrupts is examined later in this book, especially in [Chapters 7 and 14](#). However, we need to introduce the concept now to understand more clearly the nature of the instruction cycle and the implications of interrupts on the interconnection structure. The reader need not be concerned at this stage about the details of the generation and processing of interrupts, but only focus on the communication between modules that results from interrupts.

Table 3.1 Classes of Interrupts

Program	Generated by some condition that occurs as a result of an instruction execution, such as arithmetic overflow, division by zero, attempt to execute an illegal machine instruction, or reference outside a user's allowed memory space.
Timer	Generated by a timer within the processor. This allows the operating system to perform certain functions on a regular basis.
I/O	Generated by an I/O controller, to signal normal completion of an operation, request service from the processor, or to signal a variety of error conditions.
Hardware Failure	Generated by a failure such as power failure or memory parity error.

Interrupts are provided primarily as a way to improve processing efficiency. For example, most external devices are much slower than the processor. Suppose that the processor is transferring data to a printer using the instruction cycle scheme of [Figure 3.3](#). After each write operation, the processor must pause and remain idle until the printer catches up. The length of this pause may be on the order of many hundreds or even thousands of instruction cycles that do not involve memory. Clearly, this is a very wasteful use of the processor.

[Figure 3.7a](#) illustrates this state of affairs. The user program performs a series of WRITE calls interleaved with processing. Code segments 1, 2, and 3 refer to sequences of instructions that do not involve I/O. The WRITE calls are to an I/O program that is a system utility and that will perform the actual I/O operation. The I/O program consists of three sections:

✗ = interrupt occurs during course of execution of user program

Figure 3.7 Program Flow of Control without and with Interrupts

- A sequence of instructions, labeled 4 in the figure, to prepare for the actual I/O operation. This may include copying the data to be output into a special buffer and preparing the parameters for a device command.
- The actual I/O command. Without the use of interrupts, once this command is issued, the program must wait for the I/O device to perform the requested function (or periodically poll the device). The program might wait by simply repeatedly performing a test operation to determine if the I/O operation is done.
- A sequence of instructions, labeled 5 in the figure, to complete the operation. This may include setting a flag indicating the success or failure of the operation.

Because the I/O operation may take a relatively long time to complete, the I/O program is hung up waiting for the operation to complete; hence, the user program is stopped at the point of the WRITE

call for some considerable period of time.

INTERRUPTS AND THE INSTRUCTION CYCLE

With interrupts, the processor can be engaged in executing other instructions while an I/O operation is in progress. Consider the flow of control in [Figure 3.7b](#). As before, the user program reaches a point at which it makes a system call in the form of a WRITE call. The I/O program that is invoked in this case consists only of the preparation code and the actual I/O command. After these few instructions have been executed, control returns to the user program. Meanwhile, the external device is busy accepting data from computer memory and printing it. This I/O operation is conducted concurrently with the execution of instructions in the user program.

When the external device becomes ready to be serviced—that is, when it is ready to accept more data from the processor—the I/O module for that external device sends an *interrupt request* signal to the processor. The processor responds by suspending operation of the current program, branching off to a program to service that particular I/O device, known as an **interrupt handler**, and resuming the original execution after the device is serviced. The points at which such interrupts occur are indicated by an asterisk in [Figure 3.7b](#).

Let us try to clarify what is happening in [Figure 3.7](#). We have a user program that contains two WRITE commands. There is a segment of code at the beginning, then one WRITE command, then a second segment of code, then a second WRITE command, then a third and final segment of code. The WRITE command invokes the I/O program provided by the OS. Similarly, the I/O program consists of a segment of code, followed by an I/O command, followed by another segment of code. The I/O command invokes a hardware I/O operation.

From the point of view of the user program, an interrupt is just that: an interruption of the normal sequence of execution. When the interrupt processing is completed, execution resumes ([Figure 3.8](#)). Thus, the user program does not have to contain any special code to accommodate interrupts; the processor and the operating system are responsible for suspending the user program and then resuming it at the same point.

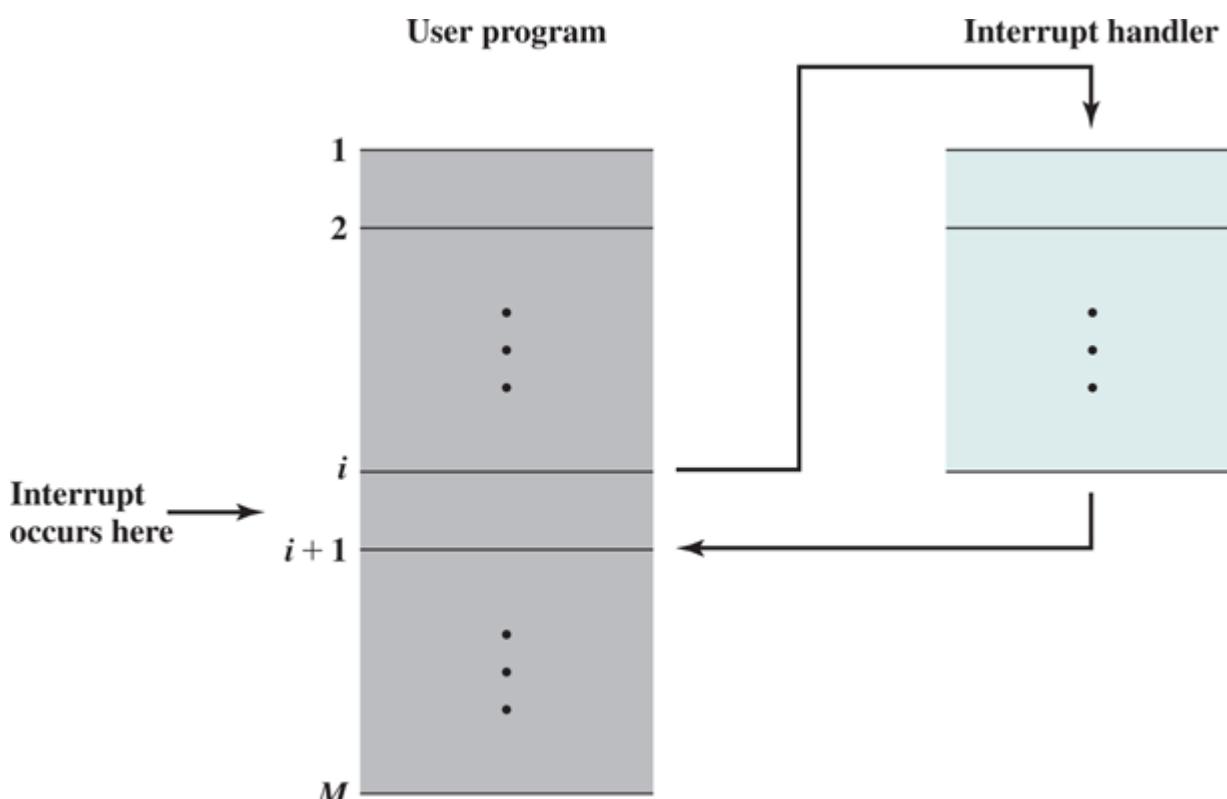

Figure 3.8 Transfer of Control via Interrupts

To accommodate interrupts, an *interrupt cycle* is added to the instruction cycle, as shown in [Figure 3.9](#). In the interrupt cycle, the processor checks to see if any interrupts have occurred, indicated by the presence of an interrupt signal. If no interrupts are pending, the processor proceeds to the fetch cycle and fetches the next instruction of the current program. If an interrupt is pending, the processor does the following:

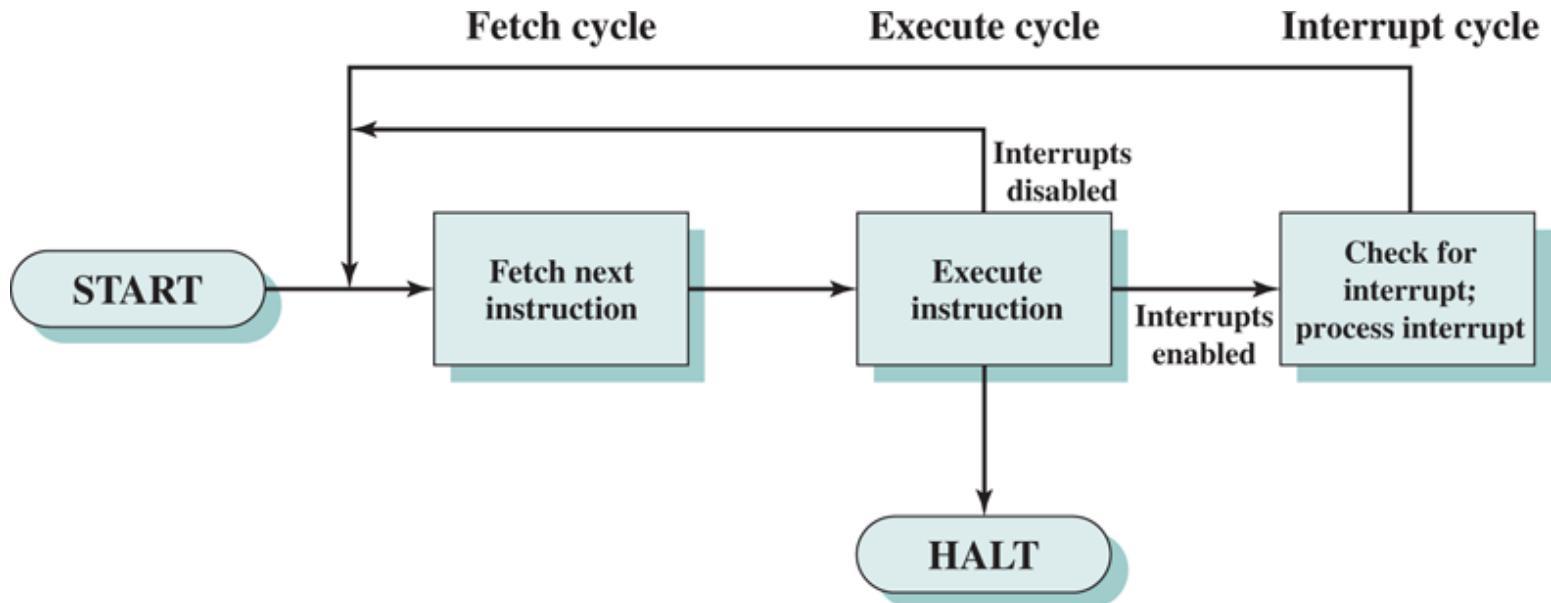

Figure 3.9 Instruction Cycle with Interrupts

- It suspends execution of the current program being executed and saves its context. This means saving the address of the next instruction to be executed (current contents of the program counter) and any other data relevant to the processor's current activity.
- It sets the program counter to the starting address of an *interrupt handler* routine.

The processor now proceeds to the fetch cycle and fetches the first instruction in the interrupt handler program, which will service the interrupt. The interrupt handler program is generally part of the operating system. Typically, this program determines the nature of the interrupt and performs whatever actions are needed. In the example we have been using, the handler determines which I/O module generated the interrupt and may branch to a program that will write more data out to that I/O module. When the interrupt handler routine is completed, the processor can resume execution of the user program at the point of interruption.

It is clear that there is some overhead involved in this process. Extra instructions must be executed (in the interrupt handler) to determine the nature of the interrupt and to decide on the appropriate action. Nevertheless, because of the relatively large amount of time that would be wasted by simply waiting on an I/O operation, the processor can be employed much more efficiently with the use of interrupts.

To appreciate the gain in efficiency, consider [Figure 3.10](#), which is a timing diagram based on the flow of control in [Figures 3.7a](#) and [3.7b](#). In this figure, user program code segments are shaded green, and I/O program code segments are shaded gray. [Figure 3.10a](#) shows the case in which interrupts are not used. The processor must wait while an I/O operation is performed.

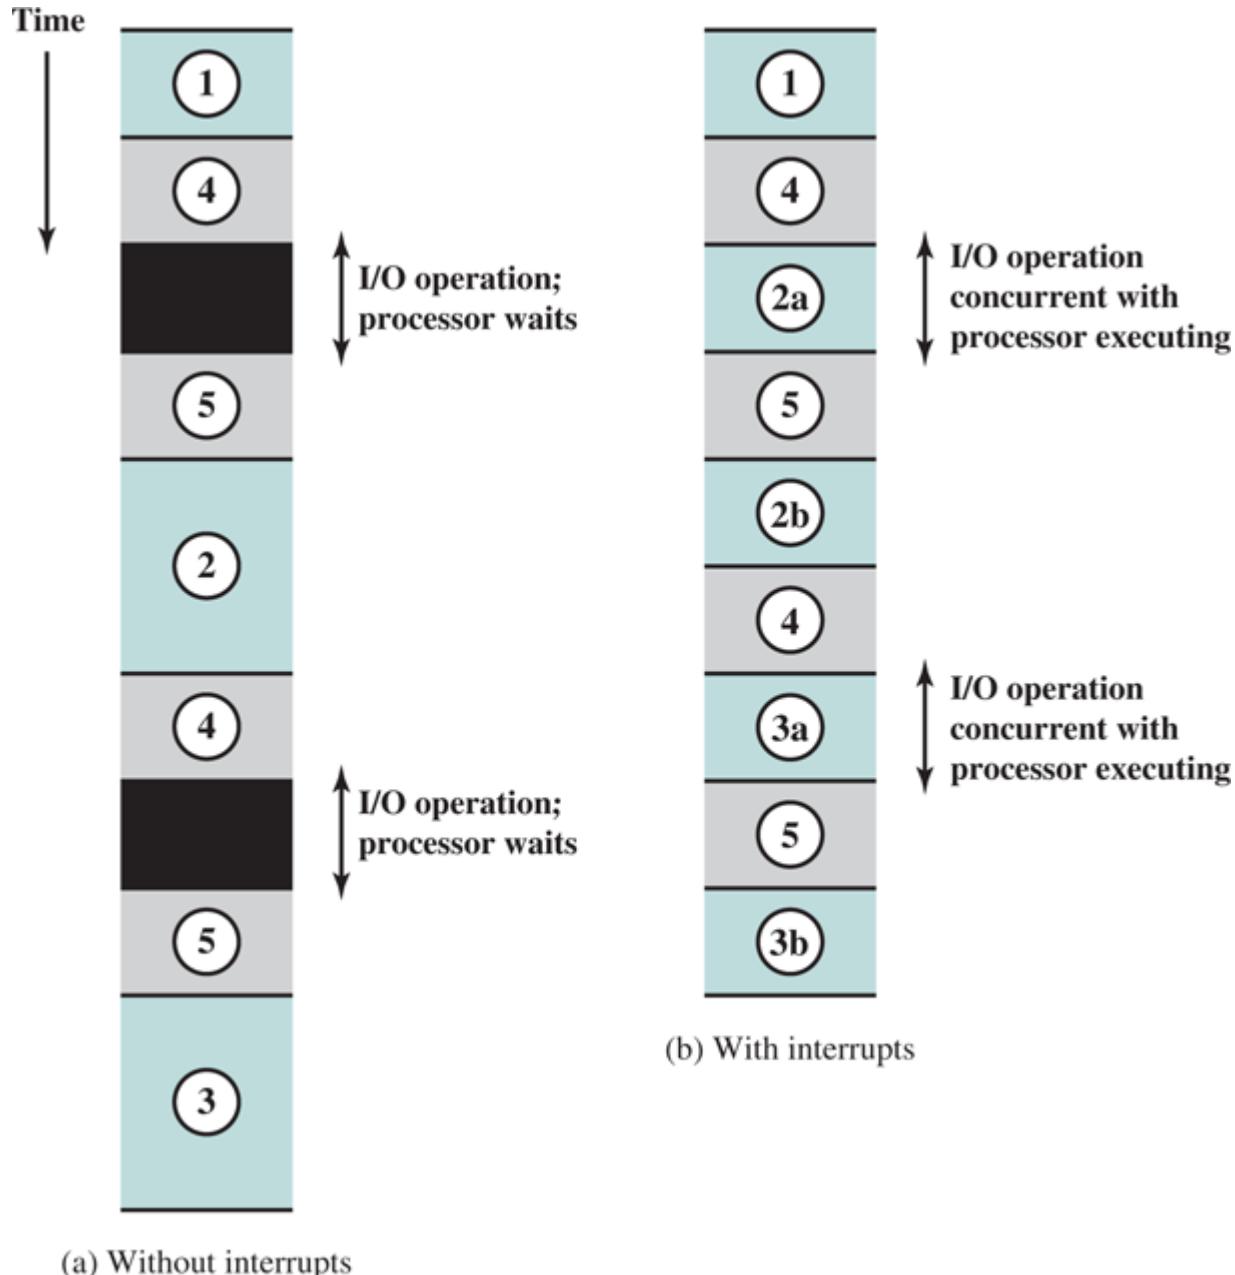

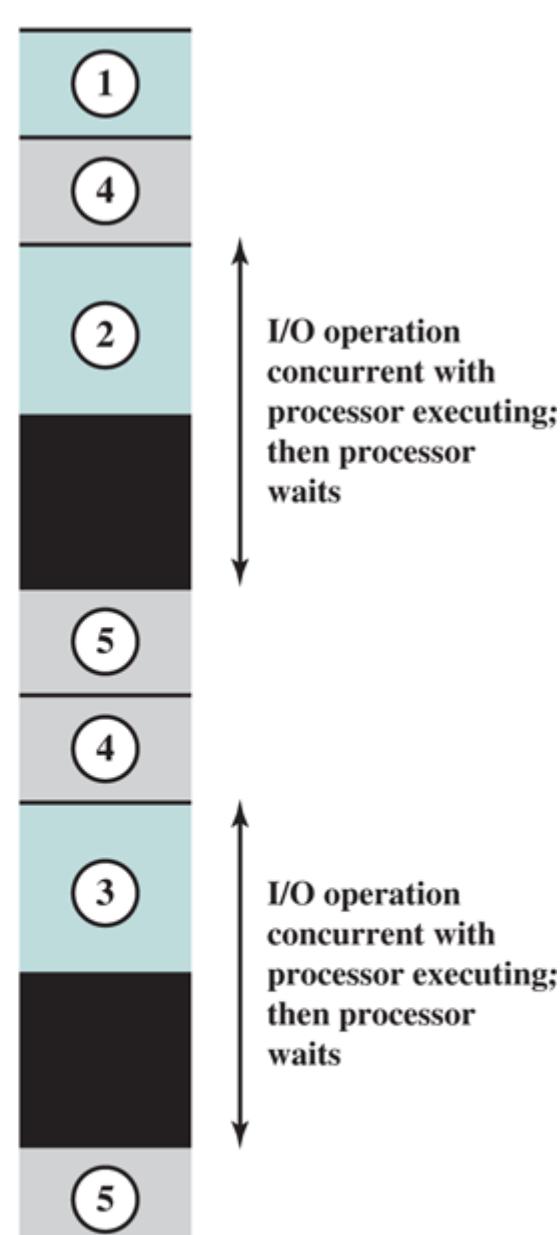

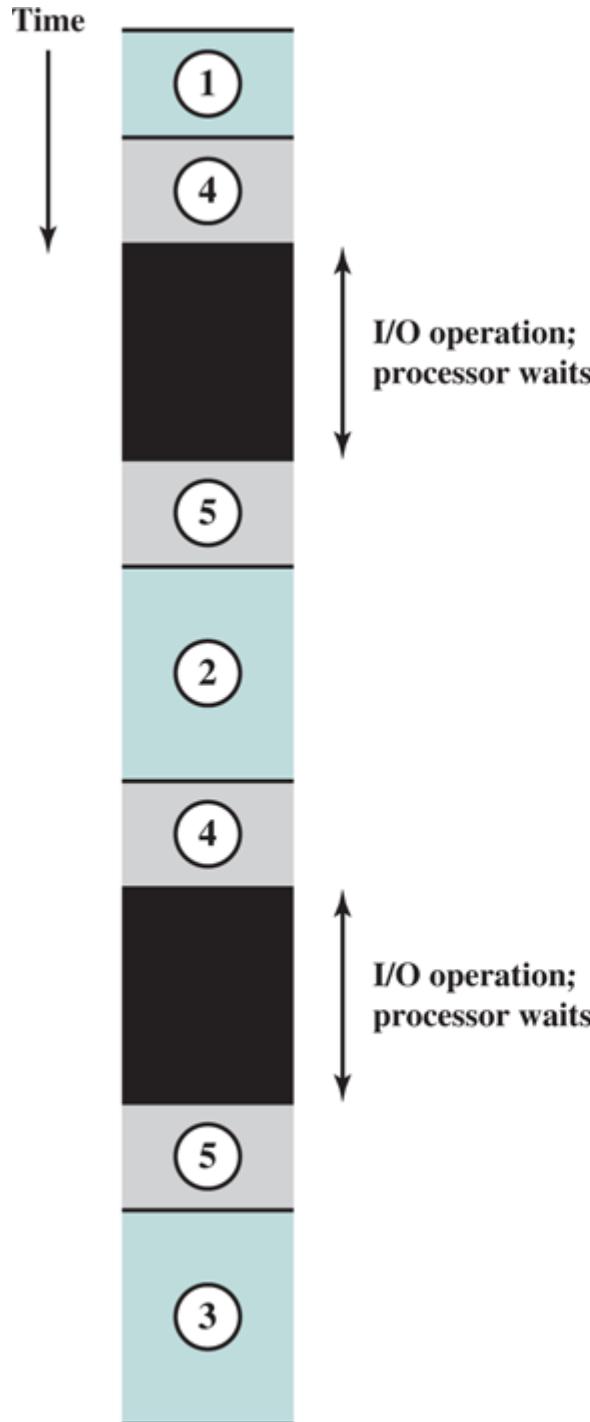

Figure 3.10 Program Timing: Short I/O Wait

Figures 3.7b and **3.10b** assume that the time required for the I/O operation is relatively short: less than the time to complete the execution of instructions between write operations in the user program. In this case, the segment of code labeled code segment 2 is interrupted. A portion of the code (2a) executes (while the I/O operation is performed) and then the interrupt occurs (upon the completion of the I/O operation). After the interrupt is serviced, execution resumes with the remainder of code segment 2 (2b).

The more typical case, especially for a slow device such as a printer, is that the I/O operation will take much more time than executing a sequence of user instructions. **Figure 3.7c** indicates this state of affairs. In this case, the user program reaches the second WRITE call before the I/O operation spawned by the first call is complete. The result is that the user program is hung up at that point. When the preceding I/O operation is completed, this new WRITE call may be processed, and a new I/O operation may be started. **Figure 3.11** shows the timing for this situation with and without the use of interrupts. We can see that there is still a gain in efficiency because part of the time during which the I/O operation is under way overlaps with the execution of user instructions.

(b) With interrupts

(a) Without interrupts

Figure 3.11 Program Timing: Long I/O Wait

Figure 3.12 shows a revised instruction cycle state diagram that includes interrupt cycle processing.

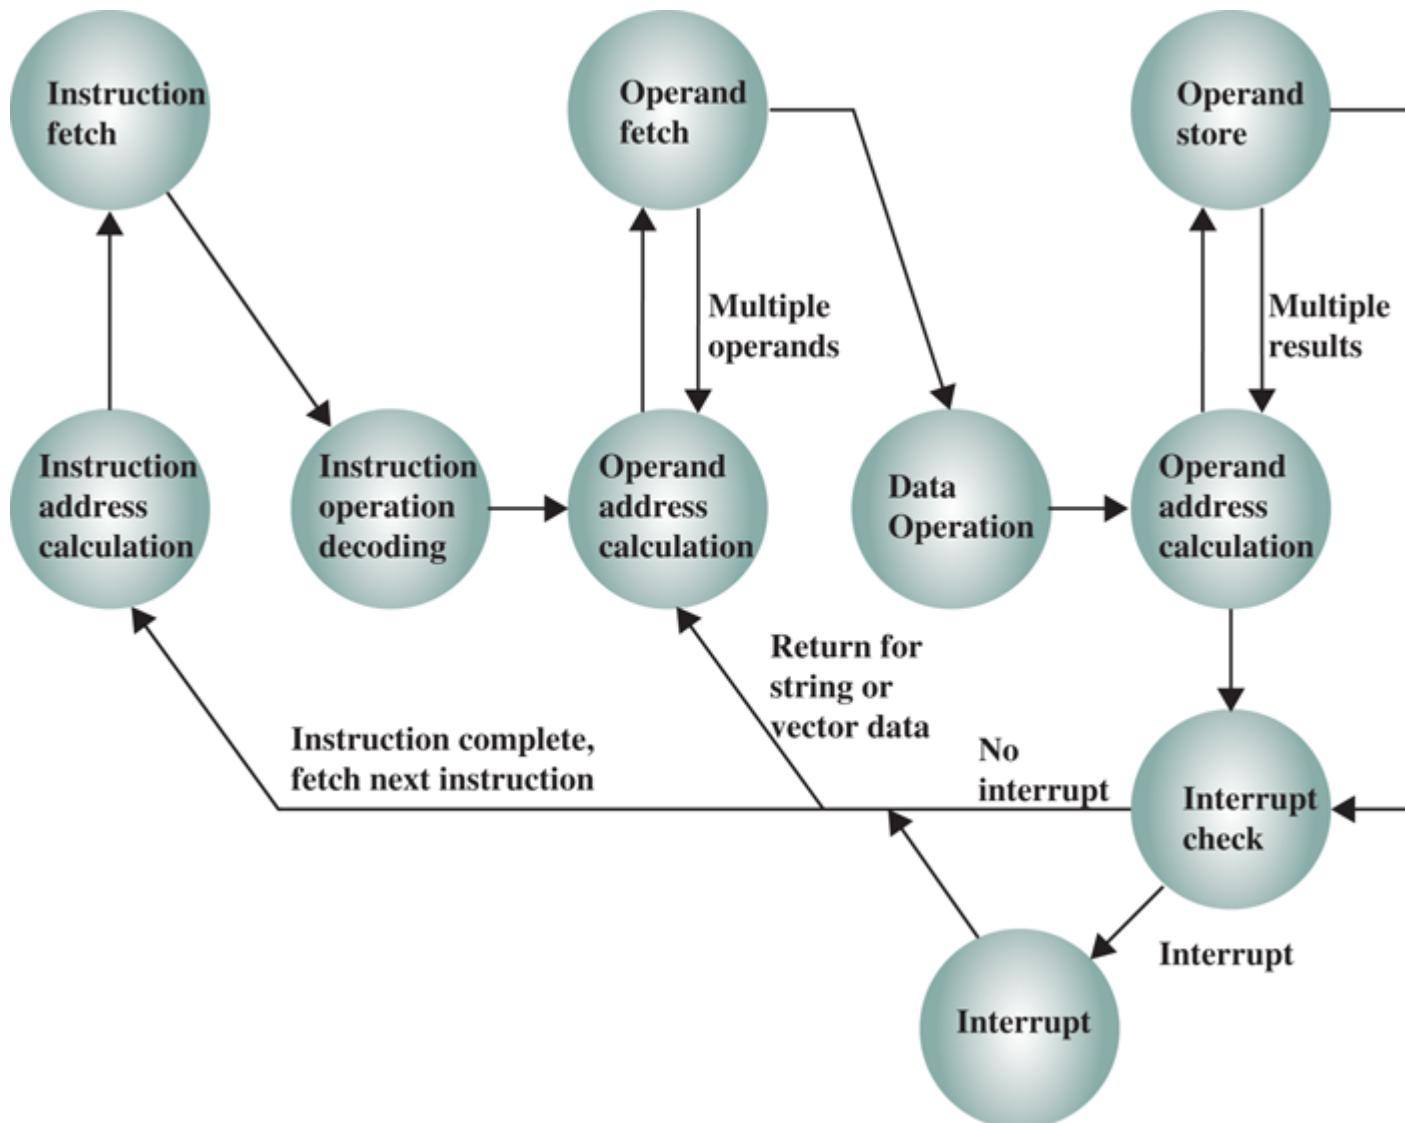

Figure 3.12 Instruction Cycle State Diagram, with Interrupts

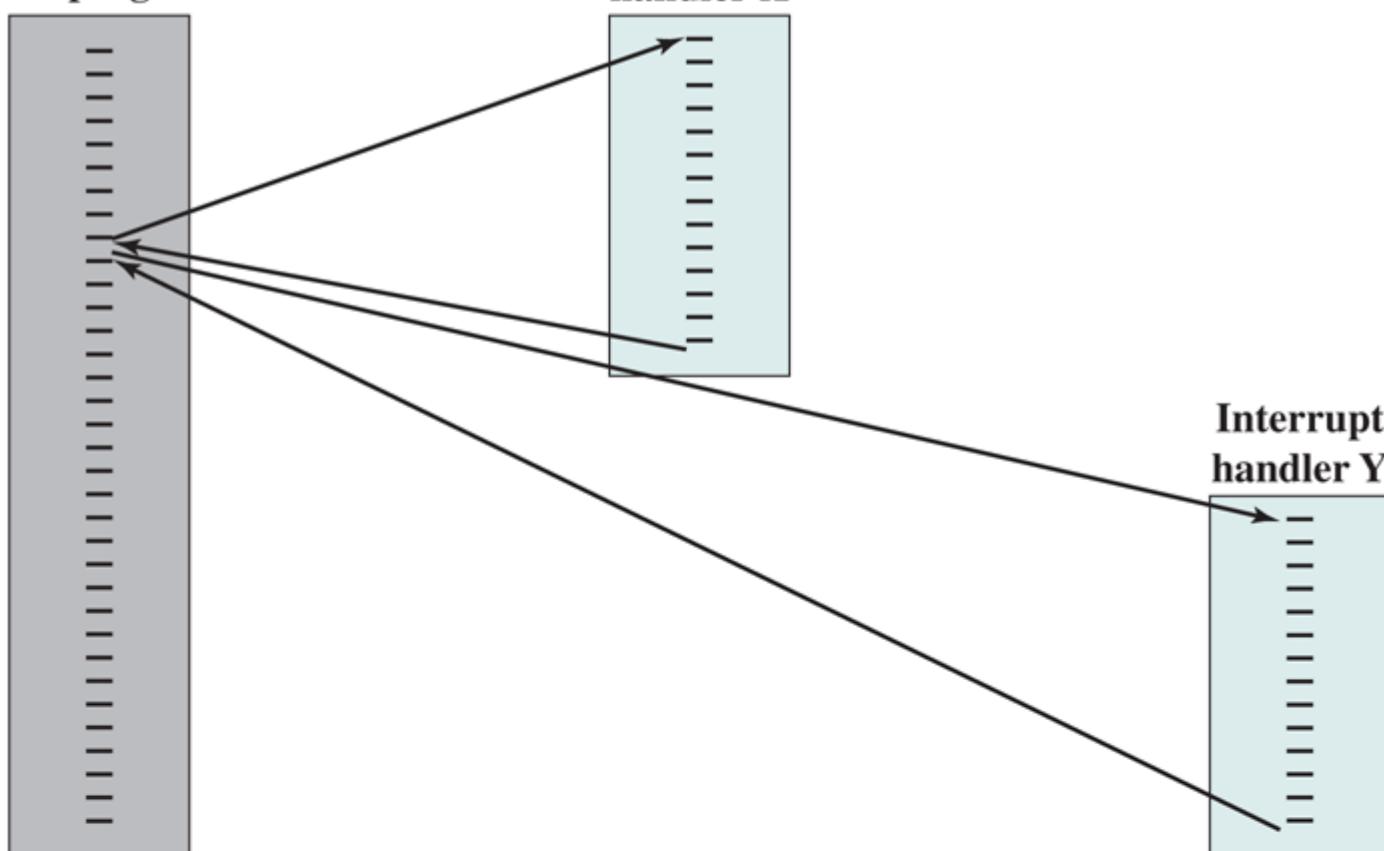

MULTIPLE INTERRUPTS

The discussion so far has focused only on the occurrence of a single interrupt. Suppose, however, that multiple interrupts can occur. For example, a program may be receiving data from a communications line and printing results. The printer will generate an interrupt every time it completes a print operation. The communication line controller will generate an interrupt every time a unit of data arrives. The unit could either be a single character or a block, depending on the nature of the communications discipline. In any case, it is possible for a communications interrupt to occur while a printer interrupt is being processed.

Two approaches can be taken to dealing with multiple interrupts. The first is to disable interrupts while an interrupt is being processed. A **disabled interrupt** simply means that the processor can and will ignore that interrupt request signal. If an interrupt occurs during this time, it generally remains pending and will be checked by the processor after the processor has enabled interrupts. Thus, when a user program is executing and an interrupt occurs, interrupts are disabled immediately. After the interrupt handler routine completes, interrupts are enabled before resuming the user program, and the processor checks to see if additional interrupts have occurred. This approach is nice and simple, as interrupts are handled in strict sequential order ([Figure 3.13a](#)).

User program

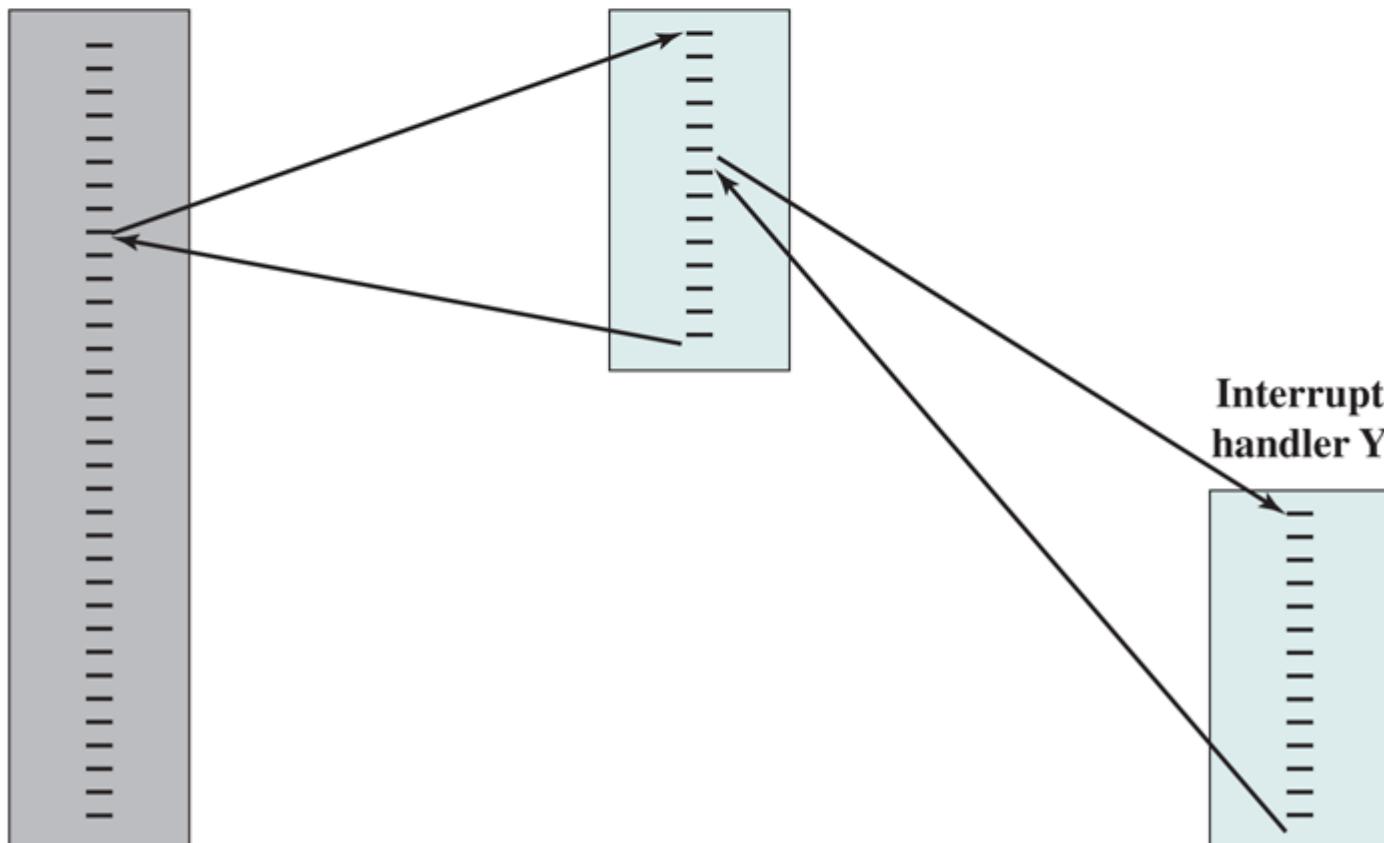

Interrupt
handler X

(a) Sequential interrupt processing

User program

Interrupt
handler X

(b) Nested interrupt processing

Figure 3.13 Transfer of Control with Multiple Interrupts

The drawback to the preceding approach is that it does not take into account relative priority or time-critical needs. For example, when input arrives from the communications line, it may need to be absorbed rapidly to make room for more input. If the first batch of input has not been processed before the second batch arrives, data may be lost.

A second approach is to define priorities for interrupts and to allow an interrupt of higher priority to cause a lower-priority interrupt handler to itself be interrupted ([Figure 3.13b](#)). As an example of this second approach, consider a system with three I/O devices: a printer, a disk, and a communications line, with increasing priorities of 2, 4, and 5, respectively. [Figure 3.14](#) illustrates a possible sequence. A user program begins at $t = 0$. At $t = 10$, a printer interrupt occurs; user information is placed on the system stack and execution continues at the printer **interrupt service routine (ISR)**. While this routine is still executing, at $t = 15$, a communications interrupt occurs. Because the communications line has higher priority than the printer, the interrupt is honored. The printer ISR is interrupted, its state is pushed onto the stack, and execution continues at the communications ISR. While this routine is executing, a disk interrupt occurs ($t = 20$). Because this interrupt is of lower priority, it is simply held, and the communications ISR runs to completion.

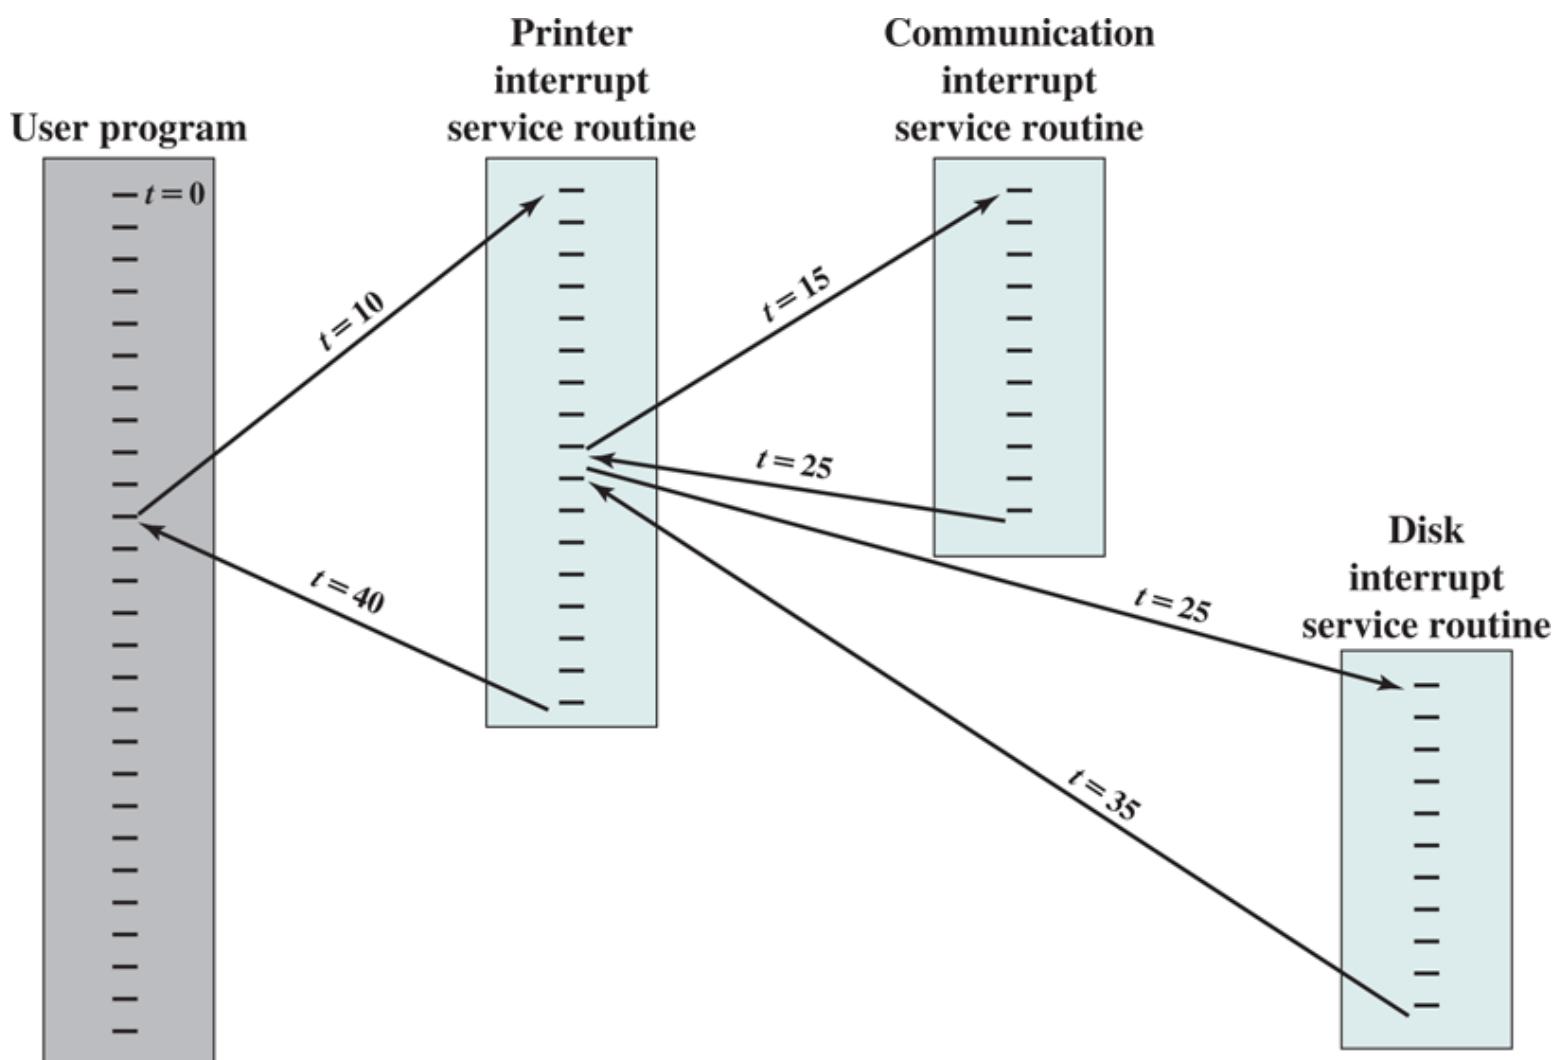

Figure 3.14 Example Time Sequence of Multiple Interrupts

When the communications ISR is complete ($t = 25$), the previous processor state is restored, which is

the execution of the printer ISR. However, before even a single instruction in that routine can be executed, the processor honors the higher-priority disk interrupt and control transfers to the disk ISR. Only when that routine is complete ($t = 35$) is the printer ISR resumed. When that routine completes ($t = 40$), control finally returns to the user program.

I/O Function

Thus far, we have discussed the operation of the computer as controlled by the processor, and we have looked primarily at the interaction of processor and memory.

The discussion has only alluded to the role of the I/O component. This role is discussed in detail in [Chapter 7](#), but a brief summary is in order here.

An I/O module (e.g., a disk controller) can exchange data directly with the processor. Just as the processor can initiate a read or write with memory, designating the address of a specific location, the processor can also read data from or write data to an I/O module. In this latter case, the processor identifies a specific device that is controlled by a particular I/O module. Thus, an instruction sequence similar in form to that of [Figure 3.5](#) could occur, with I/O instructions rather than memory-referencing instructions.

In some cases, it is desirable to allow I/O exchanges to occur directly with memory. In such a case, the processor grants to an I/O module the authority to read from or write to memory, so that the I/O-memory transfer can occur without tying up the processor. During such a transfer, the I/O module issues read or write commands to memory, relieving the processor of responsibility for the exchange. This operation is known as direct memory access (DMA) and is examined in [Chapter 7](#).

3.3 Interconnection Structures

A computer consists of a set of components or modules of three basic types (processor, memory, I/O) that communicate with each other. In effect, a computer is a network of basic modules. Thus, there must be paths for connecting the modules.

The collection of paths connecting the various modules is called the *interconnection structure*. The design of this structure will depend on the exchanges that must be made among modules.

Figure 3.15 suggests the types of exchanges that are needed by indicating the major forms of input and output for each module type²:

² The wide arrows represent multiple signal lines carrying multiple bits of information in parallel. Each narrow arrow represents a single signal line.

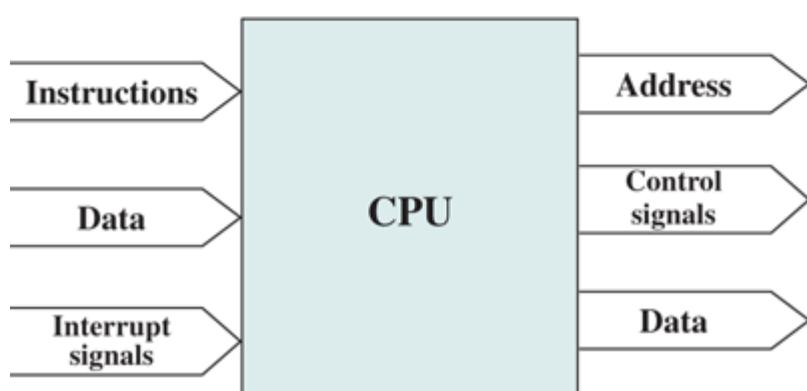

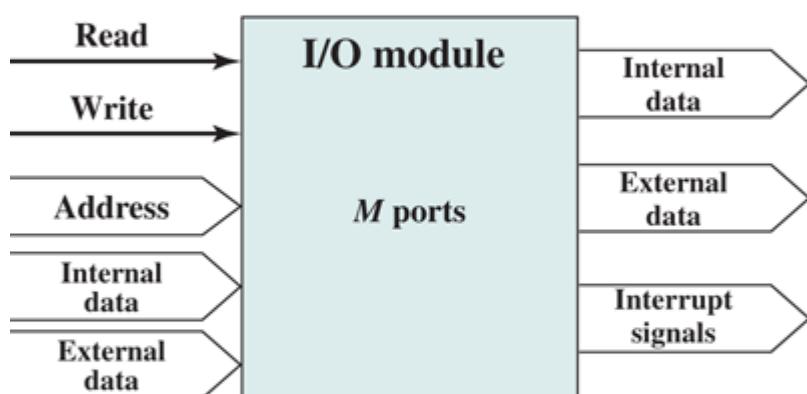

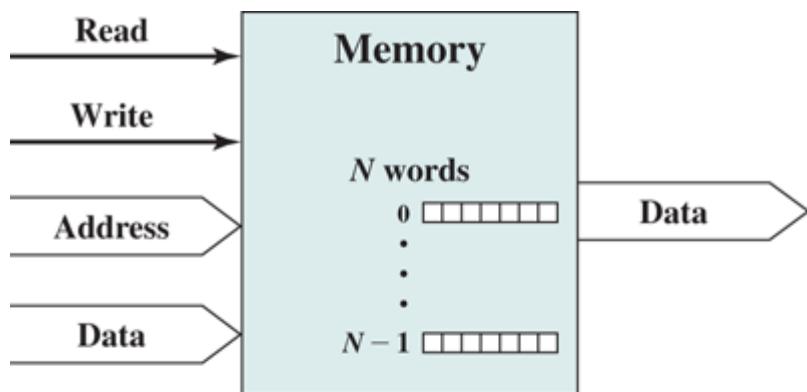

Figure 3.15 Computer Modules

- **Memory:** Typically, a memory module will consist of N words of equal length. Each word is assigned a unique numerical address ($0, 1, \dots, N - 1$). A word of data can be read from or written into the memory. The nature of the operation is indicated by read and write control signals. The location for the operation is specified by an address.
 - **I/O module:** From an internal (to the computer system) point of view, I/O is functionally similar to memory. There are two operations; read and write. Further, an I/O module may control more than one external device. We can refer to each of the interfaces to an external device as a *port* and give each a unique address (e.g., $0, 1, \dots, M - 1$). In addition, there are external data paths for the input and output of data with an external device. Finally, an I/O module may be able to send interrupt signals to the processor.
 - **Processor:** The processor reads in instructions and data, writes out data after processing, and uses control signals to control the overall operation of the system. It also receives interrupt signals.
- The preceding list defines the data to be exchanged. The interconnection structure must support the following types of transfers:
- **Memory to processor:** The processor reads an instruction or a unit of data from memory.
 - **Processor to memory:** The processor writes a unit of data to memory.
 - **I/O to processor:** The processor reads data from an I/O device via an I/O module.
 - **Processor to I/O:** The processor sends data to the I/O device.
 - **I/O to or from memory:** For these two cases, an I/O module is allowed to exchange data directly with memory, without going through the processor, using direct memory access.

Over the years, a number of interconnection structures have been tried. By far the most common are (1) the **bus** and various multiple-bus structures, and (2) point-to-point interconnection structures with packetized data transfer. We devote the remainder of this chapter to a discussion of these structures.

3.4 Bus Interconnection

The bus was the dominant means of computer system component interconnection for decades. For general-purpose computers, it has gradually given way to various point-to-point interconnection structures, which now dominate computer system design. However, bus structures are still commonly used for embedded systems, particularly microcontrollers. In this section, we give a brief overview of bus structure. Appendix A provides more detail.

A bus is a communication pathway connecting two or more devices. A key characteristic of a bus is that it is a shared transmission medium. Multiple devices connect to the bus, and a signal transmitted by any one device is available for reception by all other devices attached to the bus. If two devices transmit during the same time period, their signals will overlap and become garbled. Thus, only one device at a time can successfully transmit.

Typically, a bus consists of multiple communication pathways, or lines. Each line is capable of transmitting signals representing binary 1 and binary 0. Over time, a sequence of binary digits can be transmitted across a single line. Taken together, several lines of a bus can be used to transmit binary digits simultaneously (in parallel). For example, an 8-bit unit of data can be transmitted over eight bus lines.

Computer systems contain a number of different buses that provide pathways between components at various levels of the computer system hierarchy. A bus that connects major computer components (processor, memory, I/O) is called a **system bus**. The most common computer interconnection structures are based on the use of one or more system buses.

A system bus consists, typically, of from about fifty to hundreds of separate lines. Each line is assigned a particular meaning or function. Although there are many different bus designs, on any bus the lines can be classified into three functional groups (**Figure 3.16**): data, address, and control lines. In addition, there may be power distribution lines that supply power to the attached modules.

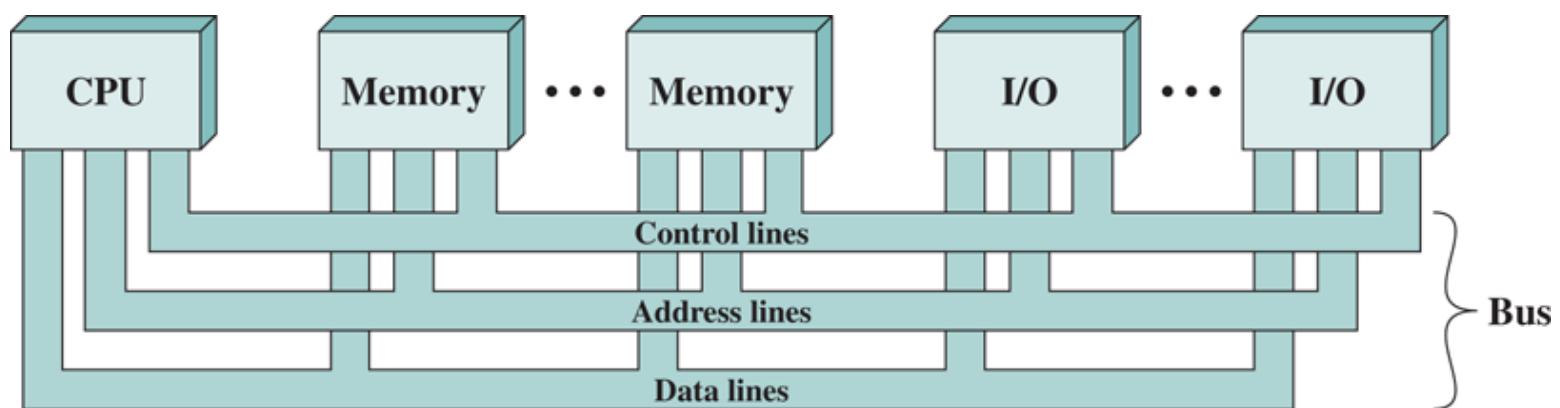

Figure 3.16 Bus Interconnection Scheme

The **data lines** provide a path for moving data among system modules. These lines, collectively, are called the **data bus**. The data bus may consist of 32, 64, 128, or even more separate lines, the number of lines being referred to as the *width* of the data bus. Because each line can carry only one bit at a time, the number of lines determines how many bits can be transferred at a time. The width of the data bus is a key factor in determining overall system performance. For example, if the data bus is 32 bits wide and each instruction is 64 bits long, then the processor must access the memory module twice during each instruction cycle.

The **address lines** are used to designate the source or destination of the data on the data bus. For example, if the processor wishes to read a word (8, 16, or 32 bits) of data from memory, it puts the address of the desired word on the address lines. Clearly, the width of the **address bus** determines the maximum possible memory capacity of the system. Furthermore, the address lines are generally also used to address I/O ports. Typically, the higher-order bits are used to select a particular module on the bus, and the lower-order bits select a memory location or I/O port within the module. For example, on an 8-bit address bus, address 01111111 and below might reference locations in a memory module (module 0) with 128 words of memory, and address 10000000 and above refer to devices attached to an I/O module (module 1).

The **control lines** are used to control the access to and the use of the data and address lines. Because the data and address lines are shared by all components, there must be a means of controlling their use. Control signals transmit both command and timing information among system modules. Timing signals indicate the validity of data and address information. Command signals specify operations to be performed. Typical control lines include:

- **Memory write:** causes data on the bus to be written into the addressed location.
- **Memory read:** causes data from the addressed location to be placed on the bus.
- **I/O write:** causes data on the bus to be output to the addressed I/O port.
- **I/O read:** causes data from the addressed I/O port to be placed on the bus.
- **Transfer ACK:** indicates that data have been accepted from or placed on the bus.
- **Bus request:** indicates that a module needs to gain control of the bus.
- **Bus grant:** indicates that a requesting module has been granted control of the bus.
- **Interrupt request:** indicates that an interrupt is pending.
- **Interrupt ACK:** acknowledges that the pending interrupt has been recognized.
- **Clock:** is used to synchronize operations.
- **Reset:** initializes all modules.

The operation of the bus is as follows. If one module wishes to send data to another, it must do two things: (1) obtain the use of the bus, and (2) transfer data via the bus. If one module wishes to request data from another module, it must (1) obtain the use of the bus, and (2) transfer a request to the other module over the appropriate control and address lines. It must then wait for that second module to send the data.

3.5 Point-to-Point Interconnect

The shared bus architecture was the standard approach to interconnection between the processor and other components (memory, I/O, and so on) for decades. But contemporary systems increasingly rely on point-to-point interconnection rather than shared buses.

The principal reason driving the change from bus to point-to-point interconnect was the electrical constraints encountered with increasing the frequency of wide synchronous buses. At higher and higher data rates, it becomes increasingly difficult to perform the synchronization and **arbitration** functions in a timely fashion. Further, with the advent of multicore chips, with multiple processors and significant memory on a single chip, it was found that the use of a conventional shared bus on the same chip magnified the difficulties of increasing bus data rate and reducing bus latency to keep up with the processors. Compared to the shared bus, the point-to-point interconnect has lower latency, higher data rate, and better scalability.

In this section, we look at an important and representative example of the point-to-point interconnect approach: Intel's **QuickPath Interconnect (QPI)**, which was introduced in 2008.

The following are significant characteristics of QPI and other point-to-point interconnect schemes:

- **Multiple direct connections:** Multiple components within the system enjoy direct pairwise connections to other components. This eliminates the need for arbitration found in shared transmission systems.
- **Layered protocol architecture:** As found in network environments, such as TCP/IP-based data networks, these processor-level interconnects use a layered protocol architecture, rather than the simple use of control signals found in shared bus arrangements.
- **Packetized data transfer:** Data are not sent as a raw bit stream. Rather, data are sent as a sequence of packets, each of which includes control headers and error control codes.

Figure 3.17 illustrates a typical use of QPI on a multicore computer. The QPI links (indicated by the green arrow pairs in the figure) form a switching fabric that enables data to move throughout the network. Direct QPI connections can be established between each pair of core processors. If core A in **Figure 3.17** needs to access the memory controller in core D, it sends its request through either cores B or C, which must in turn forward that request on to the memory controller in core D. Similarly, larger systems with eight or more processors can be built using processors with three links and routing traffic through intermediate processors.

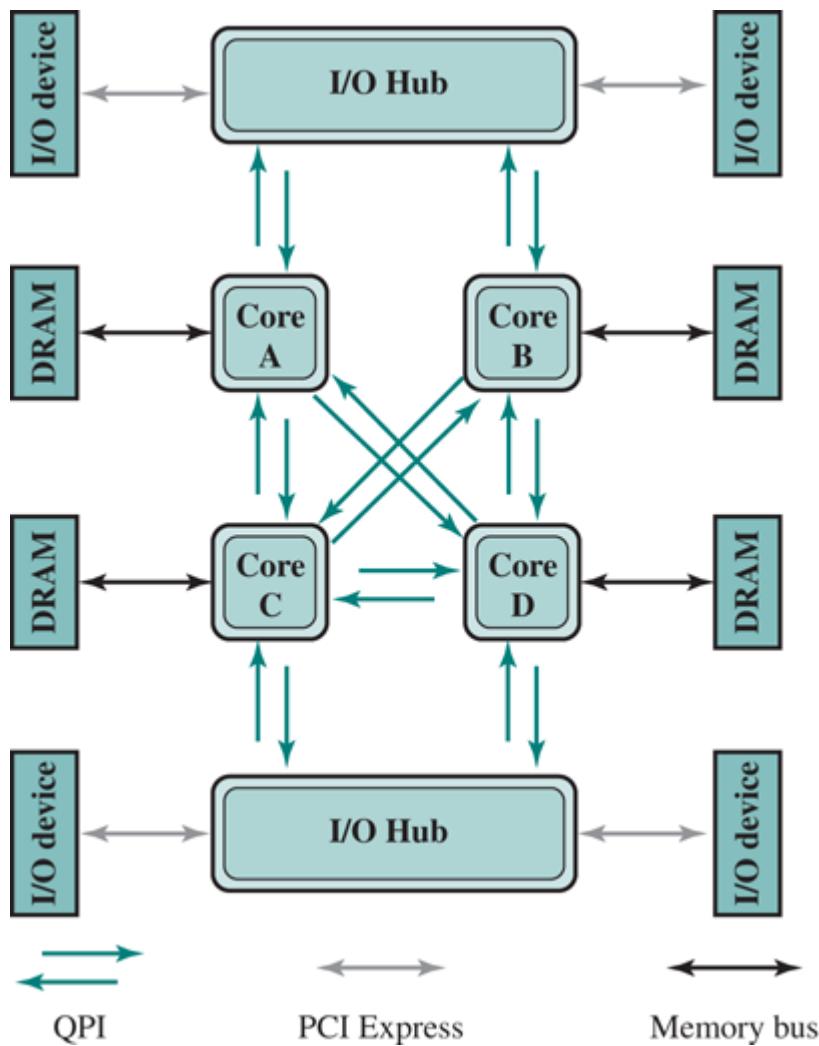

Figure 3.17 Multicore Configuration Using QPI

In addition, QPI is used to connect to an I/O module, called an I/O hub (IOH). The IOH acts as a switch directing traffic to and from I/O devices. Typically in newer systems, the link from the IOH to the I/O device controller uses an interconnect technology called PCI Express (PCIe), described later in this chapter. The IOH translates between the QPI protocols and formats and the PCIe protocols and formats. A core also links to a main memory module (typically the memory uses dynamic access random memory (DRAM) technology) using a dedicated memory bus.

QPI is defined as a four-layer protocol architecture, encompassing the following layers ([Figure 3.18](#)):

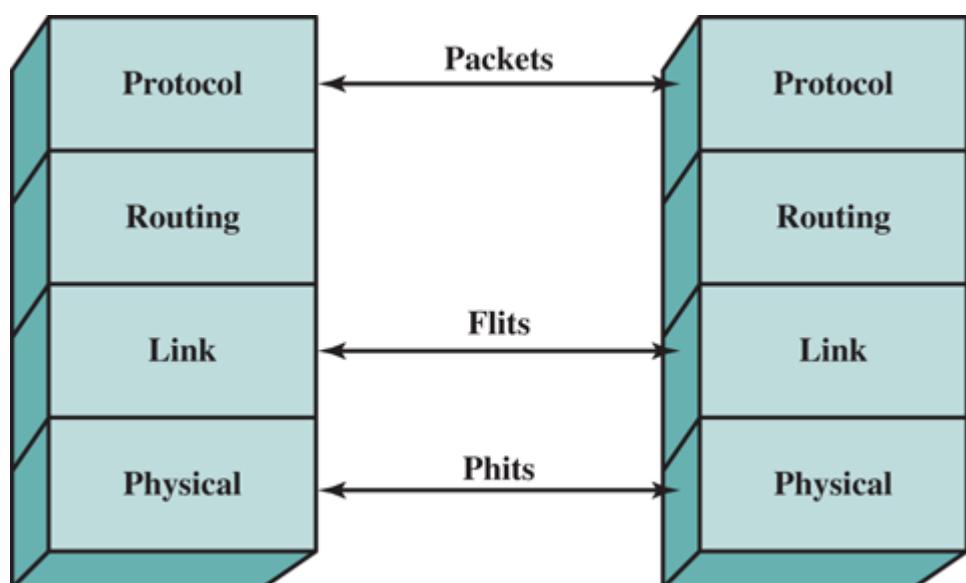

Figure 3.18 QPI Layers

- **Physical:** Consists of the actual wires carrying the signals, as well as circuitry and logic to support ancillary features required in the transmission and receipt of the 1s and 0s. The unit of transfer at the Physical layer is 20 bits, which is called a **Phit** (physical unit).
- **Link:** Responsible for reliable transmission and flow control. The Link layer's unit of transfer is an 80-bit **Flit** (flow control unit).
- **Routing:** Provides the framework for directing packets through the fabric.
- **Protocol:** The high-level set of rules for exchanging **packets** of data between devices. A packet is comprised of an integral number of Flits.

QPI Physical Layer

Figure 3.19 shows the physical architecture of a QPI port. The QPI port consists of 84 individual links grouped as follows. Each data path consists of a pair of wires that transmits data one bit at a time; the pair is referred to as a **lane**. There are 20 data lanes in each direction (transmit and receive), plus a clock lane in each direction. Thus, QPI is capable of transmitting 20 bits in parallel in each direction. The 20-bit unit is referred to as a *phit*. Typical signaling speeds of the link in current products calls for operation at 6.4 GT/s (transfers per second). At 20 bits per transfer, that adds up to 16 GB/s, and since QPI links involve dedicated bidirectional pairs, the total capacity is 32 GB/s.

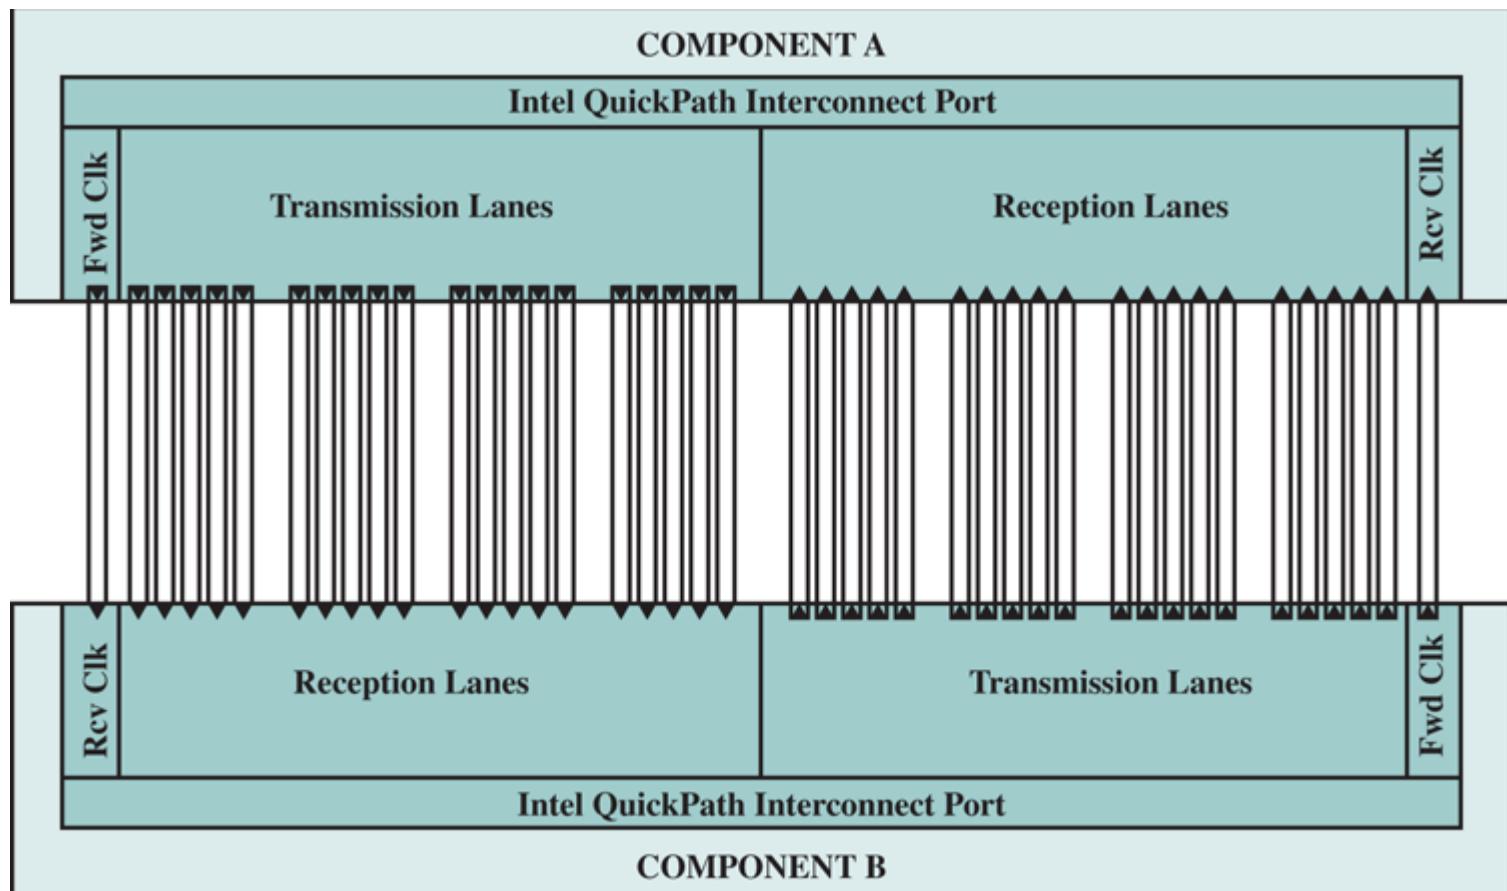

Figure 3.19 Physical Interface of the Intel QPI Interconnect

The lanes in each direction are grouped into four quadrants of 5 lanes each. In some applications, the link can also operate at half or quarter widths in order to reduce power consumption or work around failures.

The form of transmission on each lane is known as **differential signaling**, or **balanced transmission**. With balanced transmission, signals are transmitted as a current that travels down one conductor and returns on the other. The binary value depends on the voltage difference. Typically, one line has a positive voltage value and the other line has zero voltage, and one line is associated with binary 1 and the other is associated with binary 0. Specifically, the technique used by QPI is known as *low-voltage differential signaling* (LVDS). In a typical implementation, the transmitter injects a small current into one wire or the other, depending on the logic level to be sent. The current passes through a resistor at the receiving end, and then returns in the opposite direction along the other wire. The receiver senses the polarity of the voltage across the resistor to determine the logic level.

Another function performed by the physical layer is that it manages the translation between 80-bit flits and 20-bit phits using a technique known as **multilane distribution**. The flits can be considered as a bit stream that is distributed across the data lanes in a round-robin fashion (first bit to first lane, second bit to second lane, etc.), as illustrated in [Figure 3.20](#). This approach enables QPI to achieve very high data rates by implementing the physical link between two ports as multiple parallel channels.

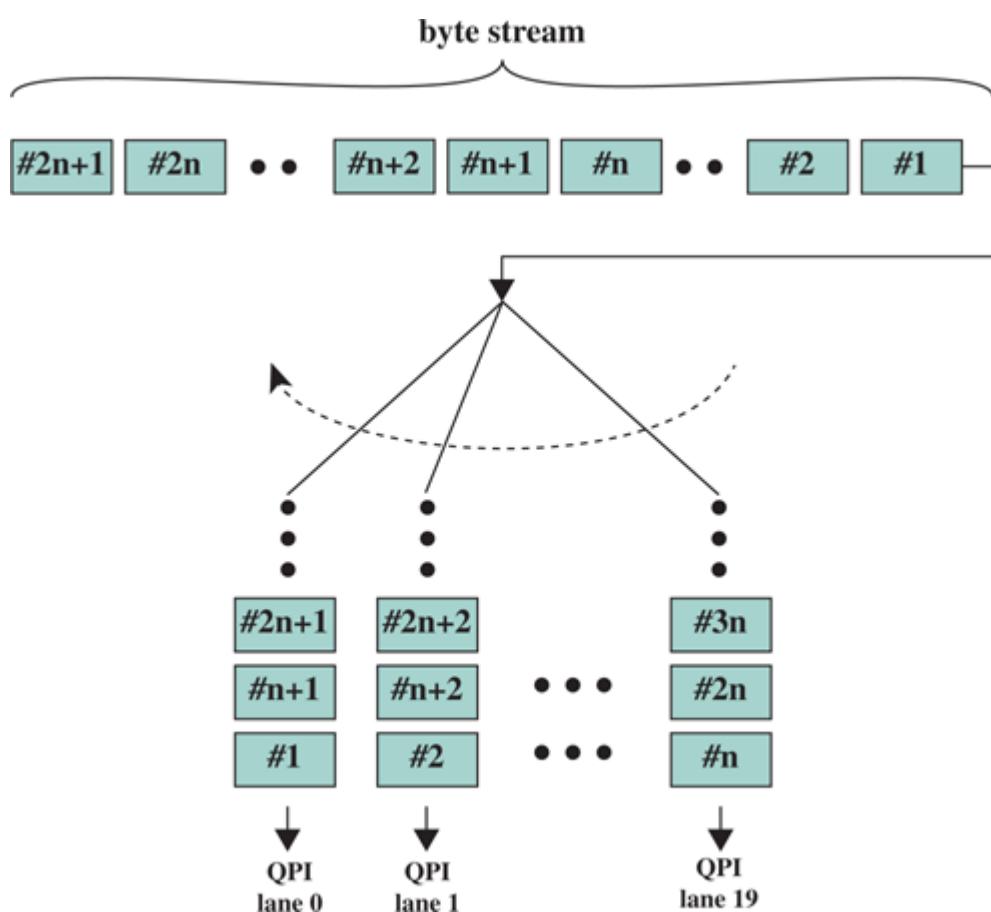

Figure 3.20 QPI Multilane Distribution

QPI Link Layer

The QPI link layer performs two key functions: flow control and error control. These functions are performed as part of the QPI link layer protocol, and operate on the level of the flit (flow control unit). Each flit consists of a 72-bit message payload and an 8-bit error control code called a cyclic redundancy check (CRC). We discuss error control codes in [Chapter 5](#).

A flit payload may consist of data or message information. The data flits transfer the actual bits of data between cores or between a core and an IOH. The message flits are used for such functions as flow control, error control, and cache coherence. We discuss cache coherence in [Chapters 5](#) and [17](#).

The **flow control function** is needed to ensure that a sending QPI entity does not overwhelm a receiving QPI entity by sending data faster than the receiver can process the data and clear buffers for more incoming data. To control the flow of data, QPI makes use of a credit scheme. During initialization, a sender is given a set number of credits to send flits to a receiver. Whenever a flit is sent to the receiver, the sender decrements its credit counters by one credit. Whenever a buffer is freed at the receiver, a credit is returned to the sender for that buffer. Thus, the receiver controls that pace at which data is transmitted over a QPI link.

Occasionally, a bit transmitted at the physical layer is changed during transmission, due to noise or some other phenomenon. The **error control function** at the link layer detects and recovers from such bit errors, and so isolates higher layers from experiencing bit errors. The procedure works as follows for a flow of data from system A to system B:

1. As mentioned, each 80-bit flit includes an 8-bit CRC field. The CRC is a function of the value of the remaining 72 bits. On transmission, A calculates a CRC value for each flit and inserts that value into the flit.
2. When a flit is received, B calculates a CRC value for the 72-bit payload and compares this value with the value of the incoming CRC value in the flit. If the two CRC values do not match, an error has been detected.
3. When B detects an error, it sends a request to A to retransmit the flit that is in error. However, because A may have had sufficient credit to send a stream of flits, so that additional flits have been transmitted after the flit in error and before A receives the request to retransmit. Therefore, the request is for A to back up and retransmit the damaged flit plus all subsequent flits.

QPI Routing Layer

The routing layer is used to determine the course that a packet will traverse across the available system interconnects. Routing tables are defined by firmware and describe the possible paths that a packet can follow. In small configurations, such as a two-socket platform, the routing options are limited and the routing tables quite simple. For larger systems, the routing table options are more complex, giving the flexibility of routing and rerouting traffic depending on how (1) devices are populated in the platform, (2) system resources are partitioned, and (3) reliability events result in mapping around a failing resource.

QPI Protocol Layer

In this layer, the packet is defined as the unit of transfer. The packet contents definition is standardized with some flexibility allowed to meet differing market segment requirements. One key function performed at this level is a cache coherency protocol, which deals with making sure that main memory values held in multiple caches are consistent. A typical data packet payload is a block of data being sent to or from a cache.

3.6 PCI Express

The **peripheral component interconnect (PCI)** is a popular high-bandwidth, processor-independent bus that can function as a mezzanine or peripheral bus. Compared with other common bus specifications, PCI delivers better system performance for high-speed I/O subsystems (e.g., graphic display adapters, network interface controllers, and disk controllers).

Intel began work on PCI in 1990 for its Pentium-based systems. Intel soon released all the patents to the public domain and promoted the creation of an industry association, the PCI Special Interest Group (SIG), to develop further and maintain the compatibility of the PCI specifications. The result is that PCI has been widely adopted and is finding increasing use in personal computer, workstation, and server systems. Because the specification is in the public domain and is supported by a broad cross-section of the microprocessor and peripheral industry, PCI products built by different vendors are compatible.

As with the system bus discussed in the preceding sections, the bus-based PCI scheme has not been able to keep pace with the data rate demands of attached devices. Accordingly, a new version, known as **PCI Express (PCIe)** has been developed. PCIe, as with QPI, is a point-to-point interconnect scheme intended to replace bus-based schemes such as PCI.

A key requirement for PCIe is high capacity to support the needs of higher data rate I/O devices, such as Gigabit Ethernet. Another requirement deals with the need to support time-dependent data streams. Applications such as video-on-demand and audio redistribution are putting real-time constraints on servers too. Many communications applications and embedded PC control systems also process data in real-time. Today's platforms must also deal with multiple concurrent transfers at ever-increasing data rates. It is no longer acceptable to treat all data as equal—it is more important, for example, to process streaming data first since late real-time data is as useless as no data. Data needs to be tagged so that an I/O system can prioritize its flow throughout the platform.

PCI Physical and Logical Architecture

Figure 3.21 shows a typical configuration that supports the use of PCIe. A **root complex** device, also referred to as a *chipset* or a *host bridge*, connects the processor and memory subsystem to the PCI Express switch fabric comprising one or more PCIe and PCIe switch devices. The root complex acts as a buffering device, to deal with differences in data rates between I/O controllers and memory and processor components. The root complex also translates between PCIe transaction formats and the processor and memory signal and control requirements. The chipset will typically support multiple PCIe ports, some of which attach directly to a PCIe device, and one or more that attach to a switch that manages multiple PCIe streams. PCIe links from the chipset may attach to the following kinds of devices that implement PCIe:

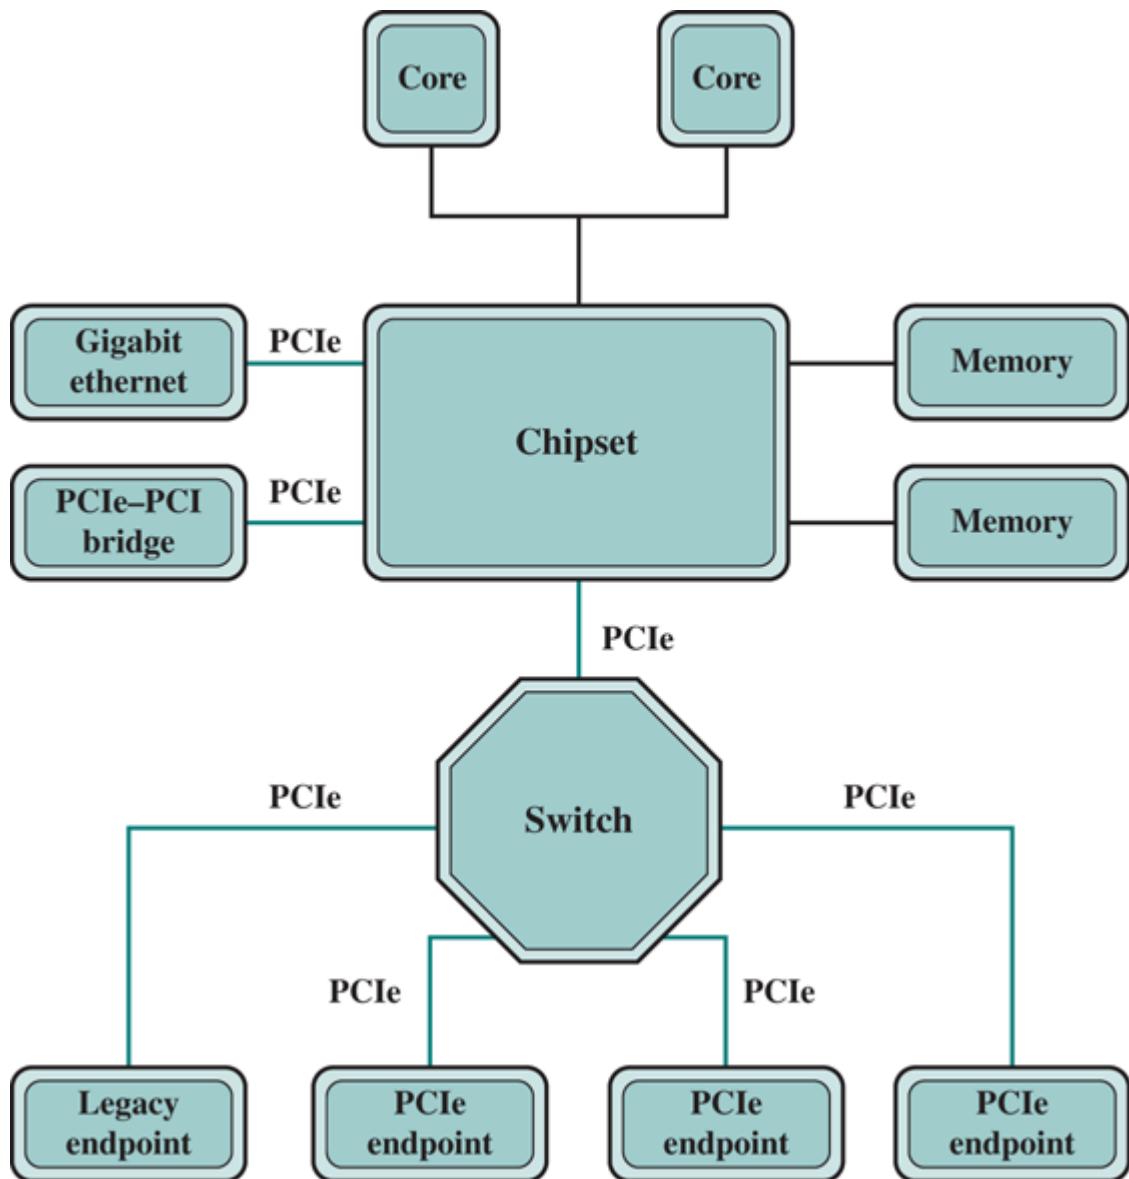

Figure 3.21 Typical Configuration Using PCIe

- **Switch:** The switch manages multiple PCIe streams.
- **PCIe endpoint:** An I/O device or controller that implements PCIe, such as a Gigabit ethernet switch, a graphics or video controller, disk interface, or a communications controller.
- **Legacy endpoint:** Legacy endpoint category is intended for existing designs that have been migrated to PCI Express, and it allows legacy behaviors such as use of I/O space and locked transactions. PCI Express endpoints are not permitted to require the use of I/O space at runtime and must not use locked transactions. By distinguishing these categories, it is possible for a system designer to restrict or eliminate legacy behaviors that have negative impacts on system performance and robustness.
- **PCIe/PCI bridge:** Allows older PCI devices to be connected to PCIe-based systems.

As with QPI, PCIe interactions are defined using a protocol architecture. The PCIe protocol architecture encompasses the following layers ([Figure 3.22](#)):

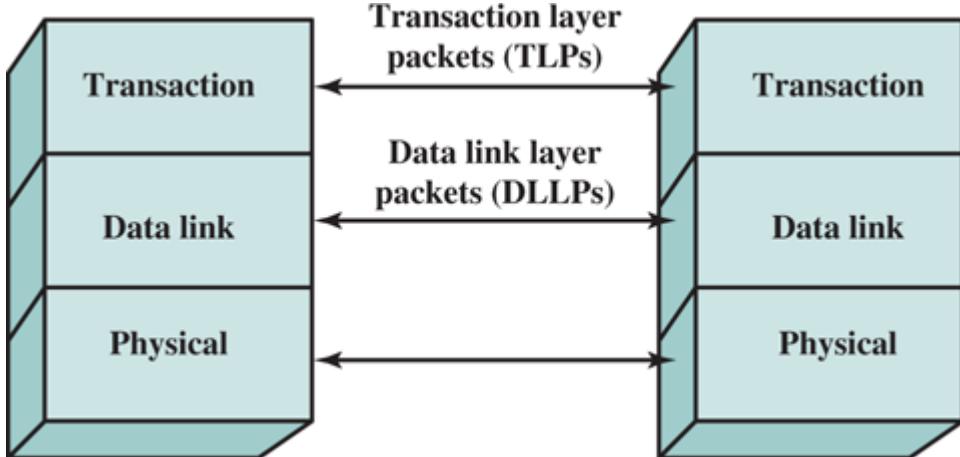

Figure 3.22 PCIe Protocol Layers

- **Physical:** Consists of the actual wires carrying the signals, as well as circuitry and logic to support ancillary features required in the transmission and receipt of the 1s and 0s.
- **Data link:** Is responsible for reliable transmission and flow control. Data packets generated and consumed by the DLL are called Data Link Layer Packets (DLLPs).
- **Transaction:** Generates and consumes data packets used to implement load/store data transfer mechanisms and also manages the flow control of those packets between the two components on a link. Data packets generated and consumed by the TL are called Transaction Layer Packets (TLPs).

Above the TL are software layers that generate read and write requests that are transported by the transaction layer to the I/O devices using a packet-based transaction protocol.

PCIe Physical Layer

Similar to QPI, PCIe is a point-to-point architecture. Each PCIe port consists of a number of bidirectional lanes (note that in QPI, the lane refers to transfer in one direction only). Transfer in each direction in a lane is by means of differential signaling over a pair of wires. A PCI port can provide 1, 4, 6, 16, or 32 lanes. In what follows, we refer to the PCIe 3.0 specification, introduced in late 2010.

As with QPI, PCIe uses a multilane distribution technique. [Figure 3.23](#) shows an example for a PCIe port consisting of four lanes. Data are distributed to the four lanes 1 byte at a time using a simple round-robin scheme. At each physical lane, data are buffered and processed 16 bytes (128 bits) at a time. Each block of 128 bits is encoded into a unique 130-bit codeword for transmission; this is referred to as 128b/130b encoding. Thus, the effective data rate of an individual lane is reduced by a factor of 128/130.

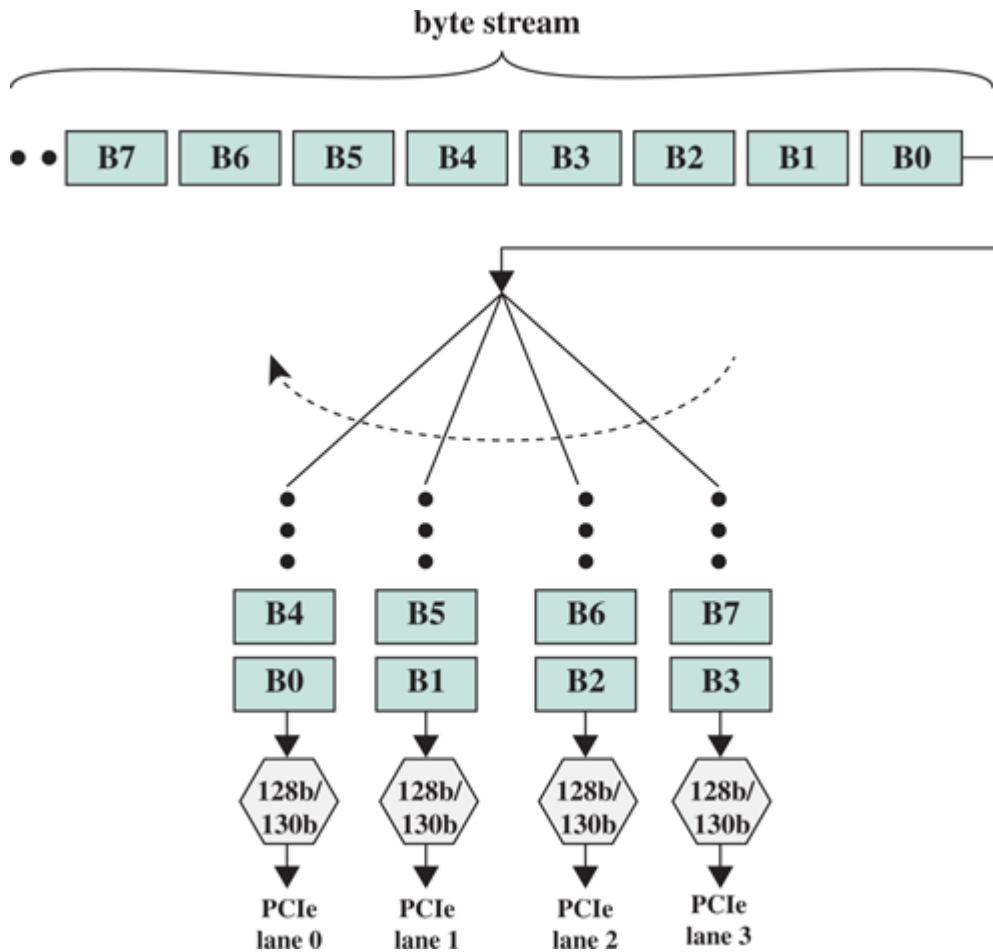

Figure 3.23 PCIe Multilane Distribution

To understand the rationale for the 128b/130b encoding, note that unlike QPI, PCIe does not use its clock line to synchronize the bit stream. That is, the clock line is not used to determine the start and end point of each incoming bit; it is used for other signaling purposes only. However, it is necessary for the receiver to be synchronized with the transmitter, so that the receiver knows when each bit begins and ends. If there is any drift between the clocks used for bit transmission and reception of the transmitter and receiver, errors may occur. To compensate for the possibility of drift, PCIe relies on the receiver synchronizing with the transmitter based on the transmitted signal. As with QPI, PCIe uses differential signaling over a pair of wires. Synchronization can be achieved by the receiver looking for transitions in the data and synchronizing its clock to the transition. However, consider that with a long string of 1s or 0s using differential signaling, the output is a constant voltage over a long period of time. Under these circumstances, any drift between the clocks of the transmitter and receiver will result in loss of synchronization between the two.

A common approach, and the one used in PCIe 3.0, to overcoming the problem of a long string of bits of one value is scrambling. Scrambling, which does not increase the number of bits to be transmitted, is a mapping technique that tends to make the data appear more random. At the receiving end, a descrambling algorithm recovers the original data sequence. The scrambling tends to spread out the number of transitions so that they appear at the receiver more uniformly spaced, which is good for synchronization. Also, other transmission properties, such as spectral properties, are enhanced if the data are more nearly of a random nature rather than constant or repetitive.

Another technique that can aid in synchronization is encoding, in which additional bits are inserted into the bit stream to force transitions. For PCIe 3.0, each group of 128 bits of input is mapped into a 130-bit block by adding a 2-bit block sync header. The value of the header is 10 for a data block and 01 for what is called an *ordered set block*, which refers to a link-level information block.

Figure 3.24 illustrates the use of scrambling and encoding. Data to be transmitted are fed into a scrambler. The scrambled output is then fed into a 128b/130b encoder, which buffers 128 bits and then maps the 128-bit block into a 130-bit block. This block then passes through a parallel-to-serial converter and is transmitted one bit at a time using differential signaling.

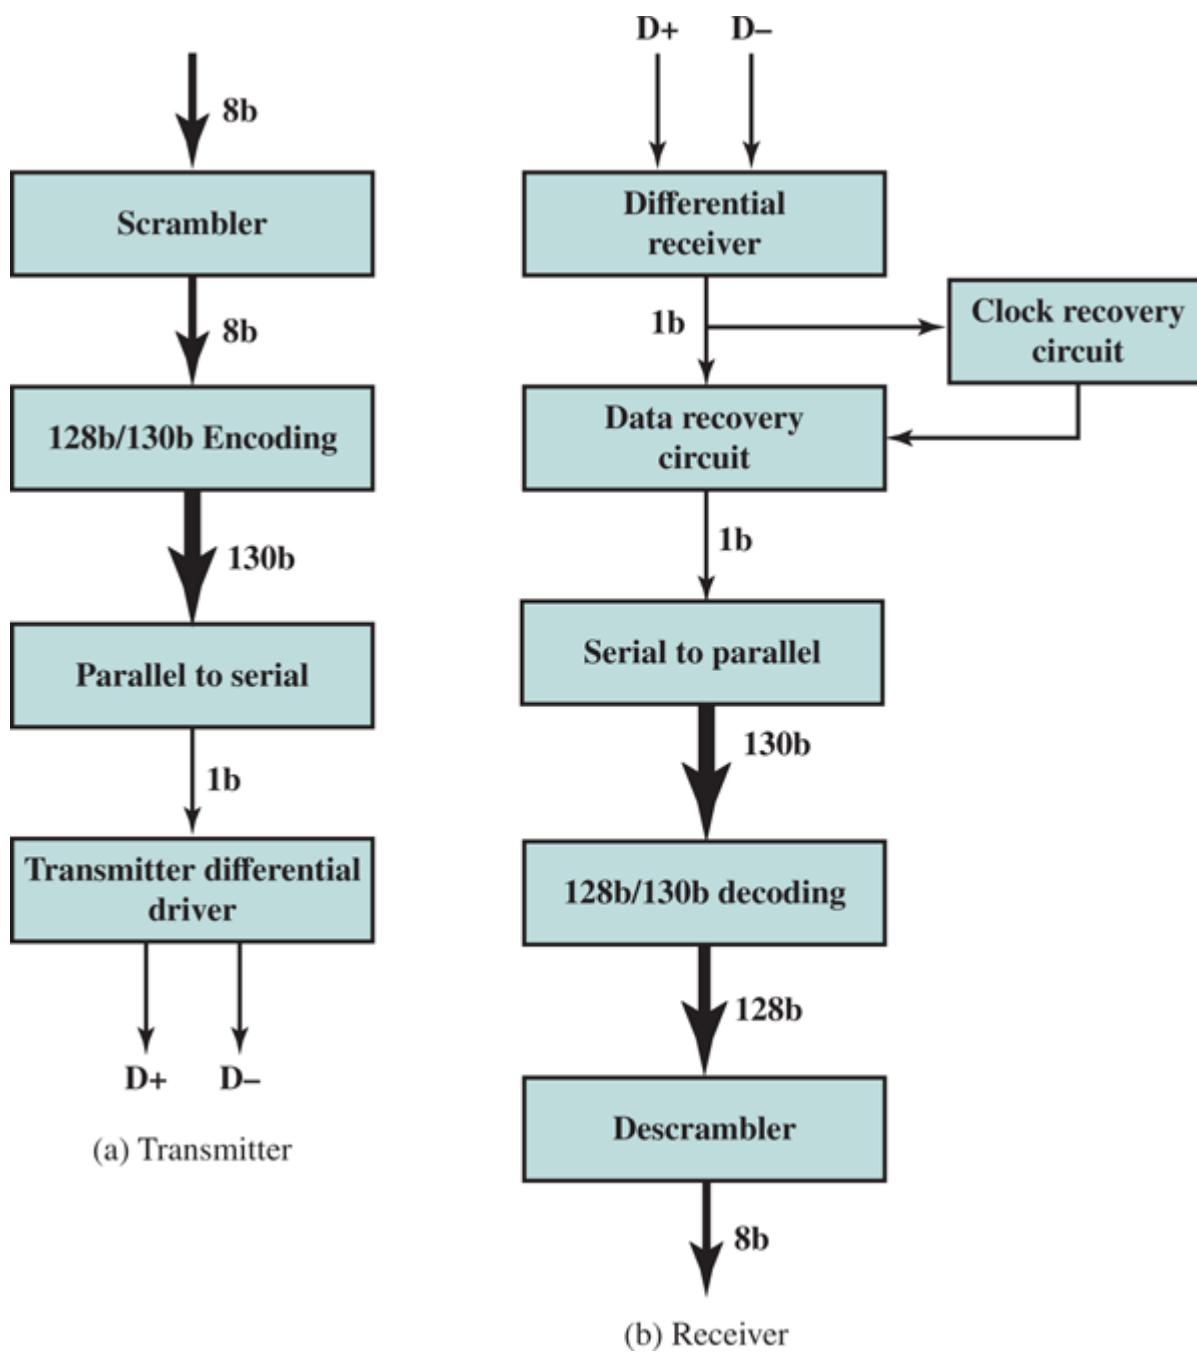

Figure 3.24 PCIe Transmit and Receive Block Diagrams

At the receiver, a clock is synchronized to the incoming data to recover the bit stream. This then passes through a serial-to-parallel converter to produce a stream of 130-bit blocks. Each block is passed through a 128b/130b decoder to recover the original scrambled bit pattern, which is then descrambled to produce the original bit stream.

Using these techniques, a data rate of 16 GB/s can be achieved. One final detail to mention; each transmission of a block of data over a PCI link begins and ends with an 8-bit framing sequence intended to give the receiver time to synchronize with the incoming physical layer bit stream.

The transaction layer (TL) receives read and write requests from the software above the TL and creates request packets for transmission to a destination via the link layer. Most transactions use a *split transaction* technique, which works in the following fashion. A request packet is sent out by a source PCIe device, which then waits for a response, called a *completion* packet. The completion following a request is initiated by the completer only when it has the data and/or status ready for delivery. Each packet has a unique identifier that enables completion packets to be directed to the correct originator. With the split transaction technique, the completion is separated in time from the request, in contrast to a typical bus operation in which both sides of a transaction must be available to seize and use the bus. Between the request and the completion, other PCIe traffic may use the link.

TL messages and some write transactions are *posted transactions*, meaning that no response is expected.

The TL packet format supports 32-bit memory addressing and extended 64-bit memory addressing. Packets also have attributes such as “no-snoop,” “relaxed-ordering,” and “priority,” which may be used to optimally route these packets through the I/O subsystem.

ADDRESS SPACES AND TRANSACTION TYPES

The TL supports four address spaces:

- **Memory:** The memory space includes system main memory. It also includes PCIe I/O devices. Certain ranges of memory addresses map into I/O devices.
- **I/O:** This address space is used for legacy PCI devices, with reserved memory address ranges used to address legacy I/O devices.
- **Configuration:** This address space enables the TL to read/write configuration registers associated with I/O devices.
- **Message:** This address space is for control signals related to interrupts, error handling, and power management.

Table 3.2 shows the transaction types provided by the TL. For memory, I/O, and configuration address spaces, there are read and write transactions. In the case of memory transactions, there is also a read lock request function. Locked operations occur as a result of device drivers requesting atomic access to registers on a PCIe device. A device driver, for example, can atomically read, modify, and then write to a device register. To accomplish this, the device driver causes the processor to execute an instruction or set of instructions. The root complex converts these processor instructions into a sequence of PCIe transactions, which perform individual read and write requests for the device driver. If these transactions must be executed atomically, the root complex locks the PCIe link while executing the transactions. This locking prevents transactions that are not part of the sequence from occurring. This sequence of transactions is called a locked operation. The particular set of processor instructions that can cause a locked operation to occur depends on the system chip set and processor architecture.

Table 3.2 PCIe TLP Transaction Types

Address Space	TLP Type	Purpose
Memory	Memory Read Request	Transfer data to or from a location in the system memory map.
	Memory Read Lock Request	

	Memory Write Request	
I/O	I/O Read Request	Transfer data to or from a location in the system memory map for legacy devices.
	I/O Write Request	
Configuration	Config Type 0 Read Request	Transfer data to or from a location in the configuration space of a PCIe device.
	Config Type 0 Write Request	
	Config Type 1 Read Request	
	Config Type 1 Write Request	
Message	Message Request	Provides in-band messaging and event reporting.
	Message Request with Data	
Memory, I/O, Configuration	Completion	Returned for certain requests.
	Completion with Data	
	Completion Locked	
	Completion Locked with Data	

To maintain compatibility with PCI, PCIe supports both Type 0 and Type 1 configuration cycles. A Type 1 cycle propagates downstream until it reaches the bridge interface hosting the bus (link) that the target device resides on. The configuration transaction is converted on the destination link from Type 1 to Type 0 by the bridge.

Finally, completion messages are used with split transactions for memory, I/O, and configuration transactions.

TLP PACKET ASSEMBLY

PCIe transactions are conveyed using transaction layer packets, which are illustrated in [Figure 3.25a](#).

A TLP originates in the transaction layer of the sending device and terminates at the transaction layer of the receiving device.

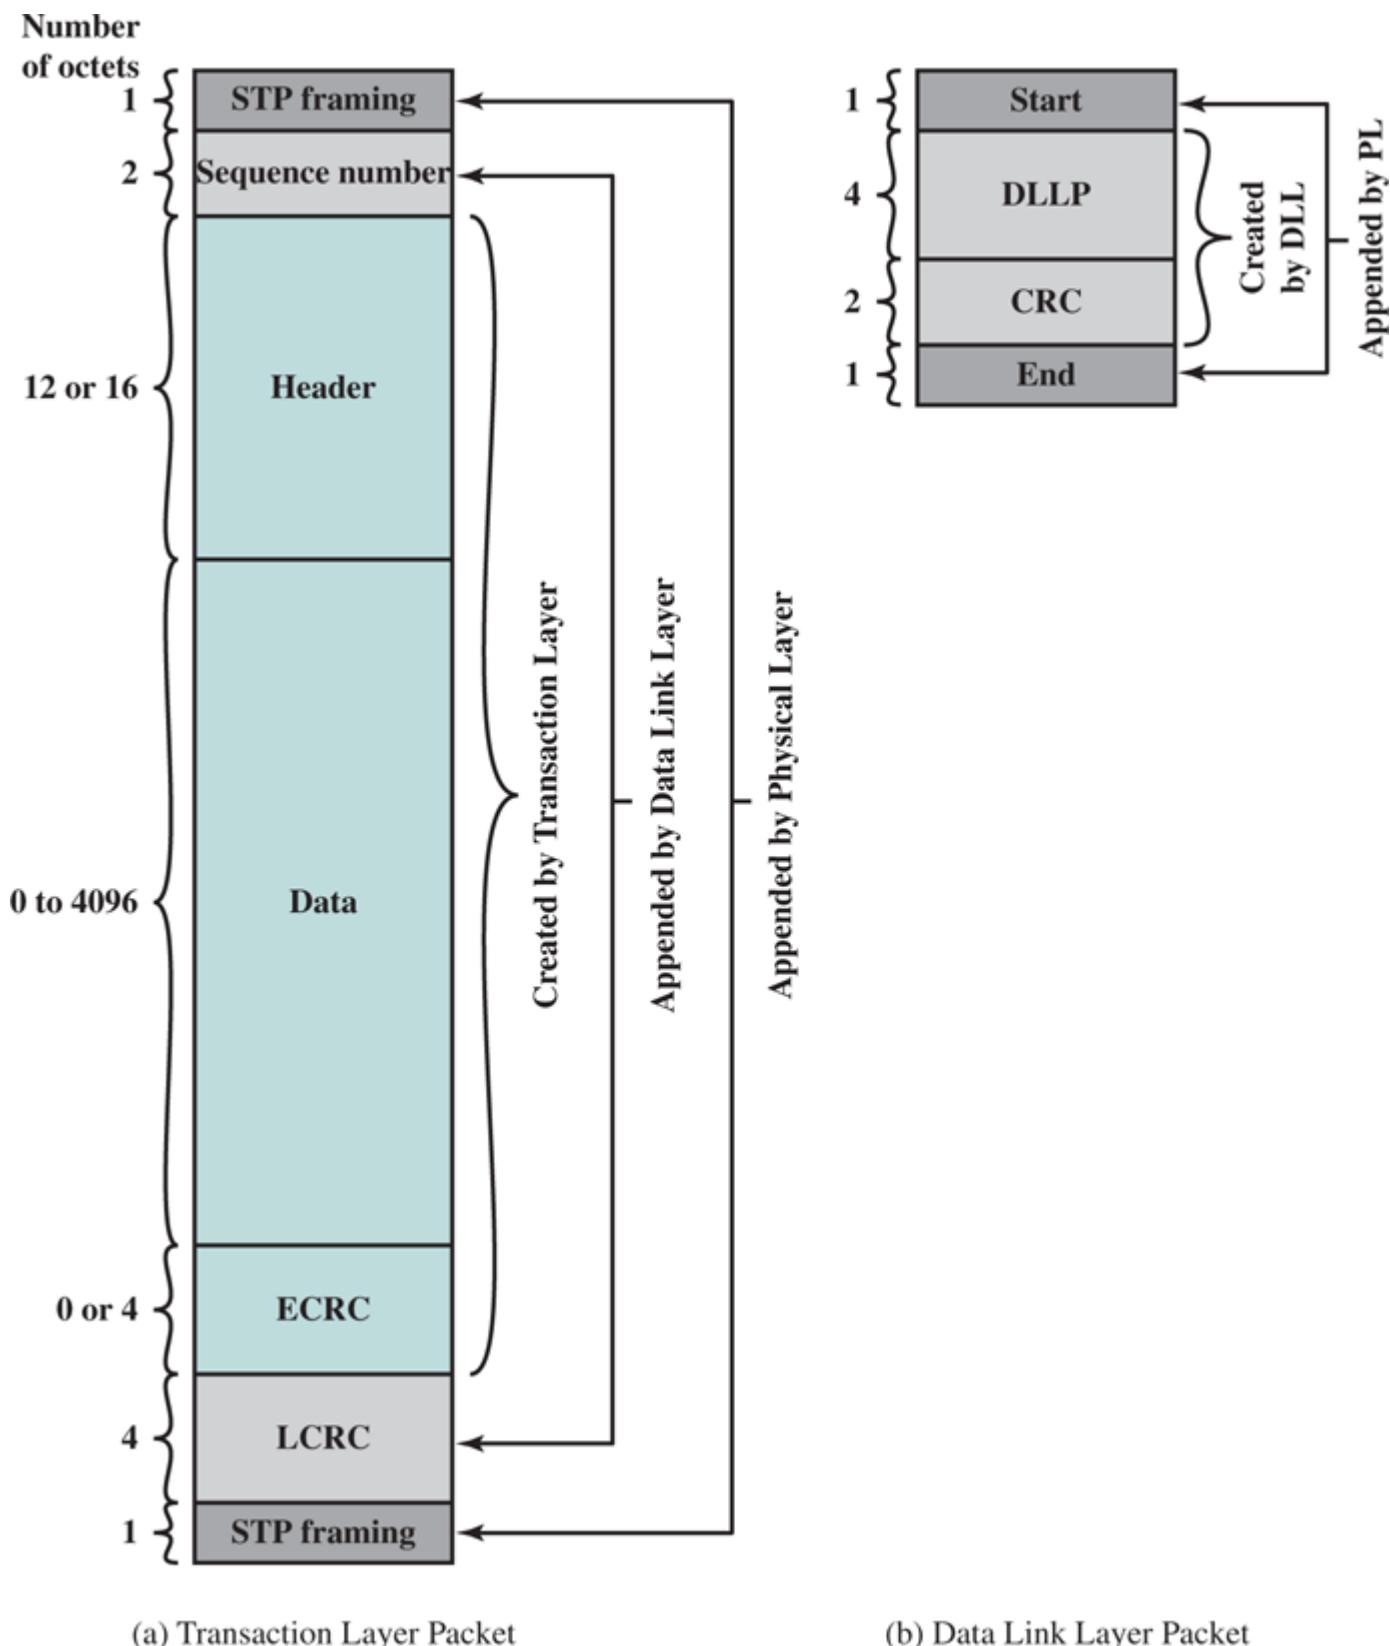

Figure 3.25 PCIe Protocol Data Unit Format

Upper layer software sends to the TL the information needed for the TL to create the core of the TLP, which consists of the following fields:

- **Header:** The header describes the type of packet and includes information needed by the receiver to process the packet, including any needed routing information. The internal header format is

discussed subsequently.

- **Data:** A data field of up to 4096 bytes may be included in the TLP. Some TLPs do not contain a data field.
- **ECRC:** An optional end-to-end CRC field enables the destination TL layer to check for errors in the header and data portions of the TLP.

PCIe Data Link Layer

The purpose of the PCIe data link layer is to ensure reliable delivery of packets across the PCIe link. The DLL participates in the formation of TLPs and also transmits DLLPs.

DATA LINK LAYER PACKETS

Data link layer packets originate at the data link layer of a transmitting device and terminate at the DLL of the device on the other end of the link. [Figure 3.25b](#) shows the format of a DLLP. There are three important groups of DLLPs used in managing a link: flow control packets, power management packets, and TLP ACK and NAK packets. Power management packets are used in managing power platform budgeting. Flow control packets regulate the rate at which TLPs and DLLPs can be transmitted across a link. The ACK and NAK packets are used in TLP processing, discussed in the following paragraphs.

TRANSACTION LAYER PACKET PROCESSING

The DLL adds two fields to the core of the TLP created by the TL ([Figure 3.25a](#)): a 16-bit sequence number and a 32-bit link-layer CRC (LCRC). Whereas the core fields created at the TL are only used at the destination TL, the two fields added by the DLL are processed at each intermediate node on the way from source to destination.

When a TLP arrives at a device, the DLL strips off the sequence number and LCRC fields and checks the LCRC. There are two possibilities:

1. If no errors are detected, the core portion of the TLP is handed up to the local transaction layer. If this receiving device is the intended destination, then the TL processes the TLP. Otherwise, the TL determines a route for the TLP and passes it back down to the DLL for transmission over the next link on the way to the destination.
2. If an error is detected, the DLL schedules an NAK DLL packet to return back to the remote transmitter. The TLP is eliminated.

When the DLL transmits a TLP, it retains a copy of the TLP. If it receives a NAK for the TLP with this sequence number, it retransmits the TLP. When it receives an ACK, it discards the buffered TLP.

3.7 Key Terms, Review Questions, and Problems

Key Terms

address bus
address lines
arbitration
balanced transmission
bus
control lines
data bus
data lines
differential signaling
disabled interrupt
distributed arbitration
error control function
execute cycle
fetch cycle
flit
flow control function
instruction cycle
interrupt
interrupt handler
interrupt service routine (ISR)
lane
memory address register (MAR)
memory buffer register (MBR)
multilane distribution
packets
PCI Express (PCIe)
peripheral component interconnect (PCI)
phit
QuickPath Interconnect (QPI)

system bus

Review Questions

- 3.1 What general categories of functions are specified by computer instructions?
- 3.2 List and briefly define the possible states that define an instruction execution.
- 3.3 List and briefly define two approaches to dealing with multiple interrupts.
- 3.4 What types of transfers must a computer's interconnection structure (e.g., bus) support?
- 3.5 List and briefly define the QPI protocol layers.
- 3.6 List and briefly define the PCIe protocol layers.

Problems

- 3.1 The hypothetical machine of [Figure 3.4](#) also has two I/O instructions:
0011 = Load AC from I/O
0111 = Store AC to I/O

In these cases, the 12-bit address identifies a particular I/O device. Show the program execution (using the format of [Figure 3.5](#)) for the following program:

1. Load AC from device 5.
2. Add contents of memory location 940.
3. Store AC to device 6.

Assume that the next value retrieved from device 5 is 3 and that location 940 contains a value of 2.

- 3.2 The program execution of [Figure 3.5](#) is described in the text using six steps. Expand this description to show the use of the MAR and MBR.

3.3 Consider a hypothetical 32-bit microprocessor having 32-bit instructions composed of two fields: the first byte contains the opcode and the remainder the immediate operand or an operand address.

- a. What is the maximum directly addressable memory capacity (in bytes)?
- b. Discuss the impact on the system speed if the microprocessor bus has:
 1. 32-bit local address bus and a 16-bit local data bus, or
 2. 16-bit local address bus and a 16-bit local data bus.
- c. How many bits are needed for the program counter and the instruction register?

3.4 Consider a hypothetical microprocessor generating a 16-bit address (for example, assume that the program counter and the address registers are 16 bits wide) and having a 16-bit data bus.

- a. What is the maximum memory address space that the processor can access directly if it is connected to a "16-bit memory"?
- b. What is the maximum memory address space that the processor can access directly if it is connected to an "8-bit memory"?
- c. What architectural features will allow this microprocessor to access a separate "I/O space"?
- d. If an input and an output instruction can specify an 8-bit I/O port number, how many 8-bit I/O ports can the microprocessor support? How many 16-bit I/O ports? Explain.

3.5 Consider a 32-bit microprocessor, with a 16-bit external data bus, driven by an 8-MHz input clock. Assume that this microprocessor has a bus cycle whose minimum duration equals four input clock cycles. What is the maximum data transfer rate across the bus that this microprocessor can sustain, in bytes/sec? To increase its performance, would it be better to make its external data bus 32 bits or to double the external clock frequency supplied to the microprocessor? State any other assumptions you make, and explain. *Hint:* Determine the number of bytes that can be transferred per bus cycle.

3.6 Consider a computer system that contains an I/O module controlling a simple keyboard/printer teletype. The following registers are contained in the processor and connected directly to the system bus:

INPR: Input Register, 8 bits

OUTR: Output Register, 8 bits

FGI: Input Flag, 1 bit

FGO: Output Flag, 1 bit

IEN: Interrupt Enable, 1 bit

Keystroke input from the teletype and printer output to the teletype are controlled by the I/O module. The teletype is able to encode an alphanumeric symbol to an 8-bit word and decode an 8-bit word into an alphanumeric symbol.

- a. Describe how the processor, using the first four registers listed in this problem, can achieve I/O with the teletype.
- b. Describe how the function can be performed more efficiently by also employing IEN.

3.7 Consider two microprocessors having 8- and 16-bit-wide external data buses, respectively. The two processors are identical otherwise and their bus cycles take just as long.

- a. Suppose all instructions and operands are two bytes long. By what factor do the maximum data transfer rates differ?
- b. Repeat assuming that half of the operands and instructions are one byte long.

3.8 **Figure 3.26** indicates a distributed arbitration scheme that can be used with an obsolete bus scheme known as Multibus I. Agents are daisy-chained physically in priority order. The left-most agent in the diagram receives a constant *bus priority in* (BPRN) signal indicating that no higher-priority agent desires the bus. If the agent does not require the bus, it asserts its *bus priority out* (BPRO) line. At the beginning of a clock cycle, any agent can request control of the bus by lowering its BPRO line. This lowers the BPRN line of the next agent in the chain, which is in turn required to lower its BPRO line. Thus, the signal is propagated the length of the chain. At the end of this chain reaction, there should be only one agent whose BPRN is asserted and whose BPRO is not. This agent has priority. If, at the beginning of a bus cycle, the bus is not busy (BUSY inactive), the agent that has priority may seize control of the bus by asserting the BUSY line.

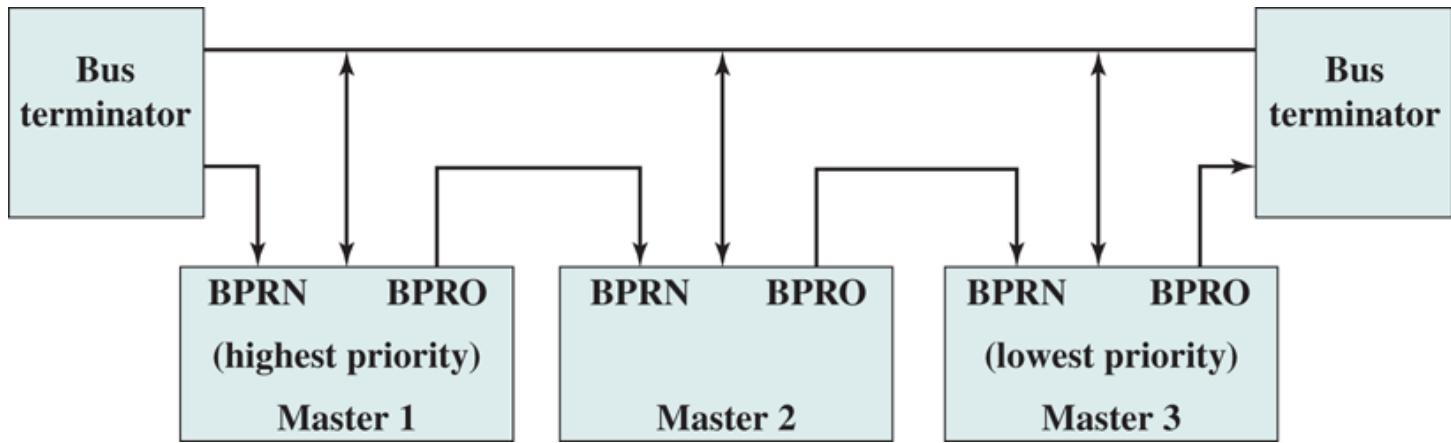

Figure 3.26 Multibus I Distributed Arbitration

It takes a certain amount of time for the BPR signal to propagate from the highest-priority agent to the lowest. Must this time be less than the clock cycle? Explain.

3.9 The VAX SBI bus uses a distributed, synchronous arbitration scheme. Each SBI device (i.e., processor, memory, I/O module) has a unique priority and is assigned a unique transfer request (TR) line. The SBI has 16 such lines (TR0, TR1, . . . , TR15), with TR0 having the highest priority. When a device wants to use the bus, it places a reservation for a future time slot by asserting its TR line during the current time slot. At the end of the current time slot, each device with a pending reservation examines the TR lines; the highest-priority device with a reservation uses the next time slot.

A maximum of 17 devices can be attached to the bus. The device with priority 16 has no TR line. Why not?

3.10 On the VAX SBI, the lowest-priority device usually has the lowest average wait time. For this reason, the processor is usually given the lowest priority on the SBI. Why does the priority 16 device usually have the lowest average wait time? Under what circumstances would this not be true?

3.11 For a synchronous read operation (Figure C.3 in [Appendix C](#)), the memory module must place the data on the bus sufficiently ahead of the falling edge of the Read signal to allow for signal settling. Assume a microprocessor bus is clocked at 10 MHz and that the Read signal begins to fall in the middle of the second half of T_3 .

- Determine the length of the memory read instruction cycle.
- When, at the latest, should memory data be placed on the bus? Allow 20 ns for the settling of data lines.

3.12 Consider a microprocessor that has a memory read timing (Figure C.3 in [Appendix C](#)). After some analysis, a designer determines that the memory falls short of providing read data on time by about 180 ns.

- How many wait states (clock cycles) need to be inserted for proper system operation if the bus clocking rate is 8 MHz?
- To enforce the wait states, a Ready status line is employed. Once the processor has issued a Read command, it must wait until the Ready line is asserted before attempting to read data. At what time interval must we keep the Ready line low in order to force the processor to insert the required number of wait states?

3.13 A microprocessor has a memory write timing Figure A.3 in [Appendix A](#) . Its manufacturer specifies that the width of the Write signal can be determined by $T - 50$, where T is the clock period in ns.

- a. What width should we expect for the Write signal if bus clocking rate is 5 MHz?
- b. The data sheet for the microprocessor specifies that the data remain valid for 20 ns after the falling edge of the Write signal. What is the total duration of valid data presentation to memory?
- c. How many wait states should we insert if memory requires valid data presentation for at least 190 ns?

3.14 A microprocessor has an increment memory direct instruction, which adds 1 to the value in a memory location. The instruction has five stages: fetch opcode (four bus clock cycles), fetch operand address (three cycles), fetch operand (three cycles), add 1 to operand (three cycles), and store operand (three cycles).

- a. By what amount (in percent) will the duration of the instruction increase if we have to insert two bus wait states in each memory read and memory write operation?
- b. Repeat assuming that the increment operation takes 13 cycles instead of 3 cycles.

3.15 The Intel 8088 microprocessor has a read bus timing similar to that of Figure C.3, but requires four processor clock cycles. The valid data is on the bus for an amount of time that extends into the fourth processor clock cycle. Assume a processor clock rate of 8 MHz.

- a. What is the maximum data transfer rate?
- b. Repeat, but assume the need to insert one wait state per byte transferred.

3.16 The Intel 8086 is a 16-bit processor similar in many ways to the 8-bit 8088. The 8086 uses a 16-bit bus that can transfer 2 bytes at a time, provided that the lower-order byte has an even address. However, the 8086 allows both even- and odd-aligned word operands. If an odd-aligned word is referenced, two memory cycles, each consisting of four bus cycles, are required to transfer the word. Consider an instruction on the 8086 that involves two 16-bit operands. How long does it take to fetch the operands? Give the range of possible answers. Assume a clocking rate of 4 MHz and no wait states.

3.17 Consider a 32-bit microprocessor whose bus cycle is the same duration as that of a 16-bit microprocessor. Assume that, on average, 20% of the operands and instructions are 32 bits long, 40% are 16 bits long, and 40% are only 8 bits long. Calculate the improvement achieved when fetching instructions and operands with the 32-bit microprocessor.

3.18 The microprocessor of Problem 3.14 initiates the fetch operand stage of the increment memory direct instruction at the same time that a keyboard activates an interrupt request line. After how long does the processor enter the interrupt processing cycle? Assume a bus clocking rate of 10 MHz.

Multilevel Memory Access

4.5 Key Terms, Review Questions, and Problems

Learning Objectives

After studying this chapter, you should be able to:

- Present an overview of the principle of locality.
- Describe key characteristics of a memory system.
- Discuss how locality influences the development of a memory hierarchy.
- Understand the performance implications of multiple levels of memory.

Although seemingly simple in concept, computer memory exhibits perhaps the widest range of type, technology, organization, performance, and cost of any feature of a computer system. No single technology is optimal in satisfying the memory requirements for a computer system. As a consequence, the typical computer system is equipped with a hierarchy of memory subsystems, some internal to the system (directly accessible by the processor) and some external (accessible by the processor via an I/O module).

This chapter focuses on the performance factors that drive the development of a computer memory system with multiple levels using different technologies.

Section 4.1 introduces the key concept of locality of reference, which has a profound influence on both the organization of memory and on operating system memory management software. Following a brief discussion of key characteristics of memory systems, the chapter turns to a presentation of the concept of a memory hierarchy and indicates the typical components in contemporary systems. Finally, Section 4.4 develops a simple but illuminating model of memory access performance.

The next three chapters look at specific aspects of memory systems, using the insights provided in this chapter. Chapter 5 examines an essential element of all

*modern computer systems: cache memory. **Chapter 6** then looks at the technology options for internal memory, including cache and main memory. **Chapter 7** is devoted to external memory.*

4.1 Principle Of Locality

One of the most important concepts related to computer systems is **principle of locality** [DENN05], also referred to as the **locality of reference**. The principle reflects the observation that during the course of execution of a program, memory references by the processor, for both instructions and data, tend to cluster. Programs typically contain a number of iterative loops and subroutines. Once a loop or subroutine is entered, there are repeated references to a small set of instructions. Similarly, operations on tables and arrays involve access to a clustered set of data words. Over a long period of time, the clusters in use change, but over a short period of time, the processor is primarily working with fixed clusters of memory references.

We can put these observations more specifically. As we discuss in [Section 4.3](#), for different types of memory, memory is accessed and retrieved in units of different sizes, ranging from individual words to large blocks of cache memory to much larger segments of disk memory. Denning observed that locality is based on three assertions [DENN72]:

1. During any interval of time, a program references memory locations non-uniformly. That is, some units of memory are more likely to be accessed than others.
2. As a function of time, the probability that a given unit of memory is referenced tends to change slowly. Put another way, the probability distribution of memory references across the entire memory space tends to change slowly over time.
3. The correlation between immediate past and immediate future memory reference patterns is high, and tapers off as the time interval increases.

Intuitively, the principle of locality makes sense. Consider the following line of reasoning:

1. Except for branch and call instructions, which constitute only a small fraction of all program instructions, program execution is sequential. Hence, in most cases, the next instruction to be fetched immediately follows the last instruction fetched.
2. It is rare to have a long uninterrupted sequence of procedure calls followed by the corresponding sequence of returns. Rather, a program remains confined to a rather narrow window of procedure-invocation depth. Thus, over a short period of time, references to instructions tend to be localized to a few procedures.
3. Most iterative constructs consist of a relatively small number of instructions repeated many times. For the duration of the iteration, computation is therefore confined to a small contiguous portion of a program.
4. In many programs, much of the computation involves processing data structures, such as arrays or sequences of records. In many cases, successive references to these data structures will be to closely located data items.

Numerous studies, stretching back to the early 1970s, confirm these observations. [FEIT15] provides a summary of many of these studies.

A distinction is made in the literature between two forms of locality:

1. **Temporal locality:** Refers to the tendency of a program to reference in the near future those units of memory referenced in the recent past. For example, when an iteration loop is executed, the processor executes the same set of instructions repeatedly. Constants, temporary variables, and working stacks are also constructs that lead to this principle.
2. **Spatial locality:** Refers to the tendency of a program to reference units of memory whose addresses are near one another. That is, if a unit of memory x is referenced at time t , it is likely

that units in the range $x - k$ through $x + k$ will be referenced in the near future, for a relatively small value of k . This reflects the tendency of a processor to access instructions sequentially. Spatial location also reflects the tendency of a program to access data locations sequentially, such as when processing a table of data.

A crude analogy may help illuminate the distinction between these two concepts ([Figure 4.1](#)). Suppose that Bob is working in an office and spends much of his time dealing with documents in file folders. Thousand of folders are stored in file cabinets in the next room, and for convenience Bob has a file organizer on his desk that can hold a few dozen files. When Bob is working on a file and temporarily is finished, it may be likely that he will need to read or write one of the documents in that file in the near future, so he keeps it in his desk organizer. This is an example of exploiting temporal locality. Bob also observes that when he retrieves a folder from the filing cabinets, it is likely that in the near future he will need access to some of the nearby folders as well, so he retrieves the folder he needs plus a few folders on either side at the same time. This is an example of exploiting spatial locality. Of course, Bob's desktop file organizer soon fills up, so that when he goes to retrieve a folder from the file cabinets, he needs to return folders from his desk. Bob needs some policy for replacing folders. If he focuses on temporal locality, Bob could choose to replace only one folder at a time, on the reasoning that he might need any of the folders currently on his desk in the near future. So Bob could replace perhaps the folder that had been on the desk the longest or the one that had been the least recently used. If Bob focuses on spatial locality, when he needs a folder not on his desk, he could return and refile all the folders on his desk and retrieve a batch of contiguous folders that includes the one he needs plus other nearby folders sufficient to fill up his desktop organizer. It is likely that neither policy is optimal. In the first case, he might have to make frequent trips to the next room to get one folder he doesn't have but which is near one he does have. In the second case, he might have to make frequent trips to the next room to get a folder that he had just recently put away. So perhaps a policy of returning and retrieving in batches equal to 10% or 20% of his desktop capacity would be closer to optimal.

Figure 4.1 Moving File Folders Between Smaller, Faster-Access Storage and Larger, Slower-Access Storage

Gualtiero boffi/Shutterstock

For cache memory, temporal locality is traditionally exploited by keeping recently used instruction and data values in cache memory and by exploiting a cache hierarchy. Spatial locality is generally exploited by using larger cache blocks and by incorporating prefetching mechanisms (fetching items of anticipated use) into the cache control logic. Over the years, there has been considerable research on

refining these techniques to achieve greater performance, but the basic strategies remain the same.

Figure 4.2 provides a rough depiction of the behavior of programs that exhibit temporal locality. For a unit of memory accessed at time t , the figure shows the distribution of probability of the time of the next access to the same memory unit. Similarly, **Figure 4.3** provides a rough depiction of the behavior of programs that exhibit spatial locality. For spatial locality, the probability distribution curve is symmetrical around the location of the most recent memory access address.

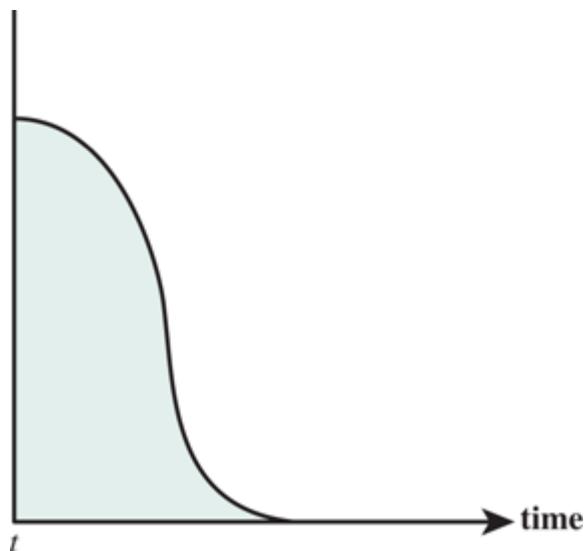

Figure 4.2 Idealized Temporal Locality Behavior: Probability Distribution for Time of Next Memory Access to Memory Unit Accessed at Time t

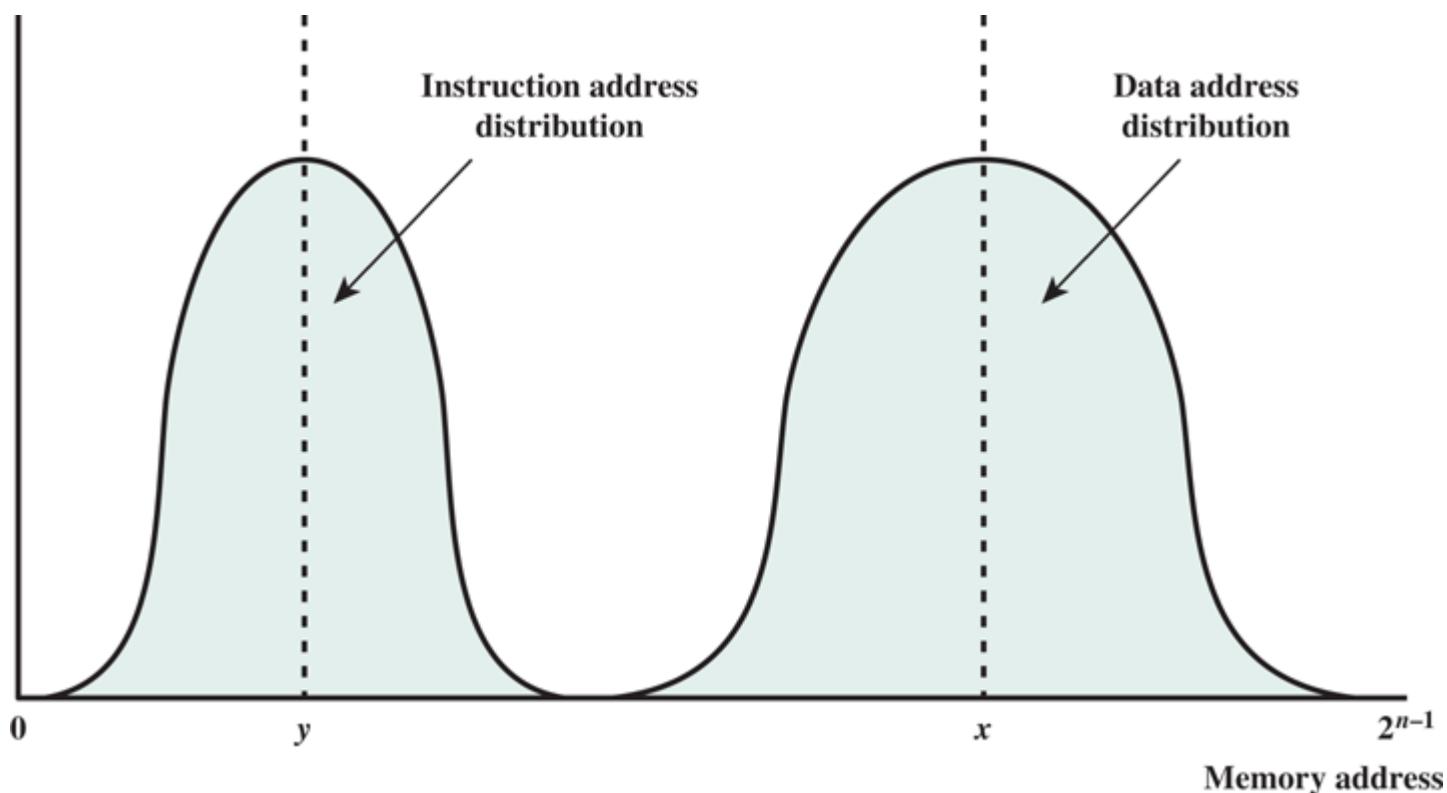

Figure 4.3 Idealized Spatial Locality Behavior: Probability Distribution for Next Memory Access (most recent data memory access at location x ; most recent instruction fetch at location y)

Many programs exhibit both temporal and spatial locality for both instruction and data access. It has been found that data access patterns generally show a greater variance than instruction access.

patterns [AHO07]. **Figure 4.3** suggests this distinction between the distribution of data location accesses (read or write) and instruction fetch addresses. Typically, each instruction execution involves fetching the instruction from memory and, during execution, accessing one or more data operands from one or more regions of memory. Thus, there is a dual locality of **data spatial locality** and **instruction spatial locality**. And, of course, temporal locality exhibits this same dual behavior: **data temporal locality** and **instruction temporal locality**. That is, when an instruction is fetched from a unit of memory, it is likely that in the near future, additional instructions will be fetched from that same memory unit; and when a data location is accessed, it is likely that in the near future, additional instructions will be fetched from that same memory unit.

An example of data locality is illustrated in **Figure 4.4** [BAEN97]. This shows the results of a study of Web-based document access patterns, where the documents are distributed among a number of servers. In this case, the unit of access is a single document and temporal locality is measured. The access scheme makes use of a document cache at the browser that can temporarily retain a small number of documents to facilitate reuse. The study covered 220,000 documents distributed over 11,000 servers. As shown in **Figure 4.4**, only a very small subset of pages incorporates a high number of references while most documents are accessed relatively infrequently.

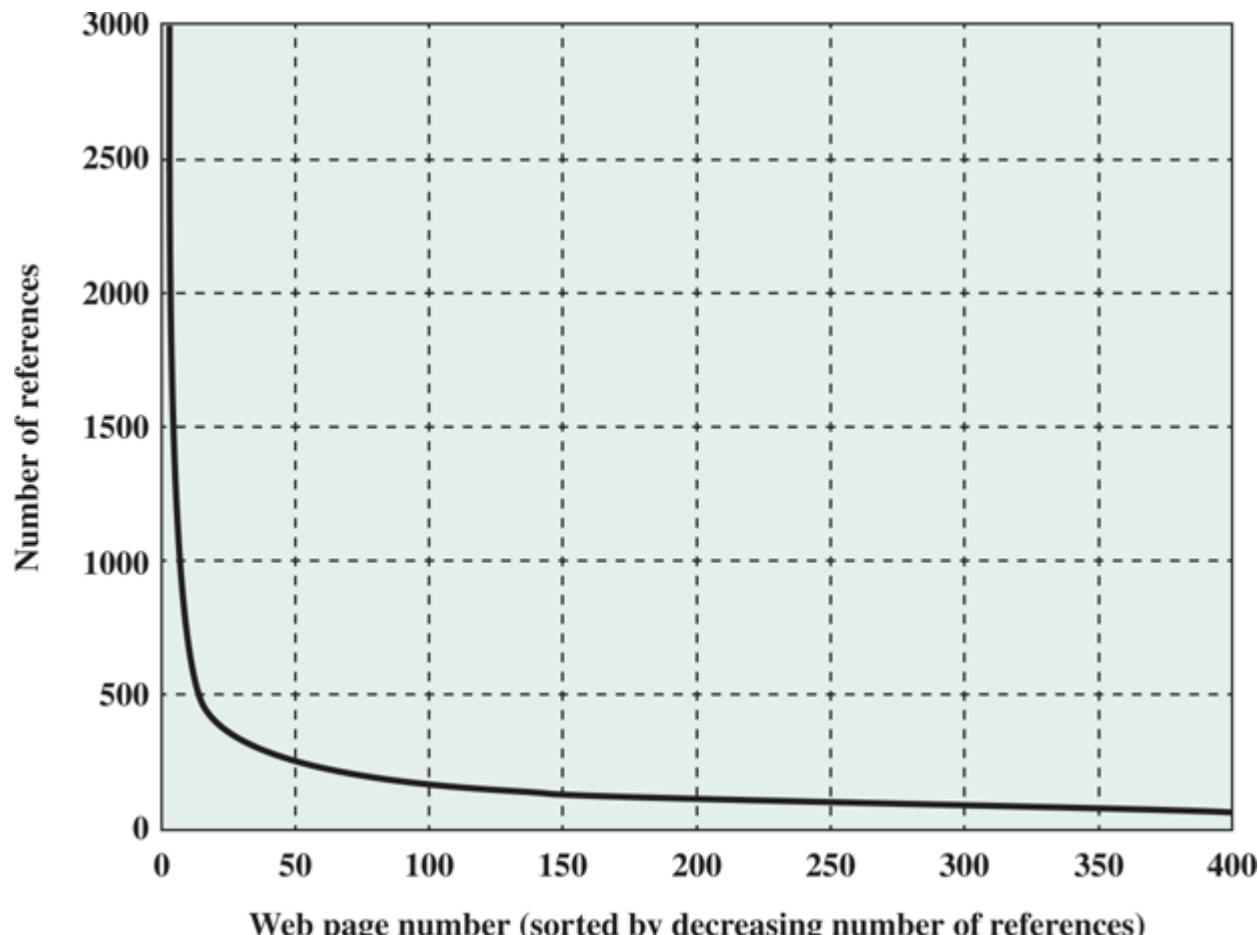

Figure 4.4 Data Locality of Reference for Web-Based Document Access Application

Figure 4.5 shows an example of instruction locality based on executing the integer benchmark programs in the SPEC CPU2006 benchmark suite; similar results were obtained for the floating-point programs. The following terms are used in the plot:

1. **Static instruction:** An instruction that exists in the code to be executed.
2. **Dynamic instruction:** Instructions that appear in the execution trace of a program.

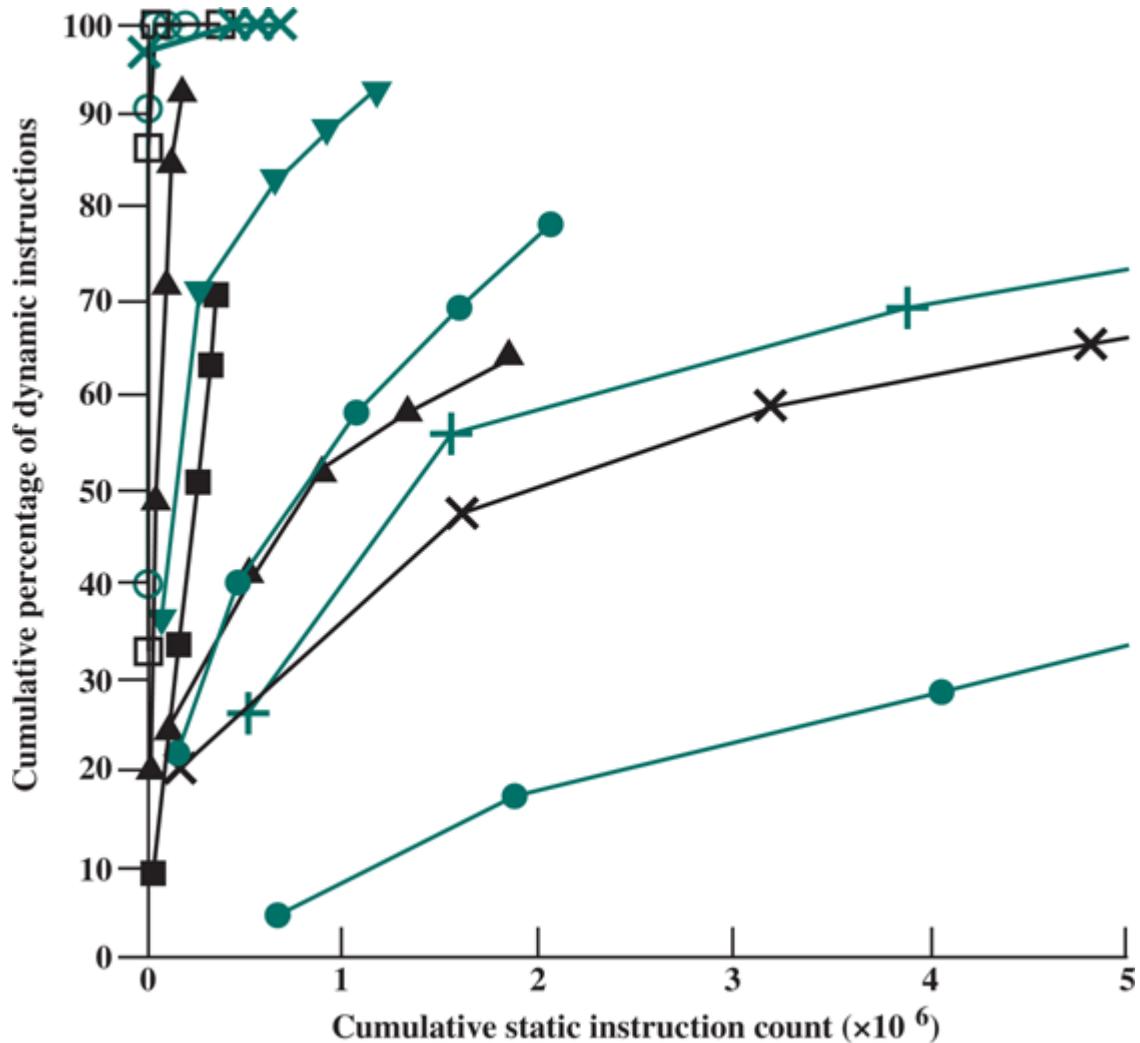

Figure 4.5 Instruction Locality Based on Code Reuse in Eleven Benchmark Programs in SPEC CPU2006

Thus, each static instruction is represented by zero or more instances of dynamic instructions when the program is executed. Each line in the graph represents a separate benchmark program. In the figure, the cumulative percentage of dynamic instructions executed by a program is shown on the y-axis and the cumulative count of static instructions is shown on the x-axis. The first point in the line plot for each benchmark represents the most frequently called subroutine, with the x coordinate showing the number of static instructions in the routine and y coordinate showing the percentage of dynamic instructions that it represents. The second, third, fourth, and fifth points respectively represent the top 5, 10, 15, and 20 most frequently called subroutines. Many programs initially show a steep upward climb as the static instruction count increases, which suggests very good instruction locality.

4.2 Characteristics Of Memory Systems

The complex subject of computer memory is made more manageable if we classify memory systems according to their key characteristics. The most important of these are listed in **Table 4.1**.

Table 4.1 Key Characteristics of Computer Memory Systems

Location	Performance
Internal (e.g., processor registers, cache, main memory)	Access time
External (e.g., optical disks, magnetic disks, tapes)	Cycle time
Capacity	Transfer rate
Number of words	Physical Type
Number of bytes	Semiconductor
Unit of Transfer	Magnetic
Word	Optical
Block	Magneto-optical
Access Method	Physical Characteristics
Sequential	Volatile/nonvolatile
Direct	Erasable/nonerasable
Random	Organization
Associative	Memory modules

The term **location** in **Table 4.1** refers to whether memory is internal or external to the computer. Internal memory is often equated with main memory, but there are other forms of internal memory. The processor requires its own local memory, in the form of registers (e.g., see **Figure 2.3**). Further, as we will see, the control unit portion of the processor may also require its own internal memory. We will defer discussion of these latter two types of internal memory to later chapters. Cache is another form of internal memory. External memory consists of peripheral storage devices, such as disk and tape, that are accessible to the processor via I/O controllers.

An obvious characteristic of memory is its **capacity**. For internal memory, this is typically expressed in terms of bytes (1byte = 8bits) or words. Common word lengths are 8, 16, and 32 bits. External memory capacity is typically expressed in terms of bytes.

A related concept is the **unit of transfer**. For internal memory, the unit of transfer is equal to the number of electrical lines into and out of the memory module. This may be equal to the word length,

but is often larger, such as 64, 128, or 256 bits. To clarify this point, consider three related concepts for internal memory:

- **Word:** The “natural” unit of organization of memory. The size of a word is typically equal to the number of bits used to represent an integer and to the instruction length. Unfortunately, there are many exceptions. For example, the CRAY C90 (an older model CRAY supercomputer) has a 64-bit word length but uses a 46-bit integer representation. The Intel x86 architecture has a wide variety of instruction lengths, expressed as multiples of bytes, and a word size of 32 bits.
- **Addressable units:** In some systems, the addressable unit is the word. However, many systems allow addressing at the byte level. In any case, the relationship between the length in bits A of an address and the number N of addressable units is $2^A = N$.
- **Unit of transfer:** For main memory, this is the number of bits read out of or written into memory at a time. The unit of transfer need not equal a word or an addressable unit. For external memory, data are often transferred in much larger units than a word, and these are referred to as blocks.

Another distinction among memory types is the **method of accessing** units of data. These include the following:

- **Sequential access:** Memory is organized into units of data, called records. Access must be made in a specific linear sequence. Stored addressing information is used to separate records and assist in the retrieval process. A shared read–write mechanism is used, and this must be moved from its current location to the desired location, passing and rejecting each intermediate record. Thus, the time to access an arbitrary record is highly variable. Tape units, discussed in [Chapter 7](#), are sequential access.
- **Direct access:** As with sequential access, direct access involves a shared read–write mechanism. However, individual blocks or records have a unique address based on physical location. Access is accomplished by direct access to reach a general vicinity plus sequential searching, counting, or waiting to reach the final location. Again, access time is variable. Disk units, discussed in [Chapter 6](#), are direct access.
- **Random access:** Each addressable location in memory has a unique, physically wired-in addressing mechanism. The time to access a given location is independent of the sequence of prior accesses and is constant. Thus, any location can be selected at random and directly addressed and accessed. Main memory and some cache systems are random access.
- **Associative:** This is a random access type of memory that enables one to make a comparison of desired bit locations within a word for a specified match, and to do this for all words simultaneously. Thus, a word is retrieved based on a portion of its contents rather than its address. As with ordinary random-access memory, each location has its own addressing mechanism, and retrieval time is constant independent of location or prior access patterns. Cache memories may employ associative access.

From a user’s point of view, the two most important characteristics of memory are capacity and **performance**. Three performance parameters are used:

- **Access time (latency):** For random-access memory, this is the time it takes to perform a read or write operation, that is, the time from the instant that an address is presented to the memory to the instant that data have been stored or made available for use. For non-random-access memory, access time is the time it takes to position the read–write mechanism at the desired location.
- **Memory cycle time:** This concept is primarily applied to random-access memory and consists of the access time plus any additional time required before a second access can commence. This additional time may be required for transients to die out on signal lines or to regenerate data if they are read destructively. Note that memory cycle time is concerned with the system bus, not the processor.
- **Transfer rate:** This is the rate at which data can be transferred into or out of a memory unit. For random-access memory, it is equal to $1/(\text{cycle time})$. For non-random-access memory, the

following relationship holds:

$$T_n = T_A + \frac{n}{R} \quad (4.1)$$

where

$$\begin{aligned} T_n &= \text{Average time to read or write } n \text{ bits} \\ T_A &= \text{Average access time} \\ n &= \text{Number of bits} \\ R &= \text{Transfer rate, in bits per second(bps)} \end{aligned}$$

A variety of **physical types** of memory have been employed. The most common today are semiconductor memory, magnetic surface memory, used for disk and tape, and optical and magneto-optical.

Several **physical characteristics** of data storage are important. In a volatile memory, information decays naturally or is lost when electrical power is switched off. In a nonvolatile memory, information once recorded remains without deterioration until deliberately changed; no electrical power is needed to retain information. Magnetic-surface memories are nonvolatile. Semiconductor memory (memory on integrated circuits) may be either volatile or nonvolatile. Nonerasable memory cannot be altered, except by destroying the storage unit. Semiconductor memory of this type is known as *read-only memory* (ROM). Of necessity, a practical nonerasable memory must also be nonvolatile.

For random-access memory, the **organization** is a key design issue. In this context, *organization* refers to the physical arrangement of bits to form words. The obvious arrangement is not always used, as is explained in **Chapter 6**.

4.3 The Memory Hierarchy

The design constraints on a computer's memory can be summed up by three questions: How much? How fast? How expensive?

The question of how much is somewhat open ended. If the capacity is there, applications will likely be developed to use it. The question of how fast is, in a sense, easier to answer. To achieve greatest performance, the memory must be able to keep up with the processor. That is, as the processor is executing instructions, we would not want it to have to pause waiting for instructions or operands. The final question must also be considered. For a practical system, the cost of memory must be reasonable in relationship to other components.

As might be expected, there is a trade-off among the three key characteristics of memory: capacity, access time, and cost. A variety of technologies are used to implement memory systems, and across this spectrum of technologies, the following relationships hold:

- Faster access time, greater cost per bit
- Greater capacity, smaller cost per bit
- Greater capacity, slower access time

The dilemma facing the designer is clear. The designer would like to use memory technologies that provide for large-capacity memory, both because the capacity is needed and because the cost per bit is low. However, to meet performance requirements, the designer needs to use expensive, relatively lower-capacity memories with short access times.

Cost and Performance Characteristics

The way out of this dilemma is not to rely on a single memory component or technology, but to employ a **memory hierarchy**. A typical hierarchy is illustrated in [Figure 4.6](#). As one goes down the hierarchy, the following occur:

- a. Decreasing cost per bit
- b. Increasing capacity
- c. Increasing access time
- d. Decreasing frequency of access of the memory by the processor

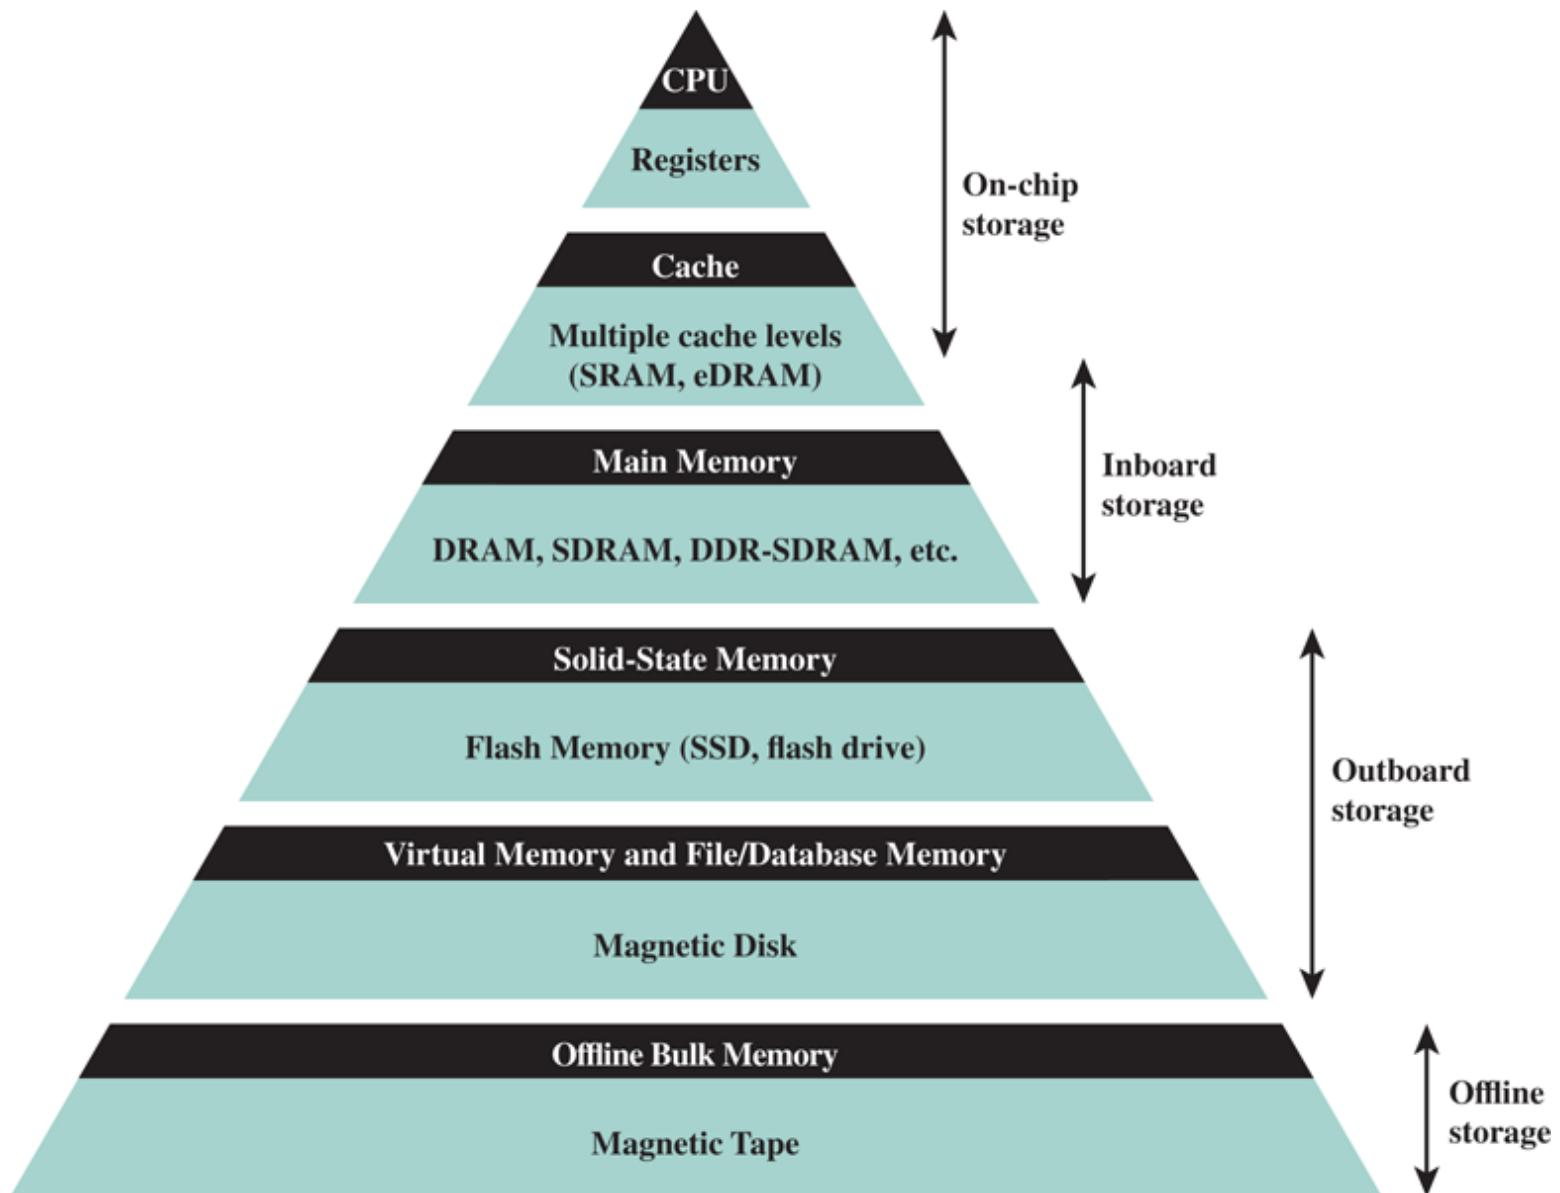

Figure 4.6 The Memory Hierarchy

Let us label the memory at level i of the memory hierarchy M_i , such that M_i is closer to the processor than M_{i+1} . If C_i , T_i , R_i , and S_i are respectively the cost per byte, average access time, average data transfer rate, and total memory size at level i , then the following relationships typically hold between levels i and $i + 1$:

$$\begin{aligned} C_i &> C_{i+1} \\ T_i &< T_{i+1} \\ R_i &> R_{i+1} \\ S_i &< S_{i+1} \end{aligned}$$

Figure 4.7 (in a general way and not to scale) illustrates these relationships across the memory hierarchy.

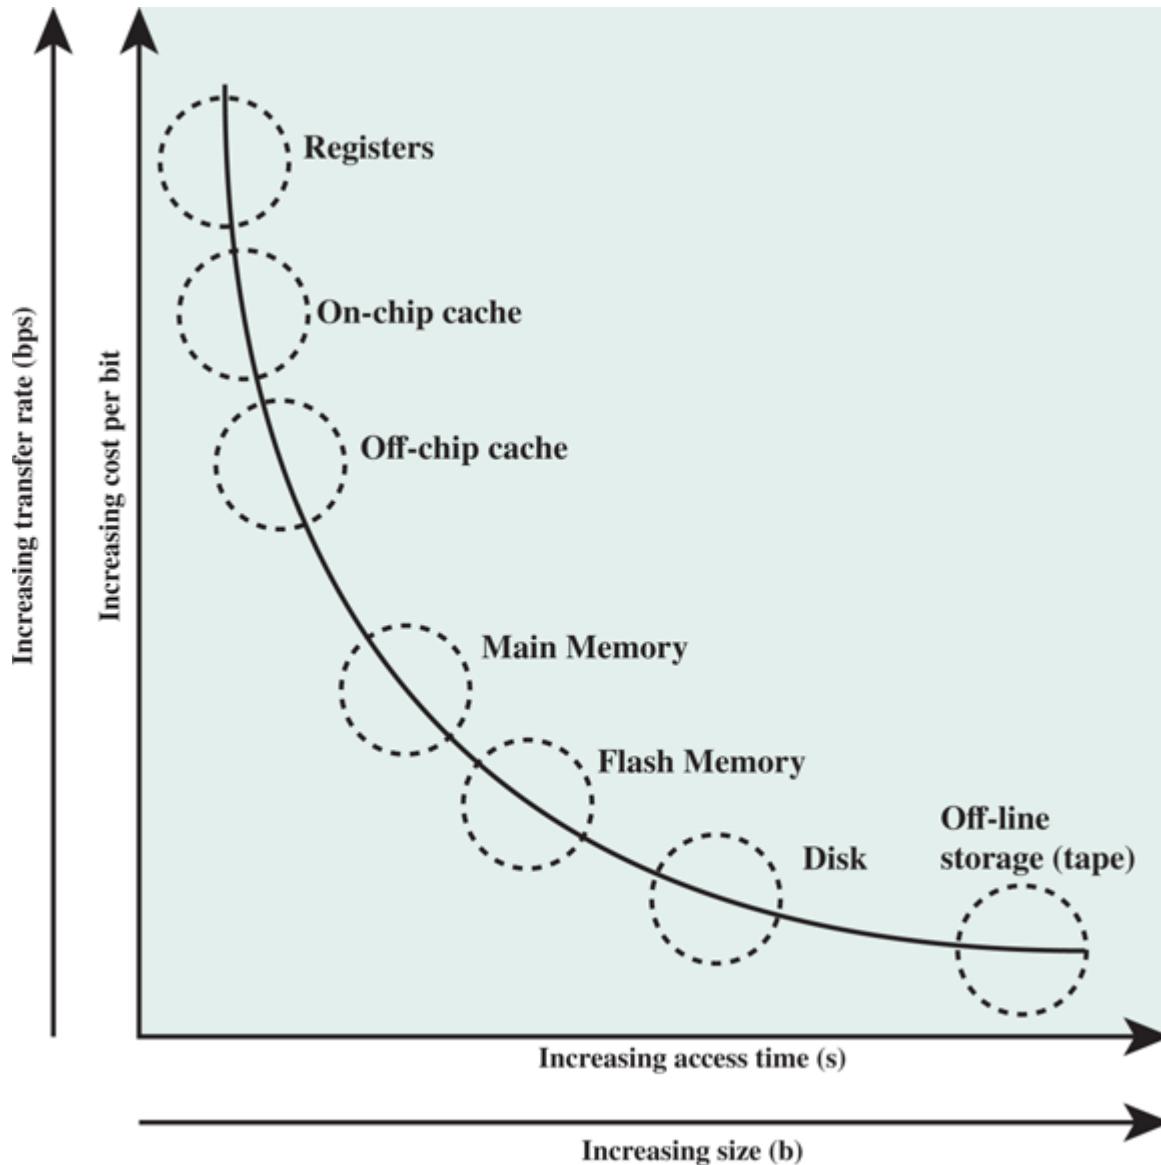

Figure 4.7 Relative Cost, Size, and Speed Characteristics Across the Memory Hierarchy

Thus, smaller, more expensive, faster memories are supplemented by larger, cheaper, slower memories. The key to the success of this organization is item (d): decreasing frequency of access, which can be achieved by exploiting the principle of locality, described in [Section 4.1](#). We discuss techniques for exploiting locality in the treatment of cache, in [Chapter 5](#), and virtual memory, in [Chapter 9](#). A general discussion is provided at this point.

It is possible to organize data across the hierarchy such that the percentage of accesses to each successively lower level is substantially less than that of the level above. Consider the following example:

EXAMPLE 4.1

Suppose that the processor has access to two levels of memory. Level 1 contains X words and has an access time of $0.01\mu s$; level 2 contains $1000 \times X$ words and has an access time of $0.1\mu s$.

Assume that if a word to be accessed is in level 1, then the processor accesses it directly. If it is in level 2, then the word is first transferred to level 1 and then accessed by the processor. For simplicity, we ignore the time required for the processor to determine whether the word is in level 1 or level 2. [Figure 4.8](#) shows the general shape of the curve that covers this situation. The figure shows the average access time to a two-level memory as a function of the hit ratio H , where H is defined as the fraction of all memory accesses that are found in the faster memory (e.g., the

cache), T_1 is the access time to level 1, and T_2 is the access time to level 2.¹ As can be seen, for high percentages of level 1 access, the average total access time is much closer to that of level 1 than that of level 2.

¹ If the accessed word is found in the faster memory, that is defined as a **hit**. A **miss** occurs if the accessed word is not found in the faster memory.

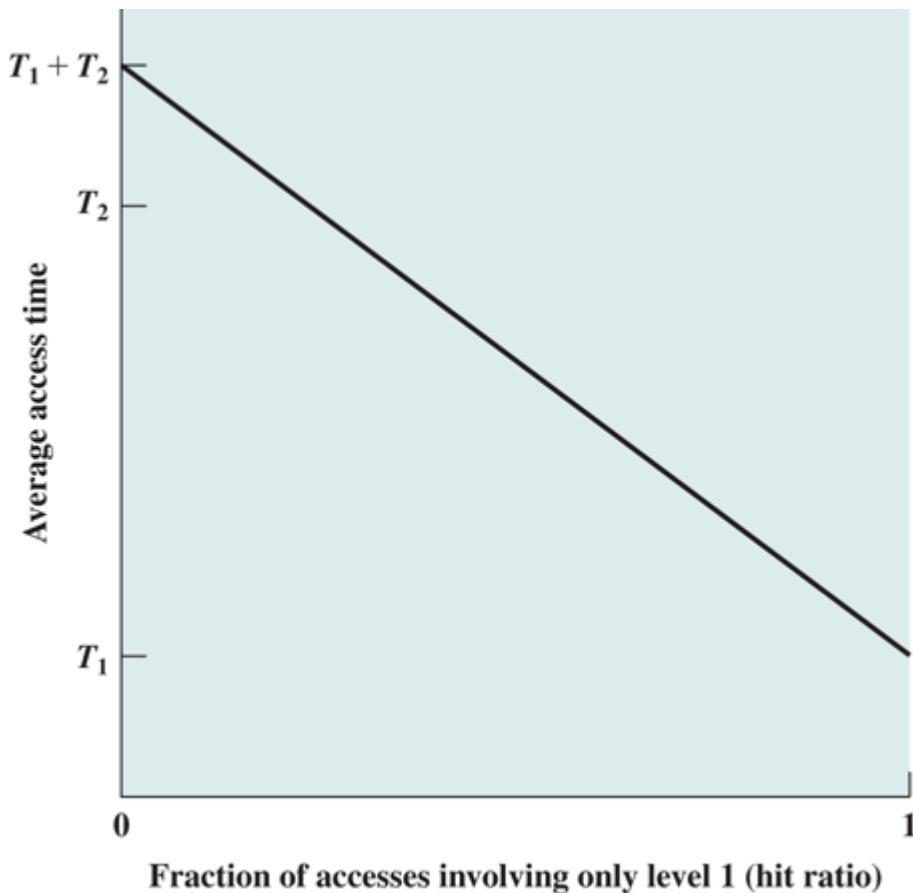

Figure 4.8 Performance of Accesses Involving only Level 1 (hit ratio)

In our example, suppose that 95% of the memory accesses are found in Level 1. Then the average time to access a word can be expressed as

$$(0.95)(0.01\mu s) + (0.05)(0.01\mu s + 0.1\mu s) = 0.0095 + 0.0055 = 0.015\mu s$$

The average access time is much closer to $0.01\mu s$ than to $0.1\mu s$, as desired.

Let level 2 memory contain all program instructions and data. Currently used clusters can be temporarily placed in level 1. From time to time, one of the clusters in level 1 will have to be swapped back to level 2 to make room for a new cluster coming in to level 1. On average, however, most references will be to instructions and data contained in level 1.

The use of two levels of memory to reduce average access time works in principle, but only if conditions (a) through (d) apply. By employing a variety of technologies, a spectrum of memory systems exists that satisfies conditions (a) through (c). Fortunately, condition (d) is also generally valid due to the principle of locality.

This principle can be applied across multiple levels of memory, as suggested by the hierarchy shown

in [Figure 4.6](#). In practice, the dynamic movement of chunks of data between levels during program execution involves registers, one or more levels of cache, main memory, and virtual memory stored on disk. This is shown in [Figure 4.9](#), with an indication of the size of the chunks of data exchanged between levels.

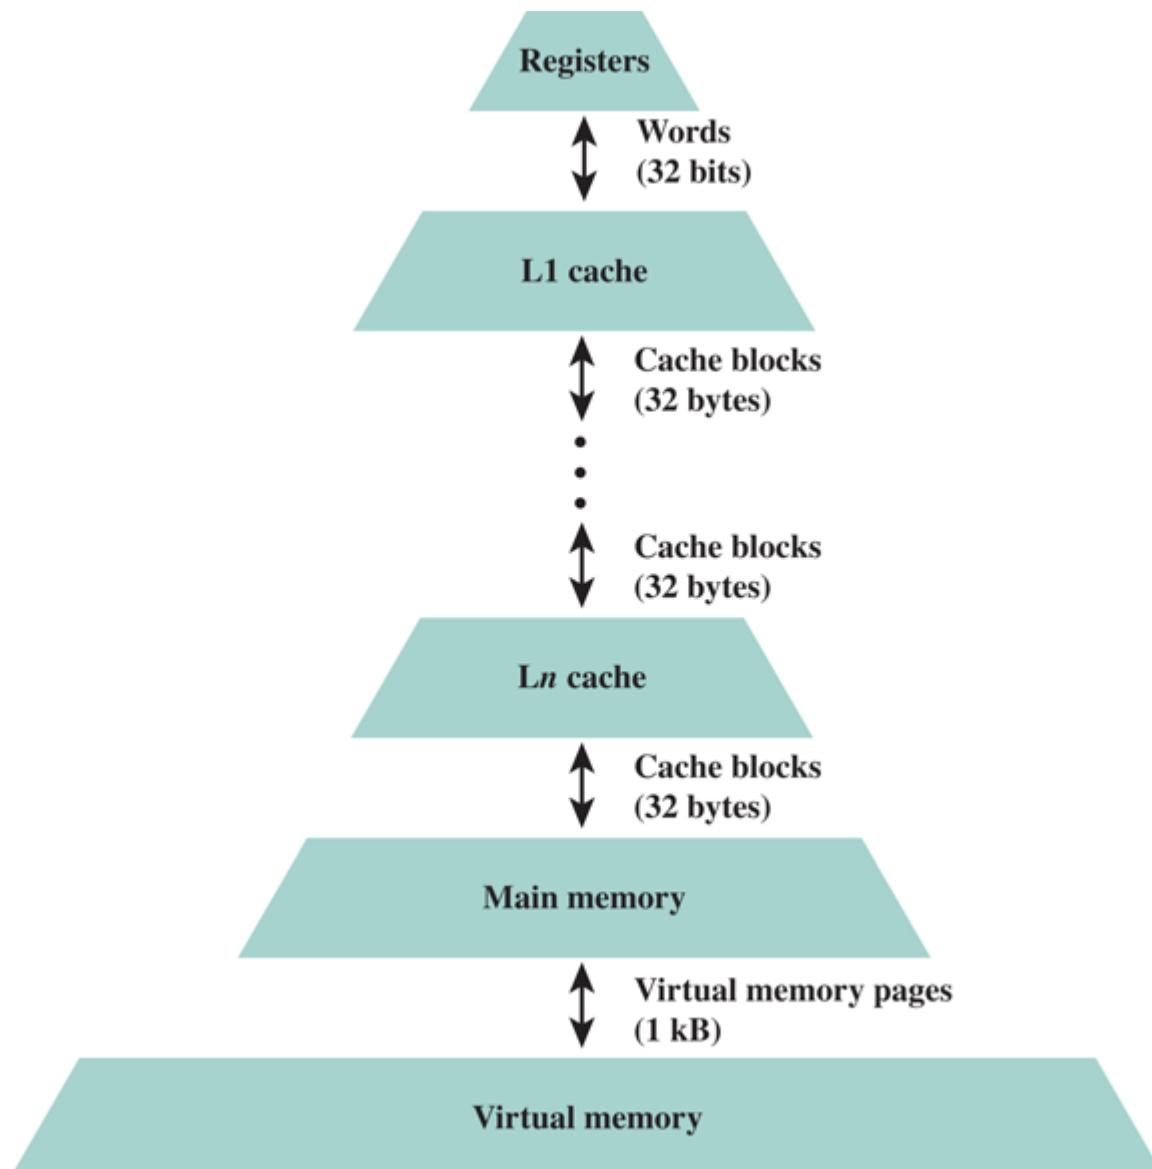

Figure 4.9 Exploiting Locality in the Memory Hierarchy (with typical transfer size)

Typical Members of the Memory Hierarchy

[Table 4.2](#) lists some characteristics of key elements of the memory hierarchy. The fastest, smallest, and most expensive type of memory consists of the registers internal to the processor. Typically, a processor will contain a few dozen such registers, although some machines contain hundreds of registers. Next will be typically multiple layers of cache. Level 1 cache ([L1 cache](#)), closest to the processor registers, is almost always divided into an instruction cache and a data cache. This split is also common for [L2 caches](#). Most contemporary machines also have an [L3 cache](#) and some have an [L4 cache](#); these two caches generally are not split between instruction and data and may be shared by multiple processors. Traditionally, cache memory has been constructed using a technology called static random access memory (SRAM). More recently, higher levels of cache on many systems have been implemented using embedded dynamic RAM (eDRAM), which is slower than SRAM but faster than the DRAM used to implement the main memory of the computer.

Table 4.2 Characteristics of Memory Devices in a Memory Architecture

Memory level	Typical technology	Unit of transfer with next larger level (typical size)	Managed by
Registers	CMOS	Word (32 bits)	Compiler
Cache	Static RAM (SRAM); Embedded dynamic RAM (eDRAM)	Cache block (32 bytes)	Processor hardware
Main memory	DRAM	Virtual memory page (1 kB)	Operating system (OS)
Secondary memory	Magnetic disk	Disk sector (512 bytes)	OS/user
Offline bulk memory	Magnetic tape		OS/User

Main memory is the principal internal memory system of the computer. Each location in main memory has a unique address. Main memory is visible to the programmer, whereas cache memory is not. The various levels of cache are controlled by hardware and are used for staging the movement of data between main memory and processor registers to improve performance.

The three forms of memory just described are, typically, volatile and employ semiconductor technology. The use of three levels exploits the fact that semiconductor memory comes in a variety of types, which differ in speed and cost. Data are stored more permanently on external mass storage devices, of which the most common are hard disk and removable media, such as removable magnetic disk, tape, and optical storage. External, nonvolatile memory is also referred to as **secondary memory** or **auxiliary memory**. These are used to store program and data files and are usually visible to the programmer only in terms of files and records, as opposed to individual bytes or words. Disk is also used to provide an extension to main memory known as virtual memory, which is discussed in [Chapter 9](#). Other forms of secondary memory include optical disks and flash memory.

The IBM z13 Memory Hierarchy

[Figure 4.10](#) illustrates the memory hierarchy for the IBM z13 mainframe computer [LASC16]. It consists of the following levels:

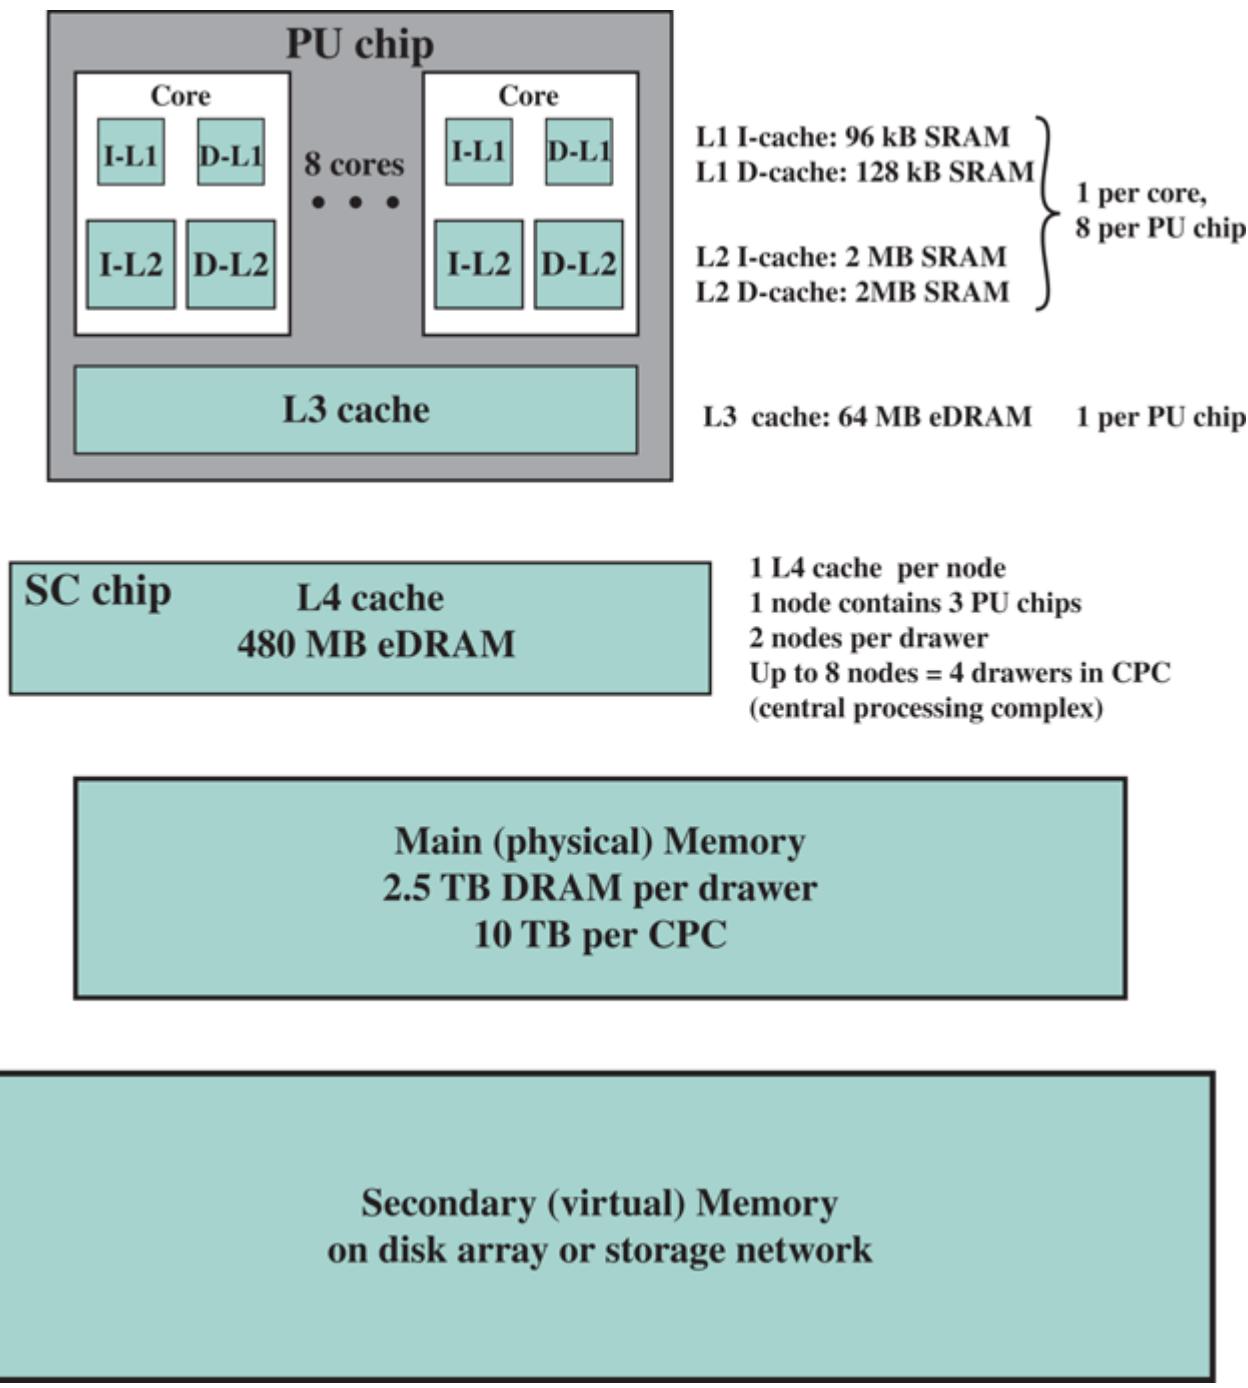

Figure 4.10 IBM z13 Memory Hierarchy

- L1 and L2 caches use SRAM, and are private for each core ([Figure 1.5](#)).
- L3 cache uses eDRAM and is shared by all eight cores within the PU chip ([Figure 1.4](#)). Each CPC drawer has six L3 caches. A four-CPC drawer system therefore has 24 of them, resulting in 1536 MB ($24 \times 64\text{MB}$) of this shared PU chip-level cache.
- L4 cache also uses eDRAM, and is shared by all PU chips on the node of a CPC drawer. Each L4 cache has 480 MB for previously owned and some least recently used (LRU) L3-owned lines and 224 MB for a non-data inclusive coherent (NIC) directory that points to L3 owned lines that have not been included in L4 cache. A four-CPC drawer system has 3840 MB ($4 \times 2 \times 384\text{MB}$) of shared L4 cache and 1792 MB ($4 \times 2 \times 224\text{MB}$) of NIC directory.
- Main storage has up to 2.5 TB addressable memory per CPC drawer, using DRAM. A four-CPC drawer system can have up to 10 TB of main storage.
- Secondary memory holds virtual memory and is stored in disks accessed by various I/O technologies.

Design Principles for a Memory Hierarchy

Three principles guide the design of a memory hierarchy and the supporting memory management hardware and software:

1. **Locality:** Locality is the principle that makes effective use of a memory hierarchy possible.
2. **Inclusion:** This principle dictates that all information items are originally stored in level M_n , where n is the level most remote from the processor. During the processing, subsets of M_n are copied into M_{n-1} . Similarly, subsets of M_{n-1} are copied into M_{n-2} , and so on. This is expressed concisely as $M_i \subseteq M_{i+1}$. Thus, this is in contrast to our simple example of **Figure 4.1**, where Bob moved a folder from the file cabinet to his desk. With the memory hierarchy, units of data are copied rather than moved, so that the data unit that is moved to M_i remains in M_{i+1} . Thus, if a word is found in M_i , then copies of the same word also exist in all subsequent layers $M_{i+1}, M_{i+2}, \dots, M_n$.
3. **Coherence:** Copies of the same data unit in adjacent memory levels must be consistent. If a word is modified in the cache, copies of that word must be updated immediately or eventually at all higher levels.

Coherence has both vertical and horizontal implications, and is required because multiple memories at one level may share the same memory at the next higher (greater value of i) level. For example, for the IBMz13, eight L2 caches share the same L3 cache, and three L3 caches share the same L4 cache. This leads to two requirements:

- **Vertical coherence:** If one core makes a change to a cache block of data at L2, that update must be returned to L3 before another L2 retrieves that block.
- **Horizontal coherence:** If two L2 caches that share the same L3 cache have copies of the same block of data, then if the block in one L2 cache is updated, the other L2 cache must be alerted that its copy is obsolete. The topic of coherence is discussed in future chapters.

4.4 Performance Modeling Of A Multilevel Memory Hierarchy

This section provides an overview of performance characteristics of memory access in a multilevel memory hierarchy. To gain insight, we begin with a look at the simplest case of two levels, and then develop models for multiple levels.

Two-Level Memory Access

In this chapter, reference is made to a cache that acts as a buffer between main memory and processor, creating a two-level internal memory. In the simplest case, rarely implemented in modern systems, there is a single level of cache to interact with main memory. This two-level architecture exploits locality to provide improved performance over a comparable one-level memory.

The main memory cache mechanism is part of the computer architecture, implemented in hardware and typically invisible to the operating system. There are two other instances of a two-level memory approach that also exploit locality and that are, at least partially, implemented in the operating system: virtual memory and the disk cache. Virtual memory is explored in [Chapter 9](#); disk cache is beyond the scope of this book but is examined in [STAL18]. In this subsection, we look at some of the performance characteristics of two-level memories that are common to all three approaches.

OPERATION OF TWO-LEVEL MEMORY

The locality property can be exploited in the formation of a two-level memory. The upper-level memory (M1) is smaller, faster, and more expensive (per bit) than the lower-level memory (M2). M1 is used as a temporary store for part of the contents of the larger M2. When a memory reference is made, an attempt is made to access the item in M1. If this succeeds, then a quick access is made. If not, then a block of memory locations is copied from M2 to M1 and the access then takes place via M1. Because of locality, once a block is brought into M1, there should be a number of accesses to locations in that block, resulting in fast overall service.

To express the average time to access an item, we must consider not only the speeds of the two levels of memory, but also the probability that a given reference can be found in M1. We have

$$\begin{aligned} T_s &= H \times T_1 + (1 - H) \times (T_1 + T_2) \\ &= T_1 + (1 - H) \times T_2 \end{aligned} \tag{4.2}$$

where

$$\begin{aligned} T_s &= \text{average (system) access time} \\ T_1 &= \text{access time of M1 (e.g., cache)} \\ T_2 &= \text{access time of M2 (e.g., main memory)} \\ H &= \text{hit ratio (fraction of time reference is found in M1)} \end{aligned}$$

[Figure 4.8](#) shows average access time as a function of hit ratio. As can be seen, for a high percentage of hits, the average total access time is much closer to that of M1 than M2.

PERFORMANCE

Let us look at some of the parameters relevant to an assessment of a two-level memory mechanism. First consider cost. We have

$$C_1 S_1 + C_2 S_2$$

$$C_s = \frac{S_1 + S_2}{S_1 S_2} \quad (4.3)$$

where

- C_s = average cost per bit for the combined two-level memory
- C_1 = average cost per bit of upper-level memory M1
- C_2 = average cost per bit of lower-level memory M2
- S_1 = size of M1
- S_2 = size of M2

We would like $C_s \approx C_2$. Given that $C_1 \gg C_2$, this requires $S_1 < S_2$. **Figure 4.11** shows the relationship.

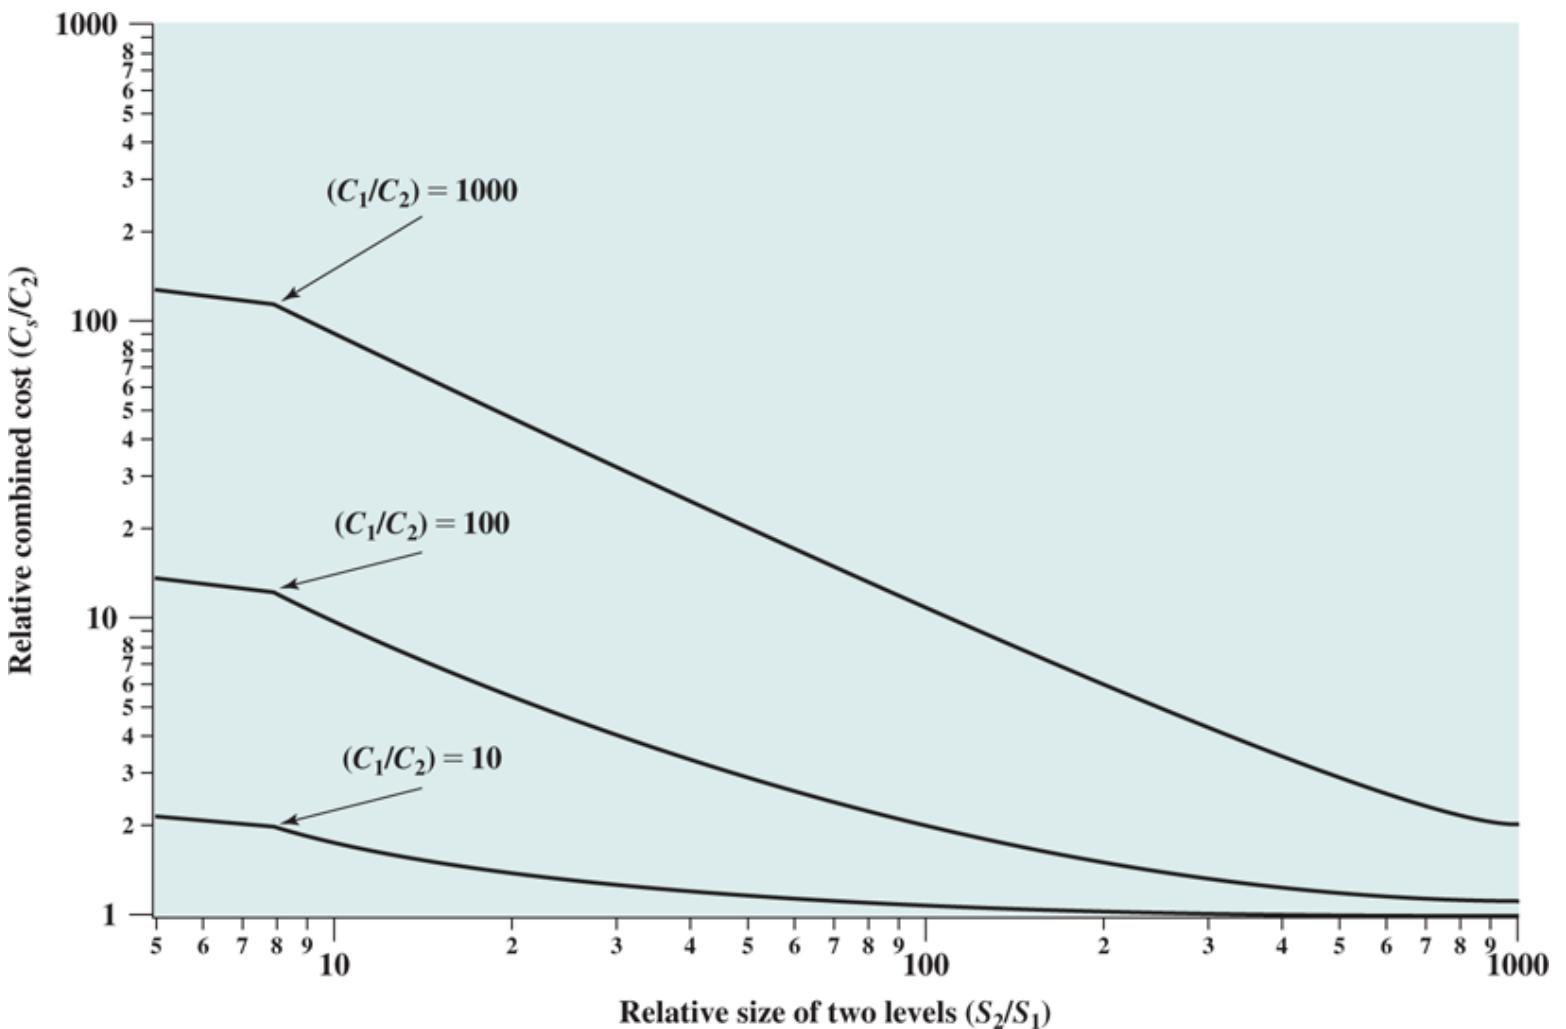

Figure 4.11 Relationship of Average Memory Cost to Relative Memory Size for a Two-Level Memory

Next, consider access time. For a two-level memory to provide a significant performance improvement, we need to have T_s approximately equal to T_1 ($T_s \approx T_1$). Given that T_1 is much less than T_2 ($T_1 \ll T_2$), a hit ratio of close to 1 is needed.

So we would like M1 to be small to hold down cost, and large to improve the hit ratio and therefore the performance. Is there a size of M1 that satisfies both requirements to a reasonable extent? We can answer this question with a series of subquestions:

- What value of hit ratio is needed so that $T_s \approx T_1$?
- What size of M1 will assure the needed hit ratio?
- Does this size satisfy the cost requirement?

To get at this, consider the quantity T_1 / T_s , which is referred to as the *access efficiency*. It is a measure of how close average access time (T_s) is to M1 access time (T_1). From [Equation \(4.2\)](#),

$$\frac{T_1}{T_s} = \frac{1}{1 + (1 - H) \frac{T_2}{T_1}} \quad (4.4)$$

Figure 4.12 plots T_1 / T_s as a function of the hit ratio H , with the quantity T_2 / T_1 as a parameter.

Typically, on-chip cache access time is about 25 to 50 times faster than main memory access time (i.e., T_2 / T_1 is 25 to 50), off-chip cache access time is about 5 to 15 times faster than main memory access time (i.e., T_2 / T_1 is 5 to 15), and main memory access time is about 1000 times faster than disk access time ($T_2 / T_1 = 1000$). Thus, a hit ratio in the range of near 0.9 would seem to be needed to satisfy the performance requirement.

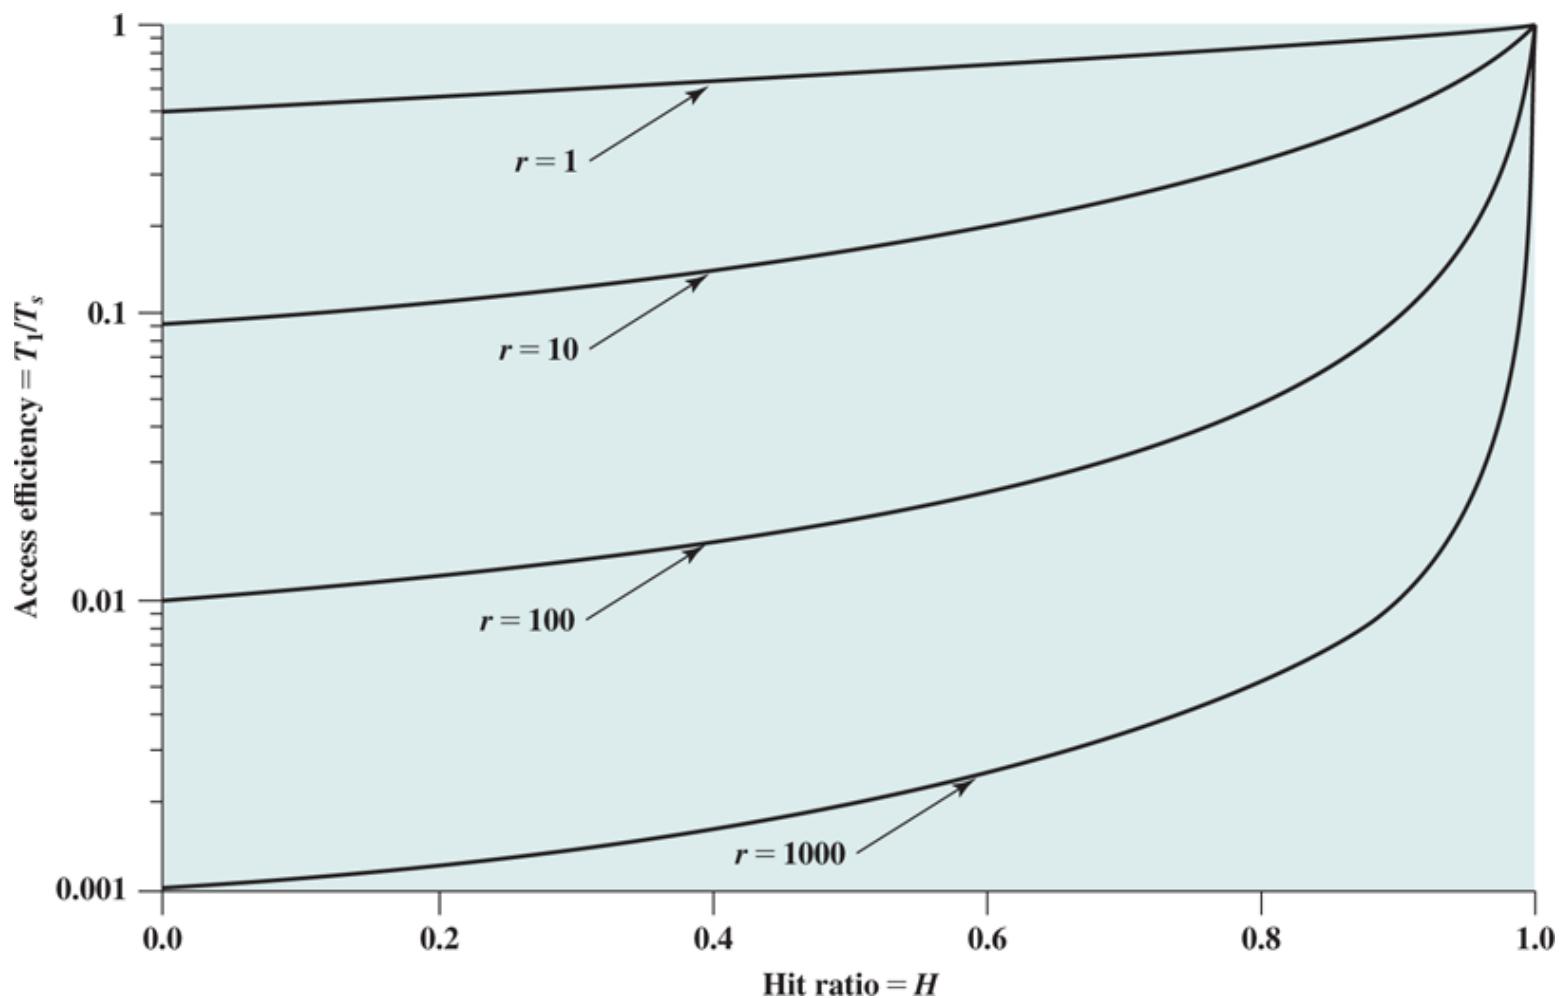

Figure 4.12 Access Efficiency as a Function of Hit Ratio ($r = T_2 / T_1$)

We can now phrase the question about relative memory size more exactly. Is a hit ratio of, say, 0.8 or better reasonable for $S_1 < < S_2$? This will depend on a number of factors, including the nature of the software being executed and the details of the design of the two-level memory. The main determinant is, of course, the degree of locality. [Figure 4.13](#) suggests the effect that locality has on the hit ratio. Clearly, if M1 is the same size as M2, then the hit ratio will be 1.0: All of the items in M2 are always

also stored in M1. Now suppose that there is no locality; that is, references are completely random. In that case, the hit ratio should be a strictly linear function of the relative memory size. For example, if M1 is half the size of M2, then at any time half of the items from M2 are also in M1 and the hit ratio will be 0.5. In practice, however, there is some degree of locality in the references. The effects of moderate and strong locality are indicated in the figure. Note that [Figure 4.13](#) is not derived from any specific data or model; the figure suggests the type of performance that is seen with various degrees of locality.

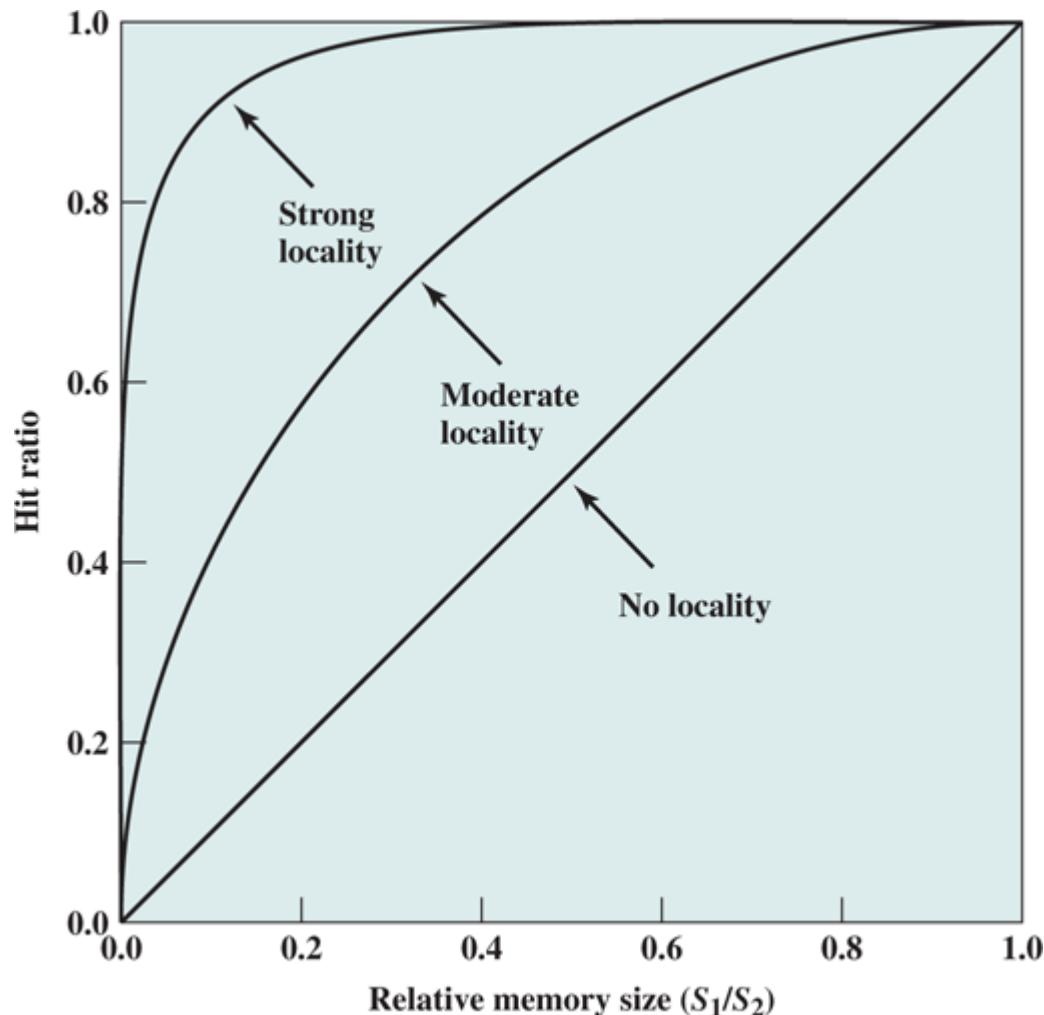

Figure 4.13 Hit Ratio as a Function of Relative Memory Size

So if there is strong locality, it is possible to achieve high values of hit ratio even with relatively small upper-level memory size. For example, numerous studies have shown that rather small cache sizes will yield a hit ratio above 0.75 *regardless of the size of main memory* (e.g., [AGAR89], [PRZY88], [STRE83], and [SMIT82]). A cache in the range of 1K to 128K words is generally adequate, whereas main memory is now typically in the gigabyte range. When we consider virtual memory and disk cache, we will cite other studies that confirm the same phenomenon, namely that a relatively small M1 yields a high value of hit ratio because of locality.

This brings us to the last question listed earlier: Does the relative size of the two memories satisfy the cost requirement? The answer is clearly yes. If we need only a relatively small upper-level memory to achieve good performance, then the average cost per bit of the two levels of memory will approach that of the cheaper lower-level memory.

Multilevel Memory Access²

I would like to thank Professor Roger Kieckhafer of Michigan Technological University for permission to use his lecture notes in developing this section.

This subsection develops a model for memory access performance in a memory hierarchy that has more than two levels. The following terminology is used:

$M_i =$	Memory level (i) where $1 \leq i \leq n$, with n levels of memory.
$S_i =$	Size, or capacity of level M_i (Bytes)
$t_i =$	Total time needed to access data in level M_i —Is the sum of all times in the path to a hit in level M_i —May be an average (t_i)
$h_i =$	Hit ratio of level M_i
$=$	Conditional probability that the data for a memory access is resident in level M_i given that it is not resident in M_{i-1}
$T_s =$	Mean time needed to access data

T_s is the performance metric that is of most interest. It measures the average time to access data, regardless of which level of the hierarchy needs to be accessed at the time of the access request. The higher the hit ratio at each level, the lower will be the value of T_s . Ideally, we would like h_1 to be very close to 1.0, in which case T_s will be very close to t_1 .

Figure 4.14 is a flowchart that provides a simplified memory access model for a memory hierarchy, which we can use to develop a formula for the average access time. It can be described as follows:

1. The processor generates a memory address request. The first step is to determine if the cache block containing that address resides in the L1 cache (memory level M_1). The probability of that is h_1 . If the desired word is present in the cache, that word is delivered to the processor. The average time required for this operation is t_1 .
2. For subsequent levels i , $2 \leq i < n$, if the addressed word is not found in M_{i-1} , then the memory management hardware checks to determine if it is in M_i , which occurs with a probability of h_i . If the desired word is present in M_i , the word is delivered from M_i to the processor, and the appropriate size block containing the word is copied to M_{i-1} . The average time for this operation is t_{i-1} .
3. In the typical memory hierarchy, M_n is a disk used in a virtual memory scheme. In this case, if the word is not found in any of the preceding levels and is found in M_n , then the word must be first moved as part of a page into main memory (M_{n-1}), from where it can be transferred to the processor. We designate the total time for this operation as t_n .

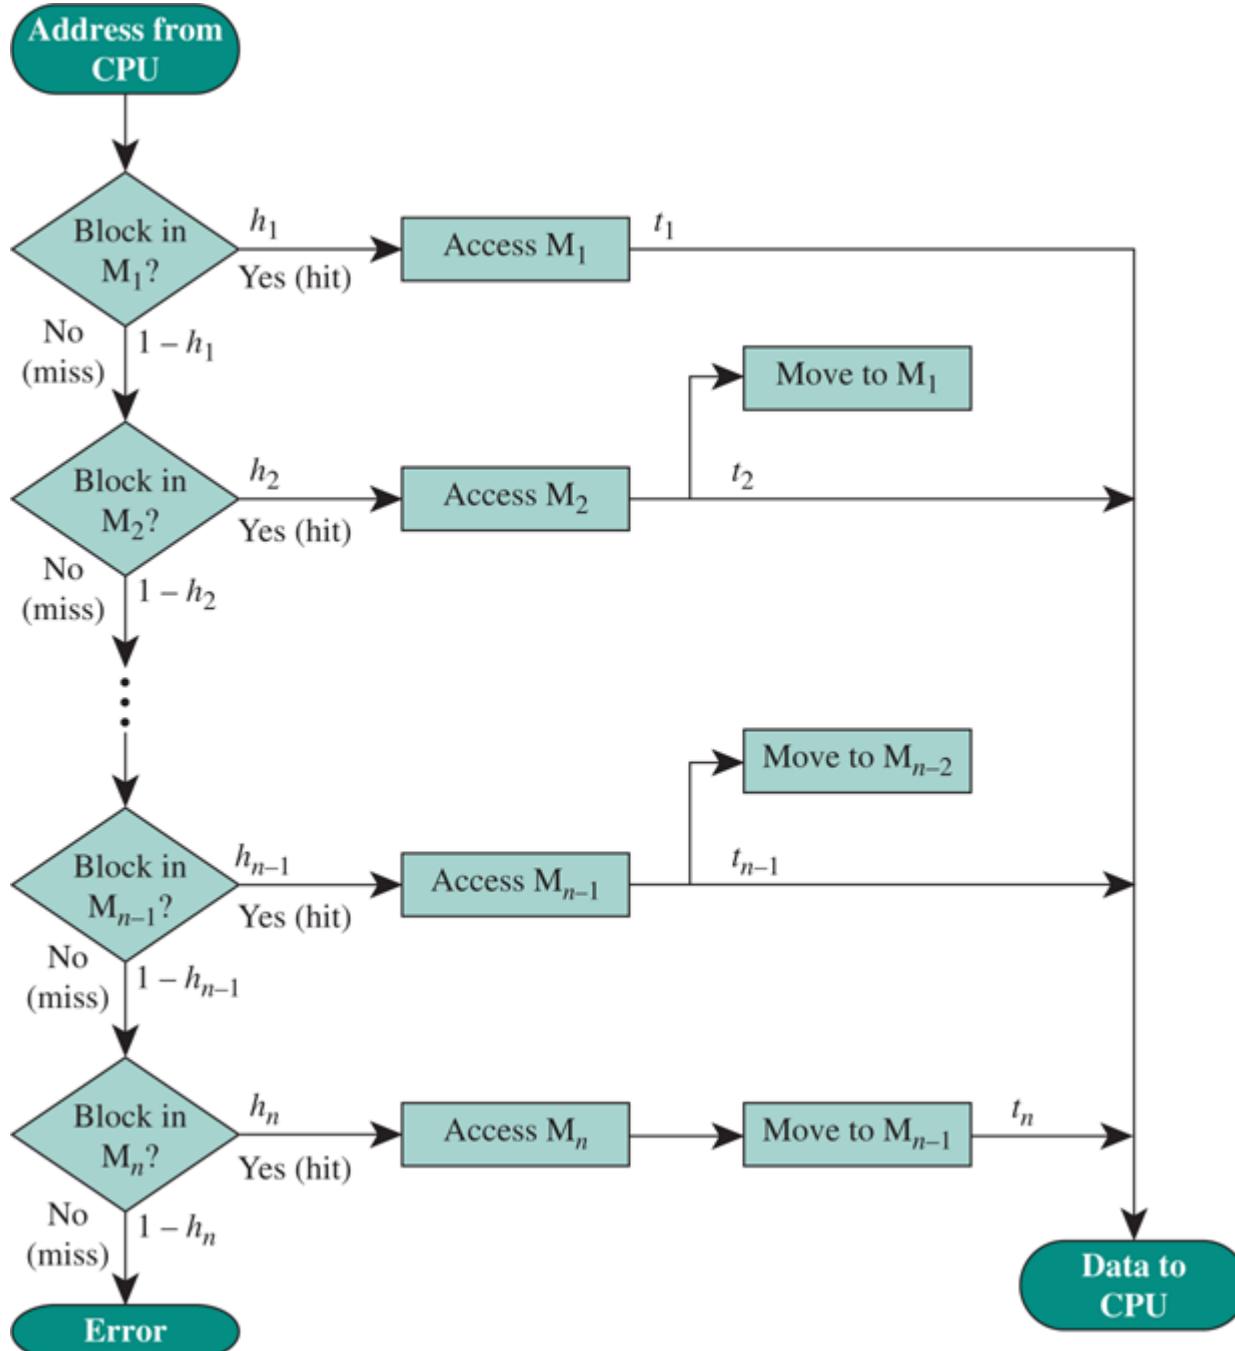

Figure 4.14 Multilevel Memory Access Performance Model

Each of the t_i consists of a number of components, including checking for the presence of the required word in level i , accessing the data if it is in level i , and transporting the data to the processor. The total value of t_i must also include the amount of time to check for a hit on all previous levels and experiencing a miss. If we designate the time expended in determining a miss at level i as t_{mis_i} , then t_i must include $t_{mis_1} + t_{mis_2} + \dots + t_{mis_{i-1}}$. In addition, **Figure 4.14** indicates that the process of accessing memory and delivering a word to the processor is performed parallel to the process of copying the appropriate block of data to the preceding level in the hierarchy. If the two operations are performed in sequence, then the extra time involved is added to t_i .

Looking at **Figure 4.14**, there are a number of different paths from start to finish. The average time T_s can be expressed as the weighted average of the time of each path:

$$T_s = \sum_{\text{all paths}} [\text{Probability of taking a path} \times \text{Duration of that a path}] \quad (4.5)$$

$$\begin{aligned}
&= \sum_{\text{all paths}} \prod (\text{All probabilities in the path}) \times \sum (\text{All times in that path}) \\
&= \sum_{i=1}^I \prod_{j=0}^{i-1} (1 - h_j) h_I \times t_I
\end{aligned}$$

where h_0 is assigned the value 0.

For example, consider a simple system consisting of one level of cache (M_1), main memory (M_2), and secondary memory (M_3). Then,

$$\begin{aligned}
T_s = & \quad \quad \quad \times t_1 \\
& + \frac{h_1}{(1 - h_1) h_2} \times t_2 \\
& + \frac{(1 - h_1)(1 - h_2)}{(1 - h_1)(1 - h_2) \times t_3}
\end{aligned}$$

Note that **Equation (4.5)** works whether the time delays for a given path are constants or variables. If the time delays are constant, then t_i is a constant equal to the sum of all the time delays (e.g. checking for presence, data access, and delivery to CPU). If one or more of the elements in the total time delay are variable, then t_i is the mean time delay calculated as the sum of the mean time delays of the component delays.

To use this model in designing a memory hierarchy, estimates are needed for the h_i and t_i . These can be developed either by simulation or by setting up a real system and varying the sizes of the various M_i .

Review Questions

- 4.1 What are the differences among sequential access, direct access, and random access?
- 4.2 What is the general relationship among access time, memory cost, and capacity?
- 4.3 How does the principle of locality relate to the use of multiple memory levels?
- 4.4 What is the distinction between spatial locality and temporal locality?
- 4.5 In general, what are the strategies for exploiting spatial locality and temporal locality?
- 4.6 How do data locality and instruction locality relate to spatial locality and temporal locality?

Problems

- 4.1 Consider these terms: instruction spatial locality, instruction temporal locality, data spatial locality, data temporal locality. Match each of these terms to one of the following definitions:

- a. Locality is quantified by computing the average distance (in terms of number of operand memory accesses) between two consecutive accesses to the same address, for every unique address in the program. The evaluation is performed in four distinct window sizes, analogous to cache block sizes.
- b. Locality metric is quantified by computing the average distance (in terms of number of instructions) between two consecutive accesses to the same static instruction, for every unique static instruction in the program that is executed at least twice.
- c. Locality for operand memory accesses is characterized by the ratio of the locality metric for window sizes mentioned in (a).
- d. Locality is characterized by the ratio of the locality metric for the window sizes mentioned in (b).

- 4.2 Consider these two programs:

```
for ( i = 1; i < n; i++) {  
    Z[i] = X[i] - Y[i]  
    Z[i] = Z[i] * Z[i]  
}
```

```
for ( i = 1; i < n; i++) {  
    Z[i] = X[i] - Y[i]  
}  
for ( i = 1; i < n; i++) {  
    Z[i] = Z[i] * Z[i]  
}
```

Program A

Program B

- The two programs perform the same function. Describe it.
- Which version performs better, and why?

4.3 Consider the following code:

```
for (i = 0; i < 20; i++)
    for (j = 0; j < 10; j++)
        a[i] = a[i] * j
```

- Give one example of the spatial locality in the code.
- Give one example of the temporal locality in the code.

4.4 Consider a memory system with the following parameters:

$T_c = 100\text{ns}$	$C_c = 10^{-4} \$ / \text{bit}$
$T_m = 1200\text{ns}$	$C_m = 10^{-5} \$ / \text{bit}$

- What is the cost of 1 MB of main memory?
- What is the cost of 1 MB of main memory using cache memory technology?
- If the effective access time is 10% greater than the cache access time, what is the hit ratio H ?

4.5

- Consider an L1 cache with an access time of 1 ns and a hit ratio of $H = 0.95$. Suppose that we can change the cache design (size of cache, cache organization) such that we increase H to 0.97, but increase access time to 1.5 ns. What conditions must be met for this change to result in improved performance?
- Explain why this result makes intuitive sense.

4.6 Consider a single-level cache with an access time of 2.5 ns, a block size of 64 bytes, and a hit ratio of $H = 0.95$. Main memory uses a block transfer capability that has a first-word (4 bytes) access time of 50 ns and an access time of 5 ns for each word thereafter.

- What is the access time when there is a cache miss? Assume that the cache waits until the line has been fetched from main memory and then re-executes for a hit.
- Suppose that increasing the block size to 128 bytes increases the H to 0.97. Does this reduce the average memory access time?

4.7 A computer has a cache, main memory, and a disk used for virtual memory. If a referenced word is in the cache, 20 ns are required to access it. If it is in main memory but not in the cache, 60 ns are needed to load it into the cache, and then the reference is started again. If the word is not in main memory, 12 ns are required to fetch the word from the disk, followed by 60 ns to copy it to the cache, and then the reference is started again. The cache hit ratio is 0.9 and the main memory hit ratio is 0.6. What is the average time in nanoseconds required to access a referenced word on this system?

4.8 On the Motorola 68020 microprocessor, a cache access takes two clock cycles. Data access from main memory over the bus to the processor takes three clock cycles in the case of no wait state insertion; the data are delivered to the processor in parallel with delivery to the cache.

- a. Calculate the effective length of a memory cycle given a hit ratio of 0.9 and a clocking rate of 16.67 MHz.
- b. Repeat the calculations assuming insertion of two wait states of one cycle each per memory cycle. What conclusion can you draw from the results?

4.9 Assume a processor having a memory cycle time of 300 ns and an instruction processing rate of 1 MIPS. On average, each instruction requires one bus memory cycle for instruction fetch and one for the operand it involves.

- a. Calculate the utilization of the bus by the processor.
- b. Suppose that the processor is equipped with an instruction cache and the associated hit ratio is 0.5. Determine the impact on bus utilization.

4.10 The performance of a single-level cache system for a read operation can be characterized by the following equation:

$$T_a = T_c + (1 - H) T_m$$

where T_a is the average access time, T_c is the cache access time, T_m is the memory access time (memory to processor register), and H is the hit ratio. For simplicity, we assume that the word in question is loaded into the cache in parallel with the load to processor register. This is the same form as [Equation \(4.2\)](#).

- a. Define T_b = time to transfer a block between cache and main memory, and W = fraction of write references. Revise the preceding equation to account for writes as well as reads, using a write-through policy.
- b. Define W_b as the probability that a block in the cache has been altered. Provide an equation for T_a for the write-back policy.

4.11 For a system with two levels of cache, define T_{c1} = first-level cache access time; T_{c2} = second-level cache access time; T_m = memory access time; H_1 = first-level cache hit ratio; H_2 = combined first/second level cache hit ratio. Provide an equation for T_a for a read operation.

4.12 Assume the following performance characteristics on a cache read miss: one clock cycle to send an address to main memory and four clock cycles to access a 32-bit word from main memory and transfer it to the processor and cache.

- a. If the cache block size is one word, what is the miss penalty (i.e., additional time required for a read in the event of a read miss)?
- b. What is the miss penalty if the cache block size is four words and a multiple, nonburst transfer is executed?
- c. What is the miss penalty if the cache block size is four words and a transfer is executed, with one clock cycle per word transfer?

4.13 For the cache design of the preceding problem, suppose that increasing the line size from one word to four words results in a decrease of the read miss rate from 3.2% to 1.1%. For both the nonburst transfer and the burst transfer case, what is the average miss penalty, averaged over all reads, for the two different line sizes?

4.14 Consider a two-level system with L1 instruction and data caches. For a given application, assume the following: instruction cache miss ratio = 0.02, data cache miss ratio = 0.04, and the fraction of instructions that are load / store = 0.36. The ideal value of CPI (cycles per instruction) without cache misses is 2.0. The penalty for a cache miss is 40 cycles. Calculate the CPI, taking misses into account.

4.15 Define H_i = probability that the data for a memory access is resident in level M_i .

- Equation 4.5** uses the conditional probabilities h_i . Explain why in this form the equation is correct with the conditional probabilities rather than the unconditional probabilities H_i . That is, show that the following expression does not equal T_s .

$$\sum_{i=1}^I \prod_{j=1}^i (1 - h_j) h_I \times t_I$$

- Rewrite **Equation 4.5** using H_i instead of h_i .

4.16 Define the access frequency f_i as the probability of successfully accessing (hit) M_i when there are misses at the preceding $i - 1$ levels.

- Derive an expression for f_i .
- Rewrite **Equation 4.5** using f_i instead of h_i .

Learning Objectives

After studying this chapter, you should be able to:

- Discuss the key elements of cache design.
- Distinguish among direct mapping, associative mapping, and set-associative mapping.
- Understand the principles of content-addressable memory.
- Explain the reasons for using multiple levels of cache.
- Understand the performance implications of cache design decisions.

With the exception of smaller embedded systems, all modern computer systems employ one or more layers of cache memory. Cache memory is vital to achieving high performance. This chapter begins with an overview of the basic principles of cache memory, then looks in detail at the key elements of cache design. This is followed by a discussion of the cache structures used in the Intel x86 family and the IBM z13 mainframe system. Finally, the chapter introduces some straightforward performance models that provide insight into cache design.

5.1 Cache Memory Principles

Cache memory is designed to combine the memory access time of expensive, high-speed memory combined with the large memory size of less expensive, lower-speed memory. The concept is illustrated in **Figure 5.1a**. There is a relatively large and slow main memory together with a smaller, faster cache memory. The cache contains a copy of portions of the main memory. When the processor attempts to read a word of memory, a check is made to determine if the word is in the cache. If so, the word is delivered to the processor. If not, a block of main memory, consisting of some fixed number of words, is read into the cache and then the word is delivered to the processor. Because of the phenomenon of locality of reference, when a block of data is fetched into the cache to satisfy a single memory reference, it is likely that there will be future references to that same memory location or to other words in the block.

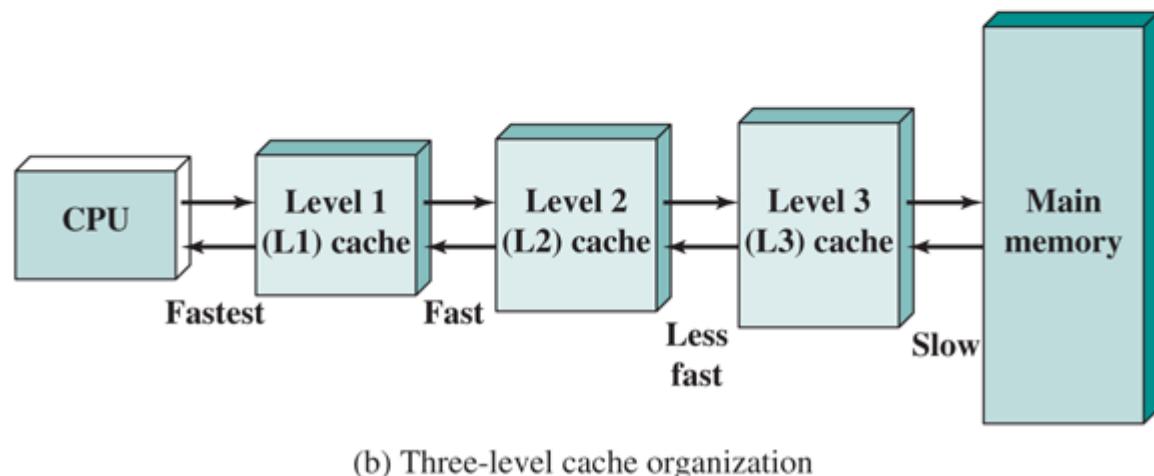

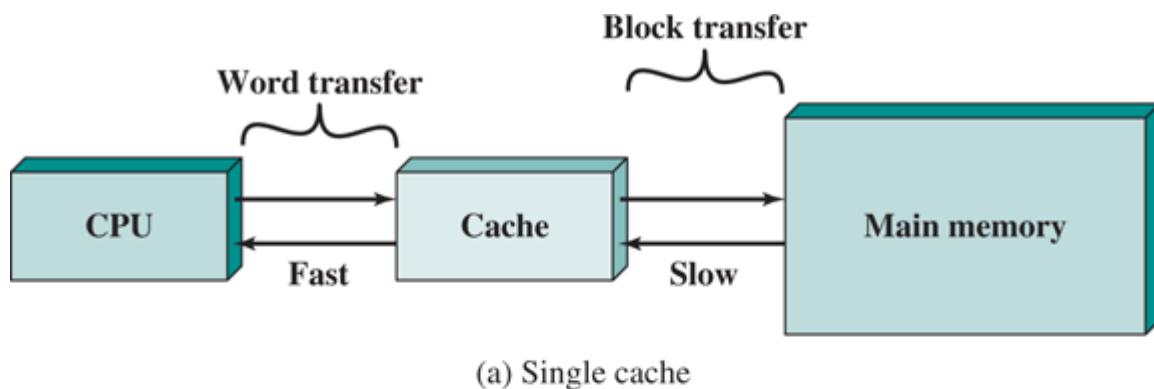

Figure 5.1 Cache and Main Memory

Figure 5.1b depicts the use of multiple levels of cache. The **L2 cache** is slower and typically larger than the **L1 cache**, and the **L3 cache** is slower and typically larger than the L2 cache.

Figure 5.2 depicts the structure of a cache/main-memory system. Several terms are introduced:

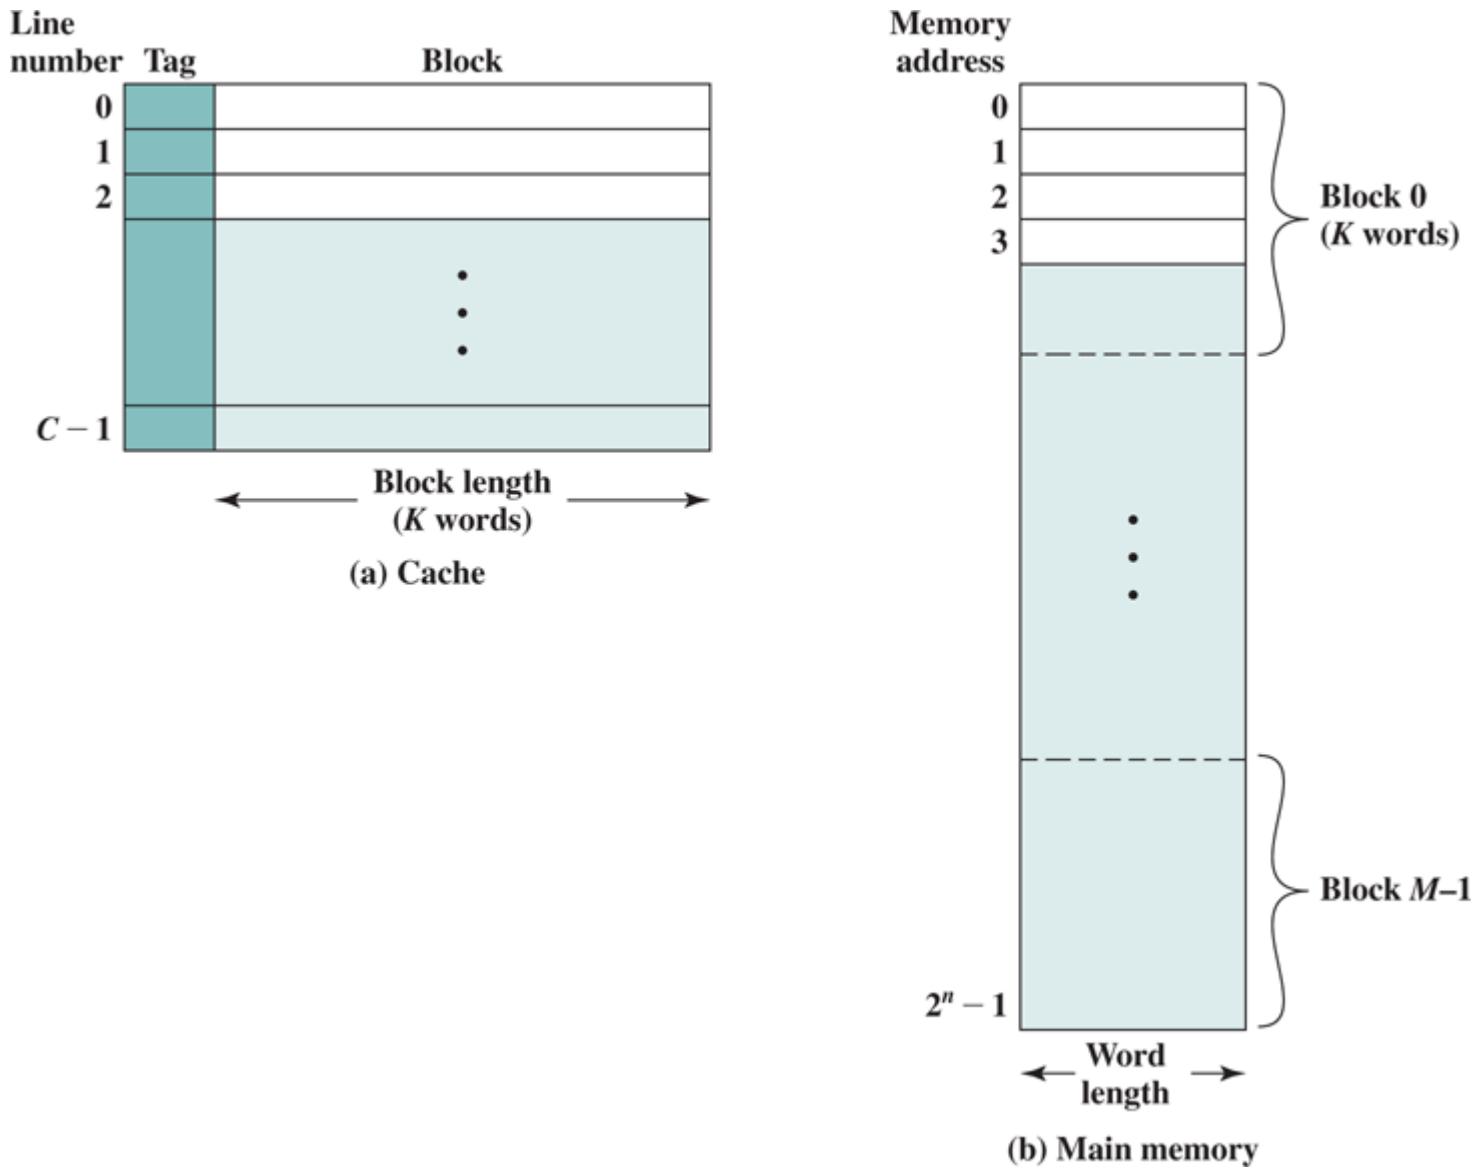

Figure 5.2 Cache/Main Memory Structure

- **Block:** The minimum unit of transfer between cache and main memory. In most of the literature, the term block refers both to the unit of data transferred and to the physical location in main memory or cache.
- **Frame:** To distinguish between the data transferred and the chunk of physical memory, the term frame, or *block frame*, is sometimes used with reference to caches. Some texts and some literature use the term with reference to the cache and some with reference to main memory. Its use is not necessary for purposes of this text.
- **Line:** A portion of cache memory capable of holding one block, so-called because it is usually drawn as a horizontal object (i.e., all bytes of the line are typically drawn in one row). A line also includes control information.
- **Tag:** A portion of a cache line that is used for addressing purposes, as explained subsequently. A cache line may also include other control bits, as will be shown.

Main memory consists of up to 2^n addressable words, with each word having a unique n -bit address. For mapping purposes, this memory is considered to consist of a number of fixed-length blocks of K words each. That is, there are $M = 2^n / K$ blocks in main memory. The cache consists of m lines. Each line contains K words, plus a tag. Each line also includes control bits (not shown), such as a bit to indicate whether the line has been modified since being loaded into the cache. The length of a line, not including tag and control bits, is the **line size**. That is, the term line size refers to the number of data bytes, or block size, contained in a line. They may be as small as 32 bits, with each “word” being

a single byte; in this case the line size is 4 bytes. The number of lines is considerably less than the number of main memory blocks ($m \ll M$). At any time, some subset of the blocks of memory resides in lines in the cache. If a word in a block of memory is read, that block is transferred to one of the lines of the cache. Because there are more blocks than lines, an individual line cannot be uniquely and permanently dedicated to a particular block. Thus, each line includes a tag that identifies which particular block is currently being stored. The tag is usually a portion of the main memory address, as described later in this section.

Figure 5.3 illustrates the read operation. The processor generates the read address (RA) of a word to be read. If the word is contained in the cache (cache hit), it is delivered to the processor.

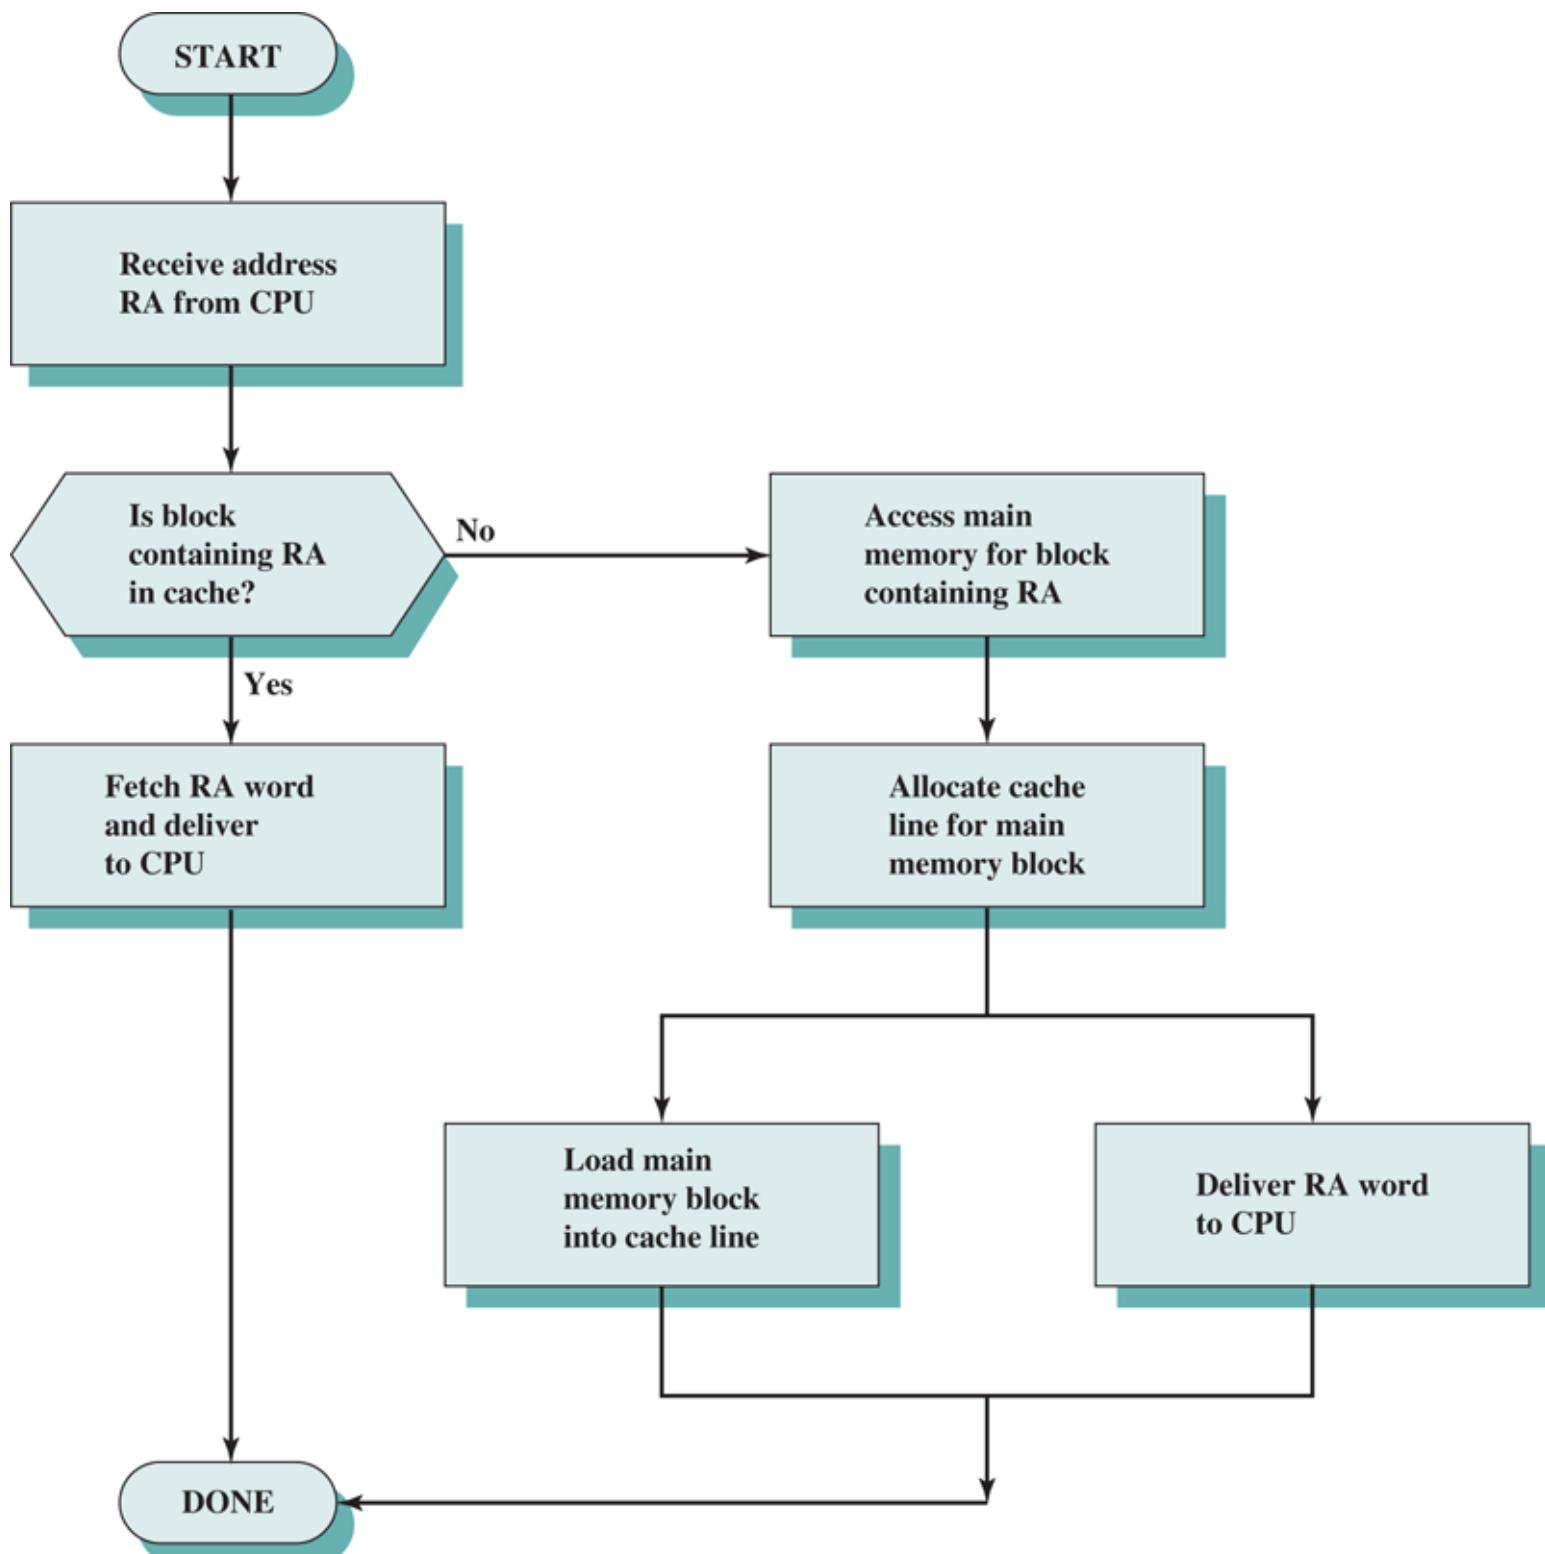

Figure 5.3 Cache Read Operation

If a cache miss occurs, two things must be accomplished: the block containing the word must be loaded in to the cache, and the word must be delivered to the processor. When a block is brought into a cache in the event of a miss, the block is generally not transferred in a single event. Typically, the transfer size between cache and main memory is less than the line size, with 128 bytes being a typical line size and a cache-main memory transfer size of 64 bits (2 bytes). To improve performance, the **critical word first** technique is commonly used. When there is a cache miss, the hardware requests the missed word first from memory and sends it to the processor as soon as it arrives. This enables the processor to continue execution while filling the rest of the words in the block. [Figure 5.3](#) shows these last two operations occurring in parallel and reflects the organization shown in [Figure 5.4](#), which is typical of contemporary cache organizations. In this organization, the cache connects to the processor via data, control, and address lines. The data and address lines also attach to data and address buffers, which attach to a system bus from which main memory is reached. When a cache hit occurs, the data and address buffers are disabled and communication is only between processor and cache, with no system bus traffic. When a cache miss occurs, the desired address is loaded onto the system bus and the data are returned through the data buffer to both the cache and the processor.

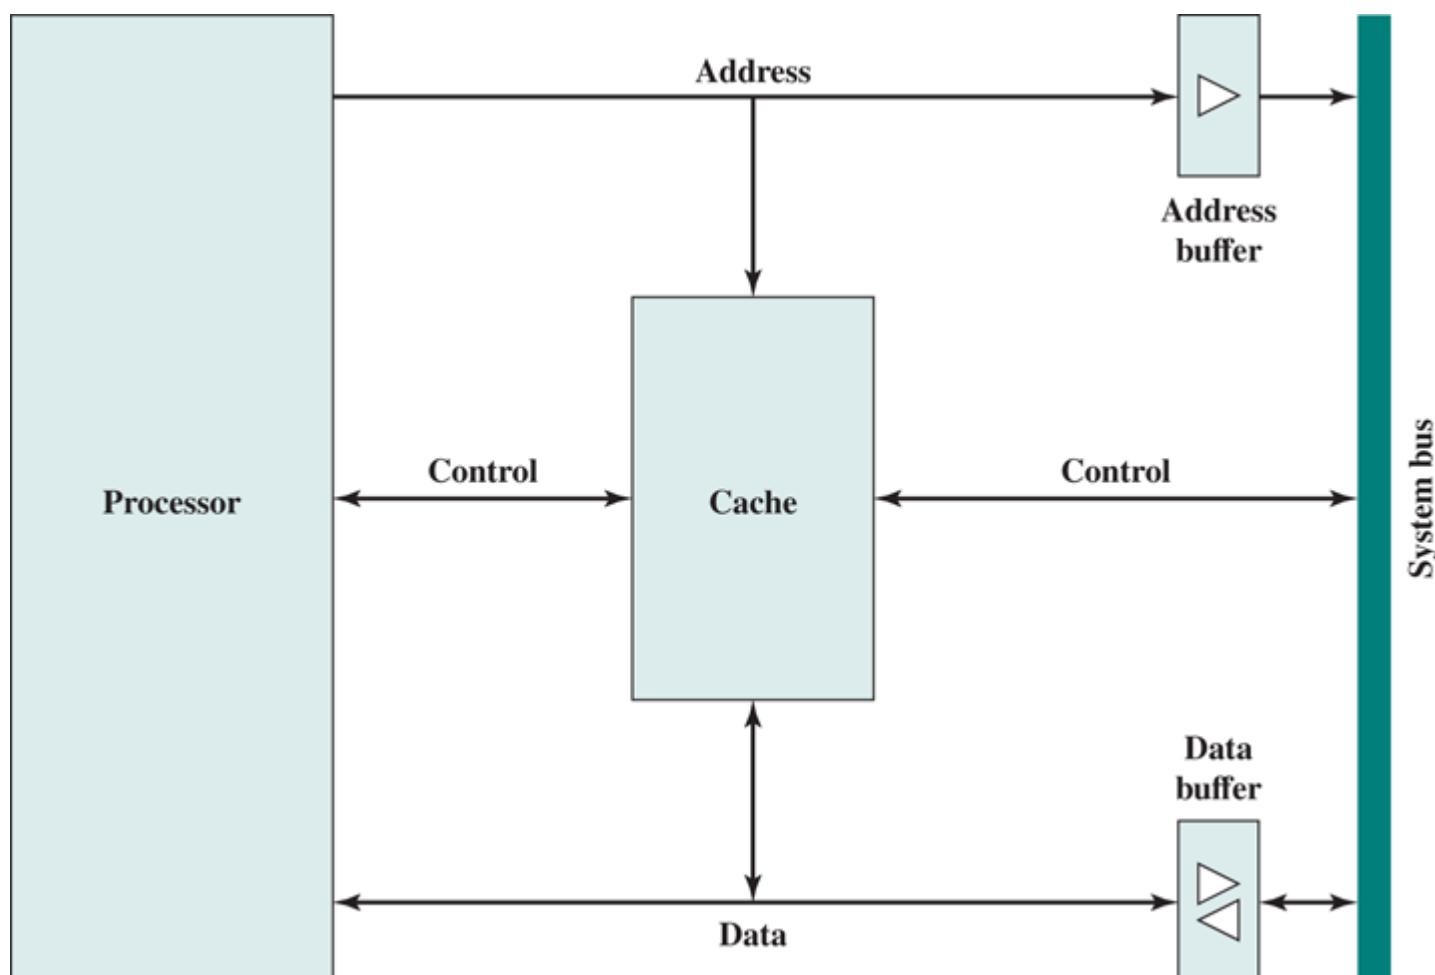

Figure 5.4 Typical Cache Organization

5.2 Elements of Cache Design

This section provides an overview of cache design parameters and reports some typical results. We occasionally refer to the use of caches in **high-performance computing (HPC)**. HPC deals with supercomputers and their software, especially for scientific applications that involve large amounts of data, vector and matrix computation, and the use of parallel algorithms. Cache design for HPC is quite different than for other hardware platforms and applications. Indeed, many researchers have found that HPC applications perform poorly on computer architectures that employ caches [BAIL93]. Other researchers have since shown that a cache hierarchy can be useful in improving performance if the application software is tuned to exploit the cache [WANG99, PRES01].⁴

⁴ For a general discussion of HPC, see [DOWD98].

Although there are a large number of cache implementations, there are a few basic design elements that serve to classify and differentiate cache architectures. **Table 5.1** lists key elements.

Table 5.1 Elements of Cache Design

Cache Addresses	Write Policy
Logical	Write through
Physical	Write back
Cache Size	Line Size
Mapping Function	Number of Caches
Direct	Single or two level
Associative	Unified or split
Set associative	
Replacement Algorithm	
Least recently used (LRU)	
First in first out (FIFO)	
Least frequently used (LFU)	
Random	

Cache Addresses

Almost all nonembedded processors, and many embedded processors, support virtual memory, a concept discussed in [Chapter 9](#). In essence, virtual memory is a facility that allows programs to address memory from a logical point of view, without regard to the amount of main memory physically available. When virtual memory is used, the address fields of machine instructions contain virtual addresses. For reads to and writes from main memory, a hardware memory management unit (MMU) translates each virtual address into a physical address in main memory.

When virtual addresses are used, the system designer may choose to place the cache between the processor and the MMU or between the MMU and main memory ([Figure 5.5](#)). A **logical cache**, also known as a **virtual cache**, stores data using **virtual addresses**. The processor accesses the cache directly, without going through the MMU. A **physical cache** stores data using main memory **physical addresses**.

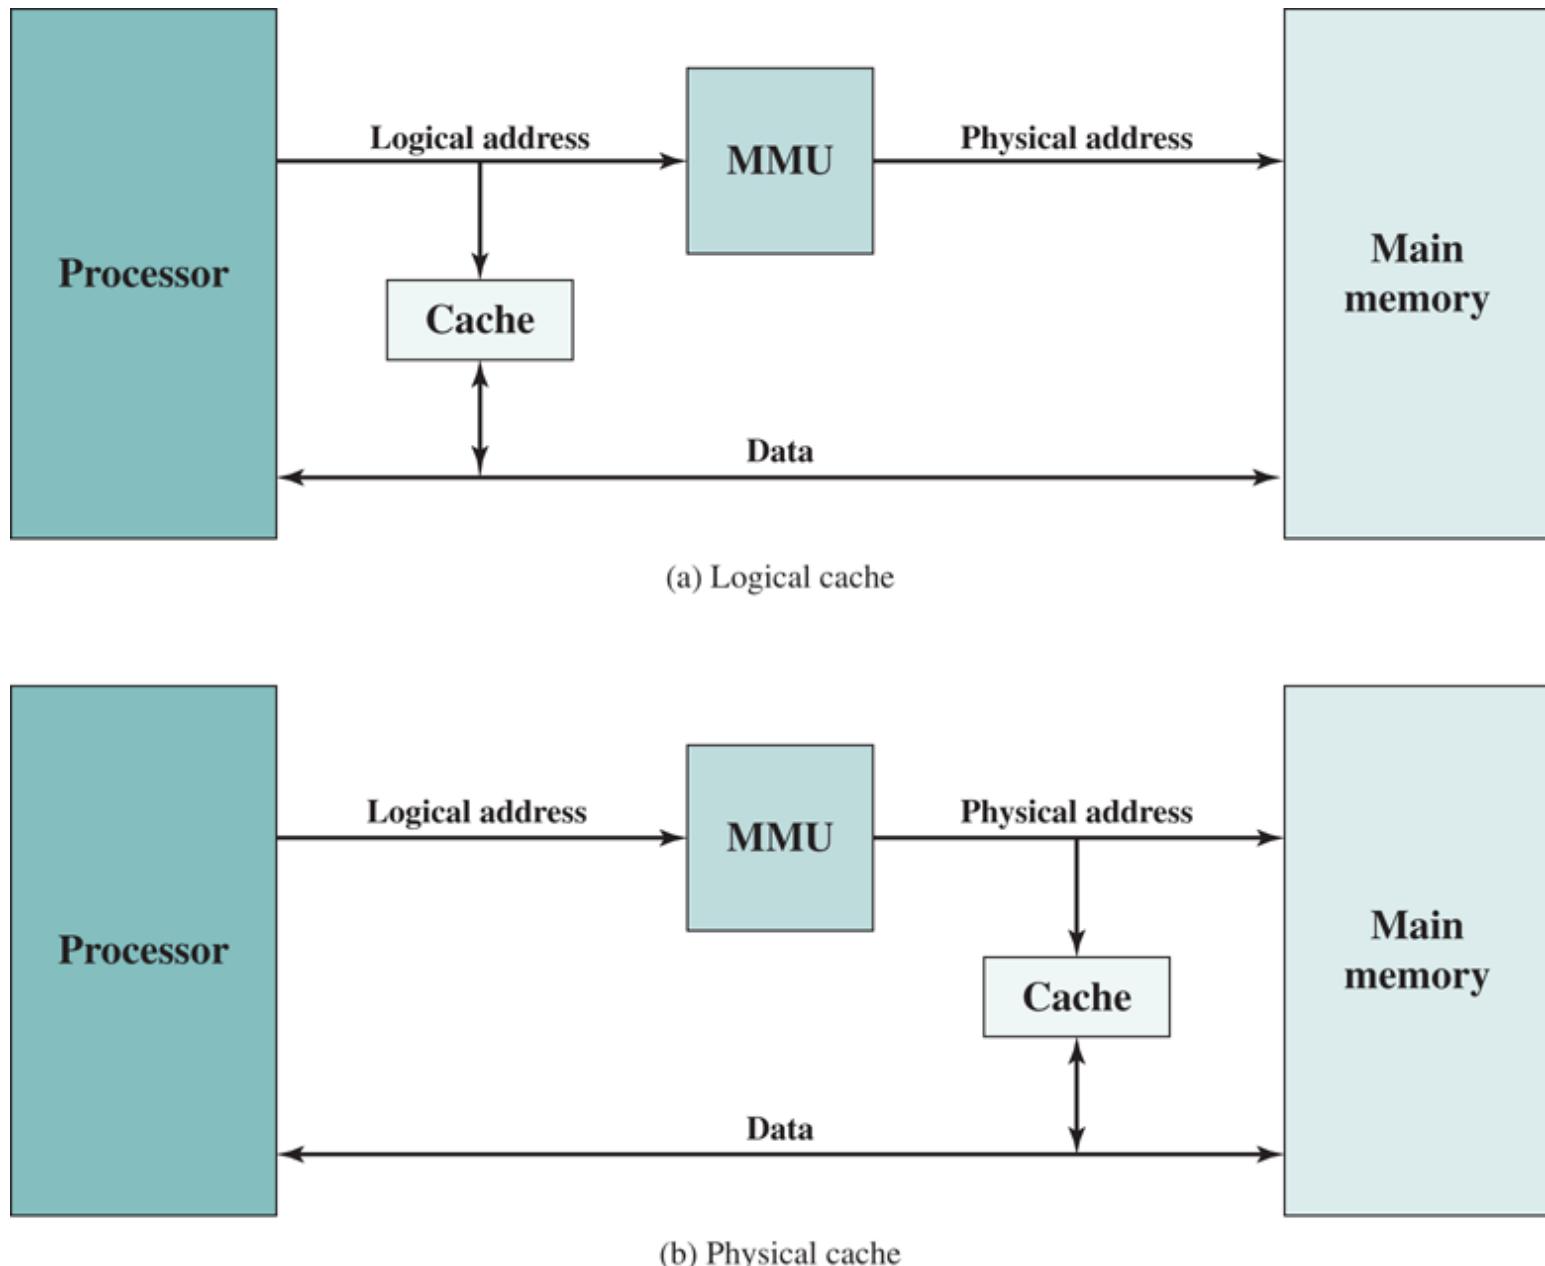

Figure 5.5 Logical and Physical Caches

One obvious advantage of the logical cache is that cache access speed is faster than for a physical cache, because the cache can respond before the MMU performs an address translation. The disadvantage has to do with the fact that most virtual memory systems supply each application with the same virtual memory address space. That is, each application sees a virtual memory that starts at

address 0. Thus, the same virtual address in two different applications refers to two different physical addresses. The cache memory must therefore be completely flushed with each application context switch, or extra bits must be added to each line of the cache to identify which virtual address space this address refers to.

The subject of logical versus physical cache is a complex one, and beyond the scope of this text. For a more in-depth discussion, see [CEKL97] and [JACO08].

Cache Size

The second item in **Table 5.1**, cache size, has already been discussed. We would like the size of the cache to be small enough so that the overall average cost per bit is close to that of main memory alone and large enough so that the overall average access time is close to that of the cache alone. There are several other motivations for minimizing cache size. The larger the cache, the larger the number of gates involved in addressing the cache. The result is that large caches tend to be slightly slower than small ones—even when built with the same integrated circuit technology and put in the same place on a chip and circuit board. The available chip and board area also limits cache size. Because the performance of the cache is very sensitive to the nature of the workload, it is impossible to arrive at a single “optimum” cache size. **Table 5.2** lists the cache sizes of some current and past processors.

Table 5.2 Cache Sizes of Some Processors

Processor	Type	Year of Introduction	L1 Cache ^a	L2 cache	L3 Cache
IBM 360/85	Mainframe	1968	16 to 32 kB	—	—
PDP-11/70	Minicomputer	1975	1 kB	—	—

^a Two values separated by a slash refer to instruction and data caches.					

Logical Cache Organization

Because there are fewer cache lines than main memory blocks, an algorithm is needed for mapping main memory blocks into cache lines. Further, a means is needed for determining which main memory block currently occupies a **cache line**. The choice of the mapping function dictates how the cache is logically organized. Three techniques can be used: direct, associative, and set-associative. We examine each of these in turn. In each case, we look at the general structure and then a specific example. **Table 5.3** provides a summary of key characteristics of the three approaches.

Table 5.3 Cache Access Methods

Method	Organization	Mapping of Main Memory Blocks to Cache	Access using Main Memory Address
Direct Mapped	Sequence of m lines	Each block of main memory maps to	<i>Line</i> portion of address used to access cache line; <i>Tag</i> portion used to check

		one unique line of cache.	for hit on that line.
Fully Associative	Sequence of m lines	Each block of main memory can map to any line of cache.	<i>Tag</i> portion of address used to check every line for hit on that line.
Set Associative	Sequence of m lines organized as v sets of k lines each ($m = v \times k$)	Each block of main memory maps to one unique cache set.	<i>Line</i> portion of address used to access cache set; <i>Tag</i> portion used to check every line in that set for hit on that line.

Example 5.1

For all three cases, the example includes the following elements:

- The cache can hold 64 kB.
- Data are transferred between main memory and the cache in blocks of 4 bytes each. This means that the cache is organized as $16K = 2^{14}$ lines of 4 bytes each.
- The main memory consists of 16 MB, with each byte directly addressable by a 24-bit address ($2^{24} = 16M$). Thus, for mapping purposes, we can consider main memory to consist of 4M blocks of 4 bytes each.

Direct Mapping

The simplest technique, known as direct mapping, maps each block of main memory into only one possible cache line. The mapping is expressed as

$$i = j \text{ modulo } m$$

where

- i = cache line number
- j = main memory block number
- m = number of lines in the cache

Figure 5.6a shows the mapping for the first m blocks of main memory. Each block of main memory maps into one unique line of the cache. The next m blocks of main memory map into the cache in the same fashion; that is, block B_m of main memory maps into line L_0 of cache, block B_{m+1} maps into line L_1 , and so on.

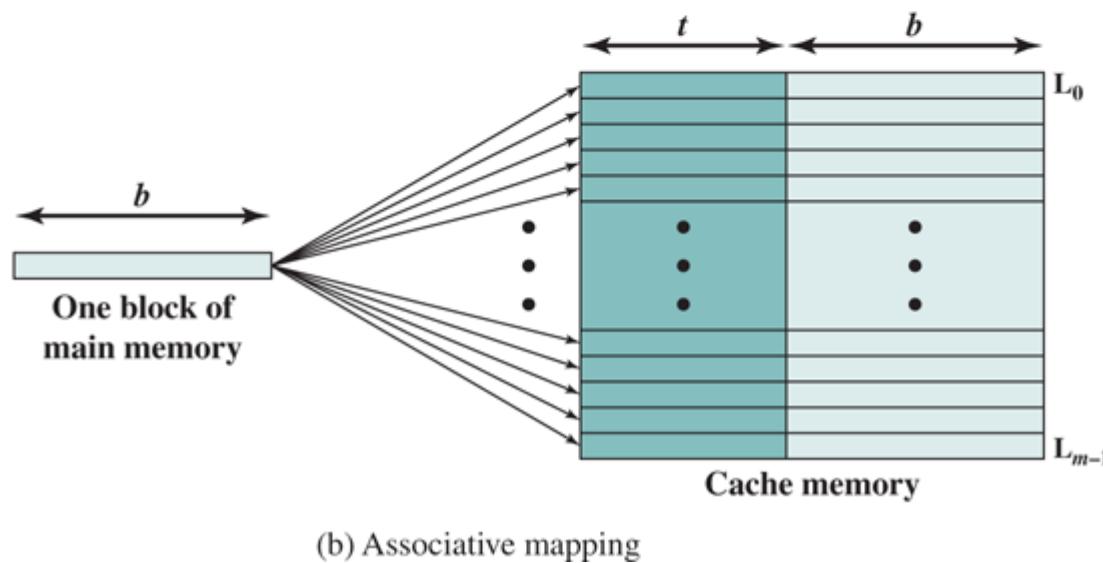

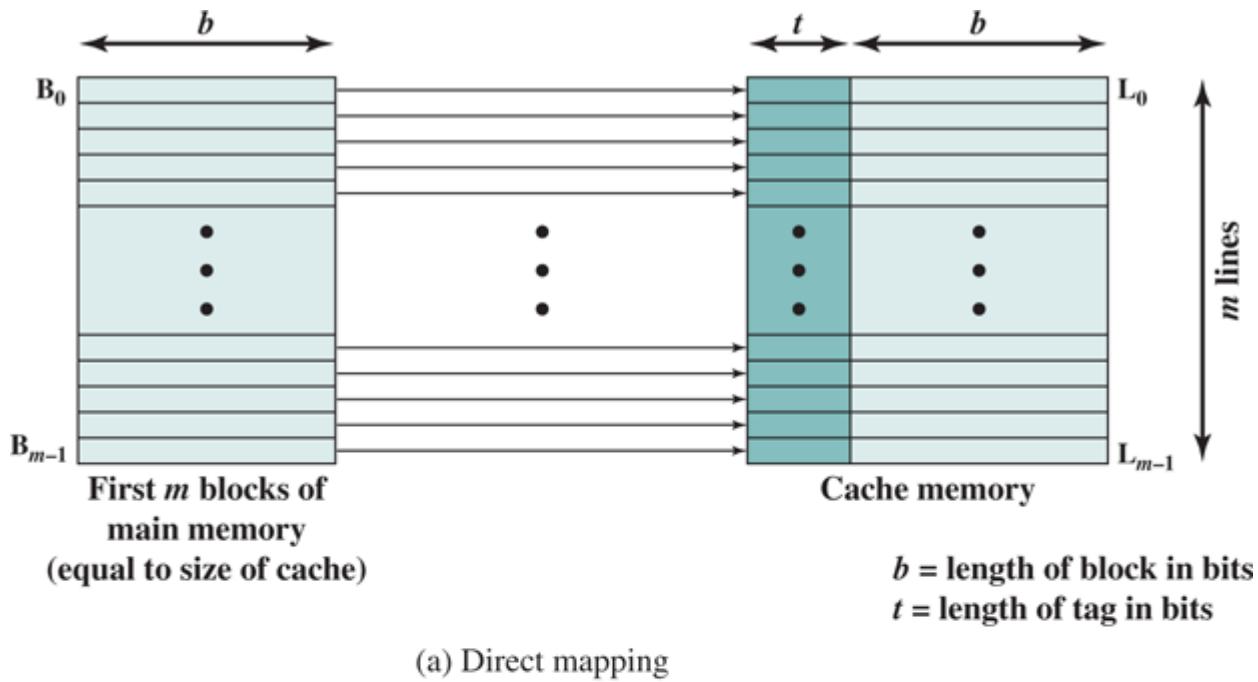

Figure 5.6 Mapping from Main Memory to Cache: Direct and Associative

The mapping function is easily implemented using the main memory address. [Figure 5.7](#) illustrates the general mechanism. For purposes of cache access, each main memory address can be viewed as consisting of three fields. The least significant w bits identify a unique word or byte within a block of main memory; in most contemporary machines, the address is at the byte level. The remaining s bits specify one of the 2^s blocks of main memory. The cache logic interprets these s bits as a tag of $s - r$ bits (most significant portion) and a line field of r bits. This latter field identifies one of the $m = 2^r$ lines of the cache. To summarize,

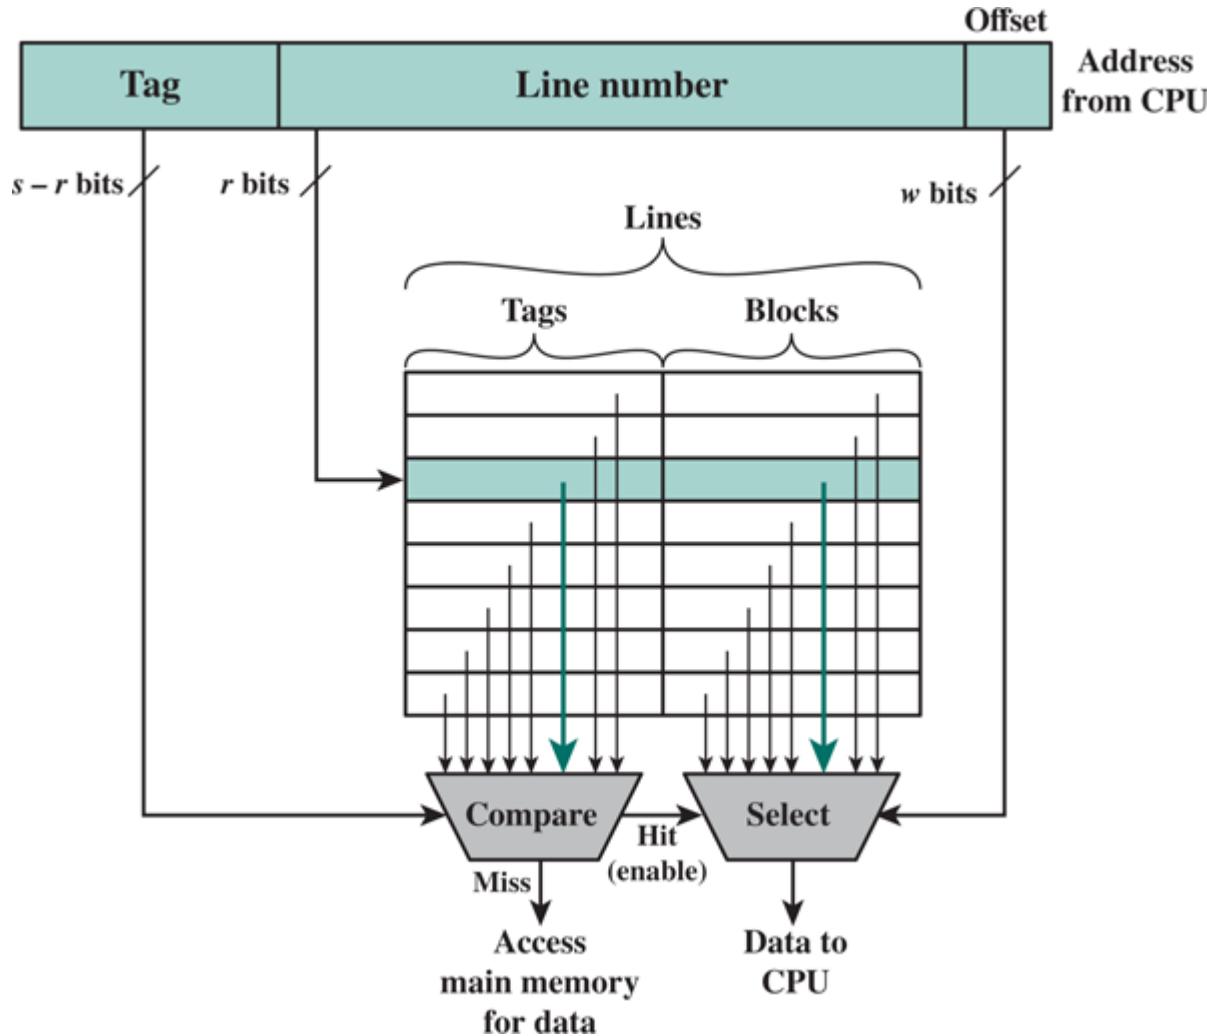

Figure 5.7 Direct-Mapping Cache Organization

- Address length = $(s + w)$ bits
- Number of addressable units = 2^{s+w} words or bytes
- Block size = line size = 2^w words or bytes
- Number of blocks in main memory = $\frac{2^{s+w}}{2^w} = 2^s$
- Number of lines in cache = $m = 2^r$
- Size of cache = 2^{r+w} words or bytes
- Size of tag = $(s - r)$ bits

The effect of this mapping is that blocks of main memory are assigned to lines of the cache as follows:

Cache line	Main memory blocks assigned
0	$0, m, 2m, \dots, 2^s - m$
1	$1, m + 1, 2m + 1, \dots, 2^s - m + 1$
:	:
$((m - 1))$	$m - 1, 2m - 1, 3m - 1, \dots, 2^s - 1$

Thus, the use of a portion of the address as a line number provides a unique mapping of each block of main memory into the cache. When a block is actually read into its assigned line, it is necessary to tag the data to distinguish it from other blocks that can fit into that line. The most significant $s - r$ bits serve this purpose.

Figure 5.7 indicates the logical structure of the cache hardware access mechanism. When the cache hardware is presented with an address from the processor, the Line Number portion of the address is used to index into the cache. A compare function compares the tag of that line with the Tag field of the address. If there is a match (hit), an enable signal is sent to a select function, which uses the Offset field of the address and the Line Number field of the address to read the desired word or byte from the cache. If there is no match (miss) then the select function is not enabled and data is accessed from main memory, or the next level of cache. **Figure 5.7** illustrates the case in which the line number refers to the third line in the cache and there is a match, as indicated by the heavier arrowed lines.

Example 5.1a

Figure 5.8 shows our example system using direct mapping.⁵ In the example, $m = 16K = 2^{14}$ and $i = j \text{ modulo } 2^{14}$. The mapping becomes

⁵ In this and subsequent figures, memory values are represented in hexadecimal notation. See **Chapter 9** for a basic refresher on number systems (decimal, binary, hexadecimal).

Cache Line	Starting Memory Address of Block
0	000000, 010000, ..., FF0000
1	000004, 010004, ..., FF0004
:	:
$2^{14} - 1$	00FFFC, 01FFFC, ..., FFFFFC

Note that no two blocks that map into the same line number have the same tag number. Thus, blocks with starting addresses 000000, 010000, ..., FF0000 have tag numbers 00, 01, ..., FF, respectively.

Referring back to **Figure 5.3**, a read operation works as follows. The cache system is presented with a 24-bit address. The 14-bit line number is used as an index into the cache to access a particular line. If the 8-bit tag number matches the tag number currently stored in that line, then the 2-bit word number is used to select one of the 4 bytes in that line. Otherwise, the 22-bit tag-plus-line field is used to fetch a block from main memory. The actual address that is used for the fetch is the 22-bit tag-plus-line concatenated with two 0 bits, so that 4 bytes are fetched starting on a block boundary.

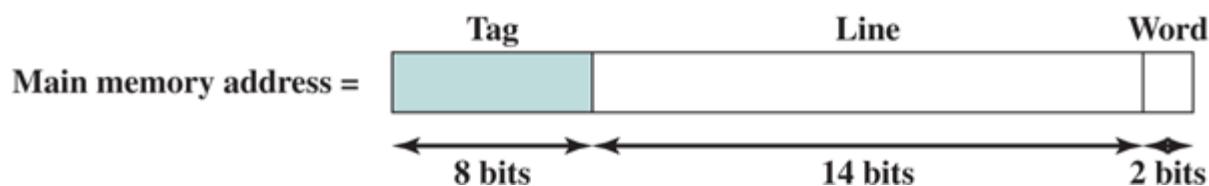

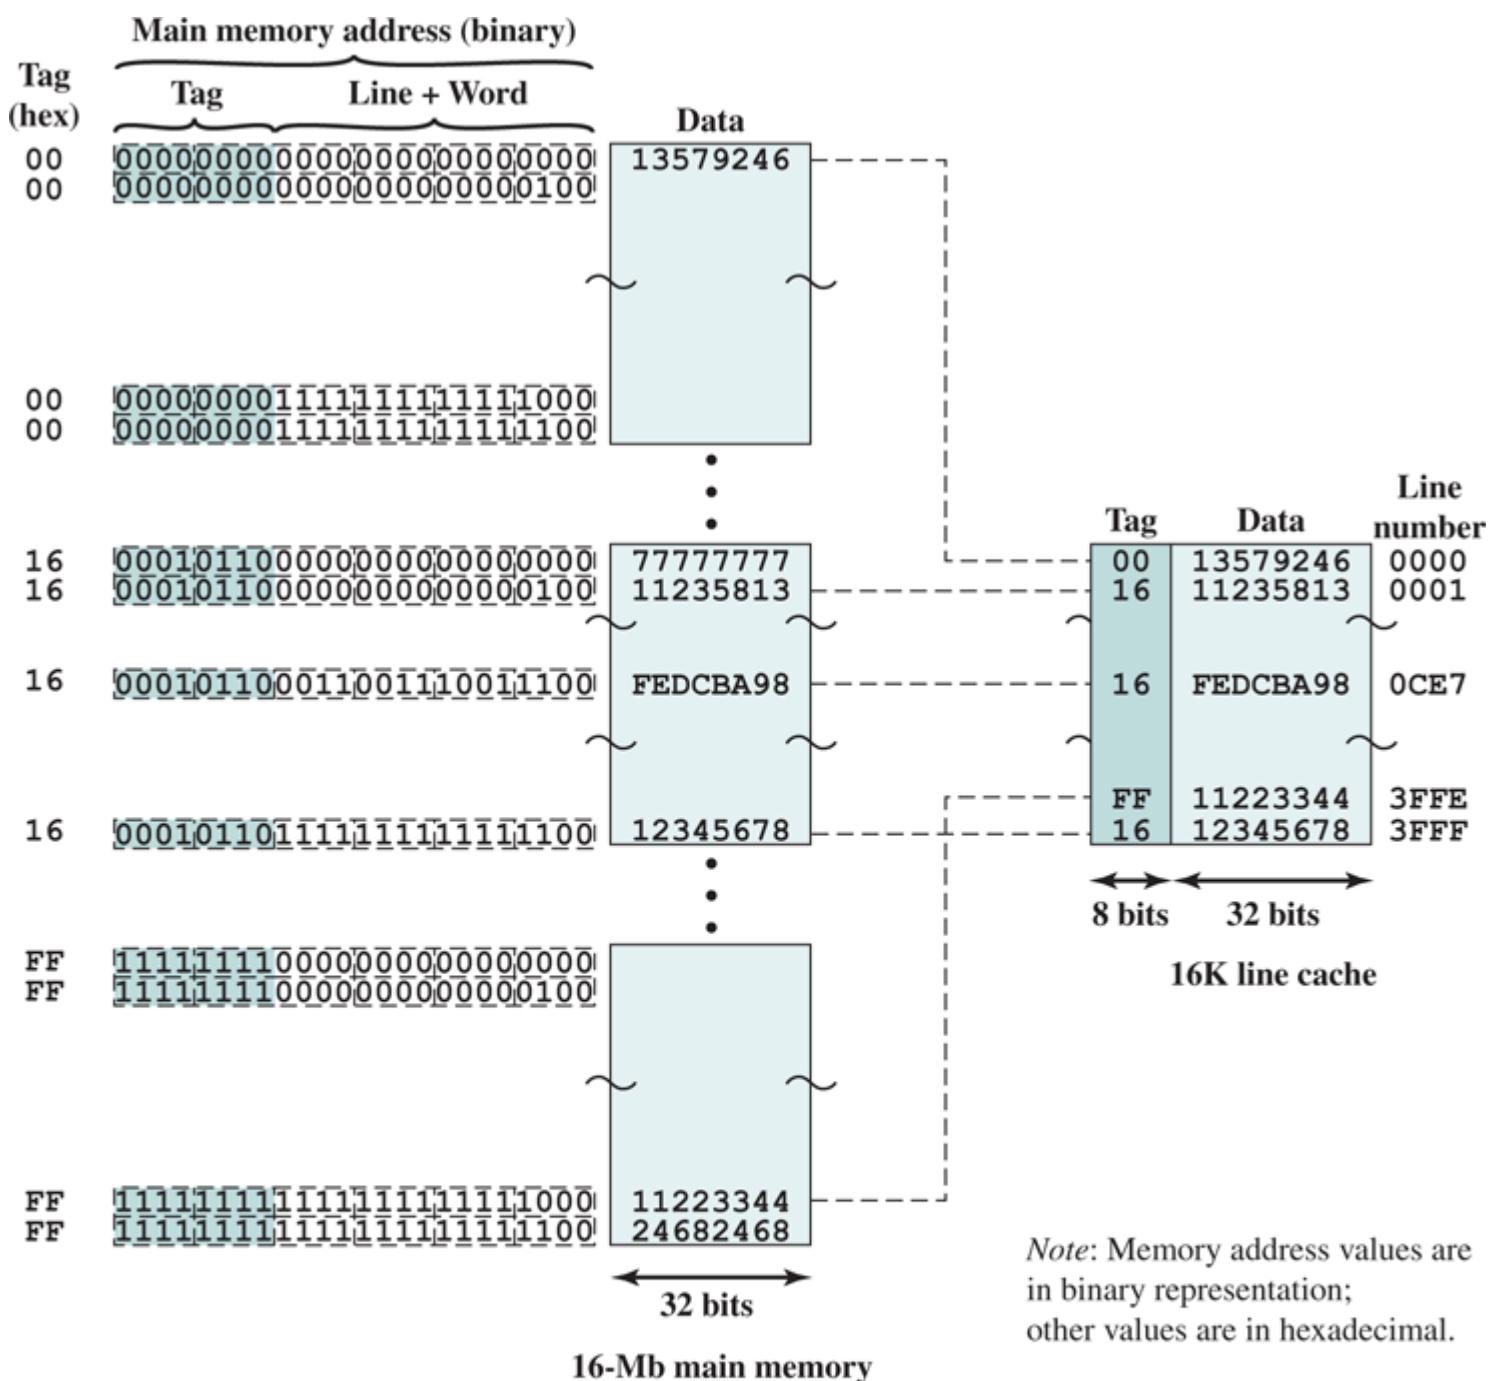

Figure 5.8 Direct Mapping Example

The direct mapping technique is simple and inexpensive to implement. Its main disadvantage is that there is a fixed cache location for any given block. Thus, if a program happens to reference words repeatedly from two different blocks that map into the same line, then the blocks will be continually swapped in the cache, and the hit ratio will be low (a phenomenon known as *thrashing*).

Aleksandr Lukin/123RF

Selective Victim Cache Simulator

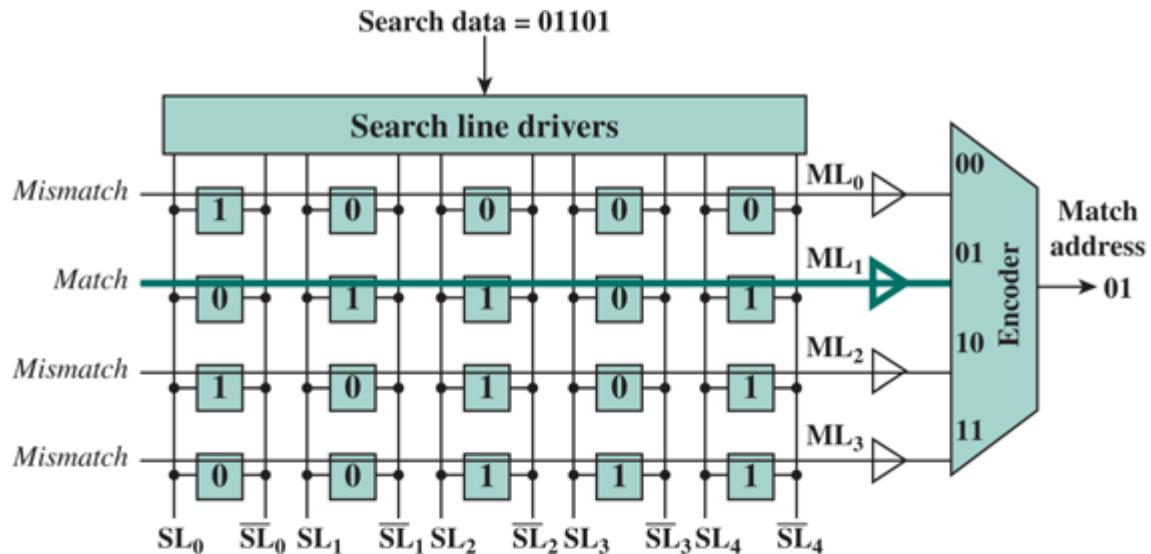

One approach to lower the **miss** penalty is to remember what was discarded in case it is needed again. Since the discarded data has already been fetched, it can be used again at a small cost. Such recycling is possible using a **victim cache**. Victim cache was originally proposed as an approach to reduce the conflict misses of direct mapped caches without affecting its fast access time. Victim cache is a fully associative cache, whose size is typically 4 to 16 cache lines, residing between a direct mapped L1 cache and the next level of memory. This concept is explored in [Appendix B](#).

CONTENT-ADDRESSABLE MEMORY

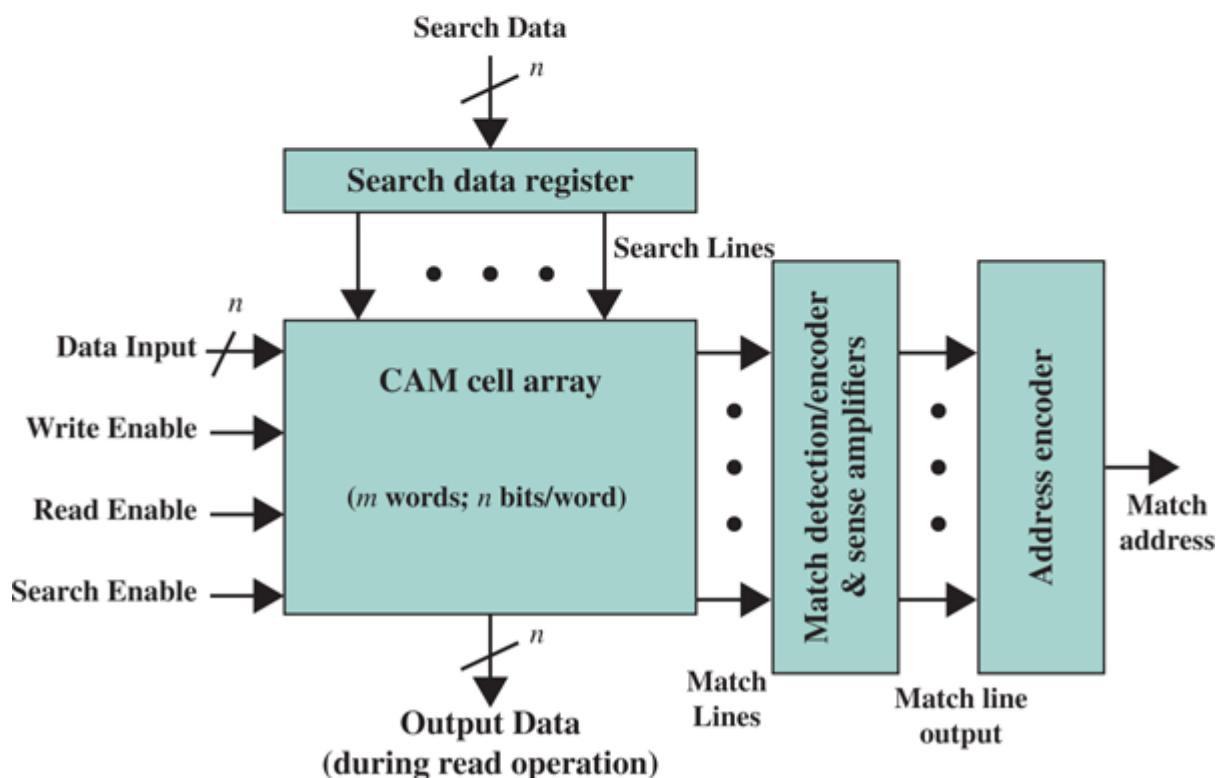

Before discussing associative cache organization, we need to introduce the concept of content-addressable memory (CAM), also known as associative storage [PAGI06]. Content-addressable memory (CAM) is constructed of static RAM (SRAM) cells (see static RAM) but is considerably more expensive and holds much less data than regular SRAM chips. Put another way, a CAM with the same data capacity as a regular SRAM is about 60% larger [SHAR03].

A CAM is designed such that when a bit string is supplied, the CAM searches its entire memory in parallel for a match. If the content is found, the CAM returns the address where the match is found and, in some architectures, also returns the associated data word. This process takes only one clock cycle.

Figure 5.9a is a simplified illustration of the search function of a small CAM with four horizontal words, each word containing five bits, or cells. CAM cells contain both storage and comparison circuitry. There is a match line corresponding to each word, feeding into match line sense amplifiers, and there is a differential search line pair corresponding to each bit of the search word. The encoder maps the match line of the matching location to its encoded address.

(a) Simplified CAM circuitry

(b) Logical organization of CAM

Figure 5.9 Content-Addressable Memory

Figure 5.9b shows a logical block diagram of a CAM cell array, consisting of m words of n bits each. Search, read, and write enable pins are used to enable one of the three operating modes of the CAM. For a search operation, the data to be searched is loaded in an n -bit search register that sets/resets the logic states of the search lines. The logic within and between cells of a row is such that a match lines is asserted if and only if all the cells in a row match the search line values. A simple read operation, as opposed to a search, is performed to read the data stored in the storage nodes of CAM cells using Read Enable control signal. The data words to be stored in CAM cell array are provided during a write operation through data input port.

Associative mapping overcomes the disadvantage of direct mapping by permitting each main memory block to be loaded into any line of the cache ([Figure 5.6b](#)). In this case, the cache control logic interprets a memory address simply as a Tag and a Word field. The Tag field uniquely identifies a block of main memory. To determine whether a block is in the cache, the cache control logic must simultaneously examine every line's tag for a match. [Figure 5.10](#) illustrates the logic.

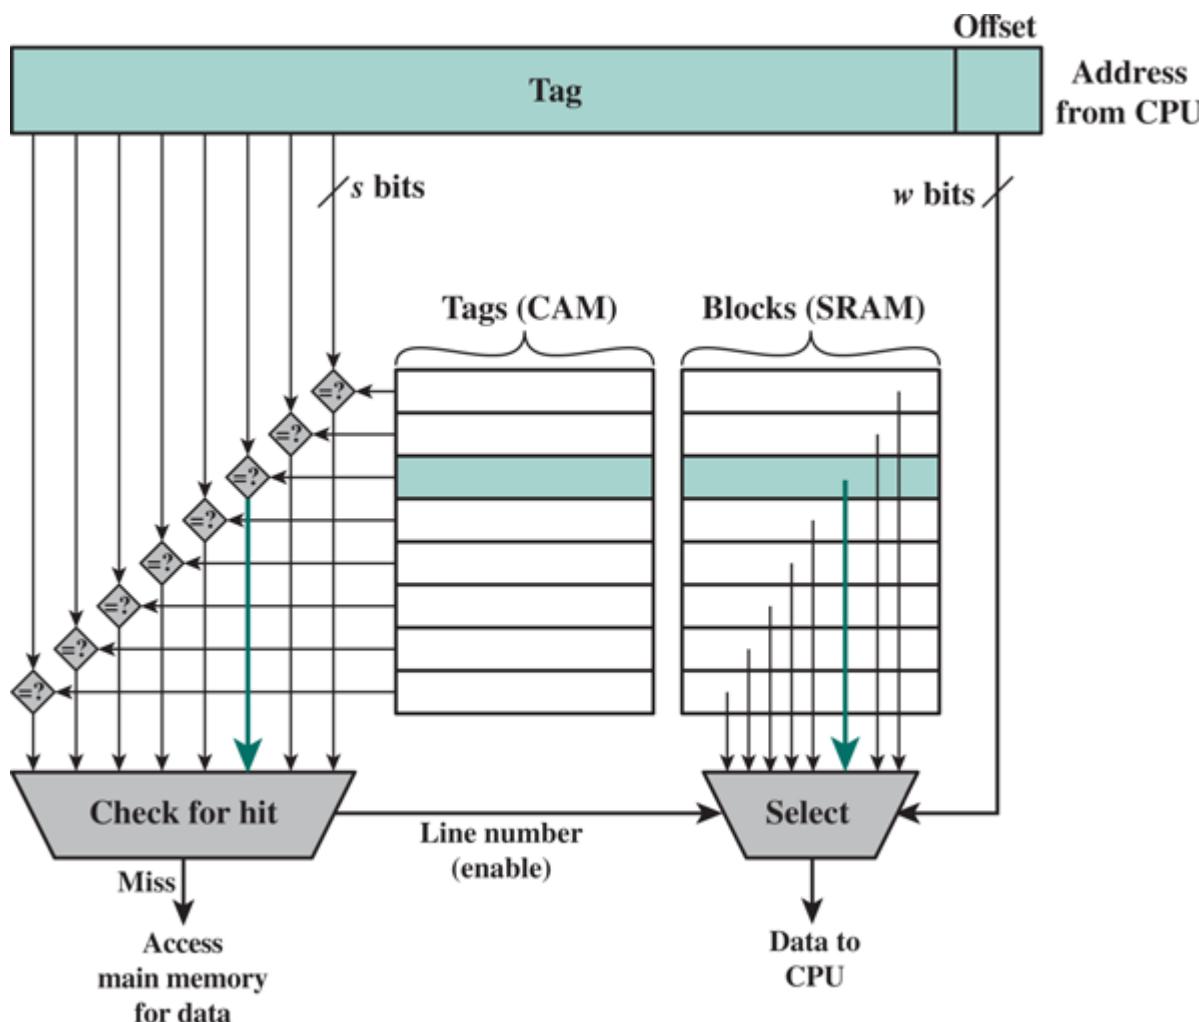

Figure 5.10 Fully Associative Cache Organization

Note that no field in the address corresponds to the line number, so that the number of lines in the cache is not determined by the address format. Instead, if there is a hit, the line number of the hit is sent to the select function by the cache hardware, as shown in [Figure 5.9](#). To summarize,

- Address length = $(s + w)$ bits
- Number of addressable units = 2^{s+w} words or bytes
- Block size = line size = 2^w words or bytes
- Number of blocks in main memory = $\frac{2^{s+w}}{2^w} = 2^s$
- Number of lines in cache = undetermined
- Size of tag = s bits

Example 5.1b

[Figure 5.11](#) shows our example using associative mapping. A main memory address consists of a 22-bit tag and a 2-bit byte number. The 22-bit tag must be stored with the 32-bit block of data for

each line in the cache. Note that it is the leftmost (most significant) 22 bits of the address that form the tag. Thus, the 24-bit hexadecimal address 16339C has the 22-bit tag 058CE7. This is easily seen in binary notation:

Memory address	0001	0110	0011	0011	1001	1100	(binary)
	1	6	3	3	9	C	(hex)
Tag (leftmost 22 bits)	00	0101	1000	1100	1110	0111	(binary)
	0	5	8	C	E	7	(hex)

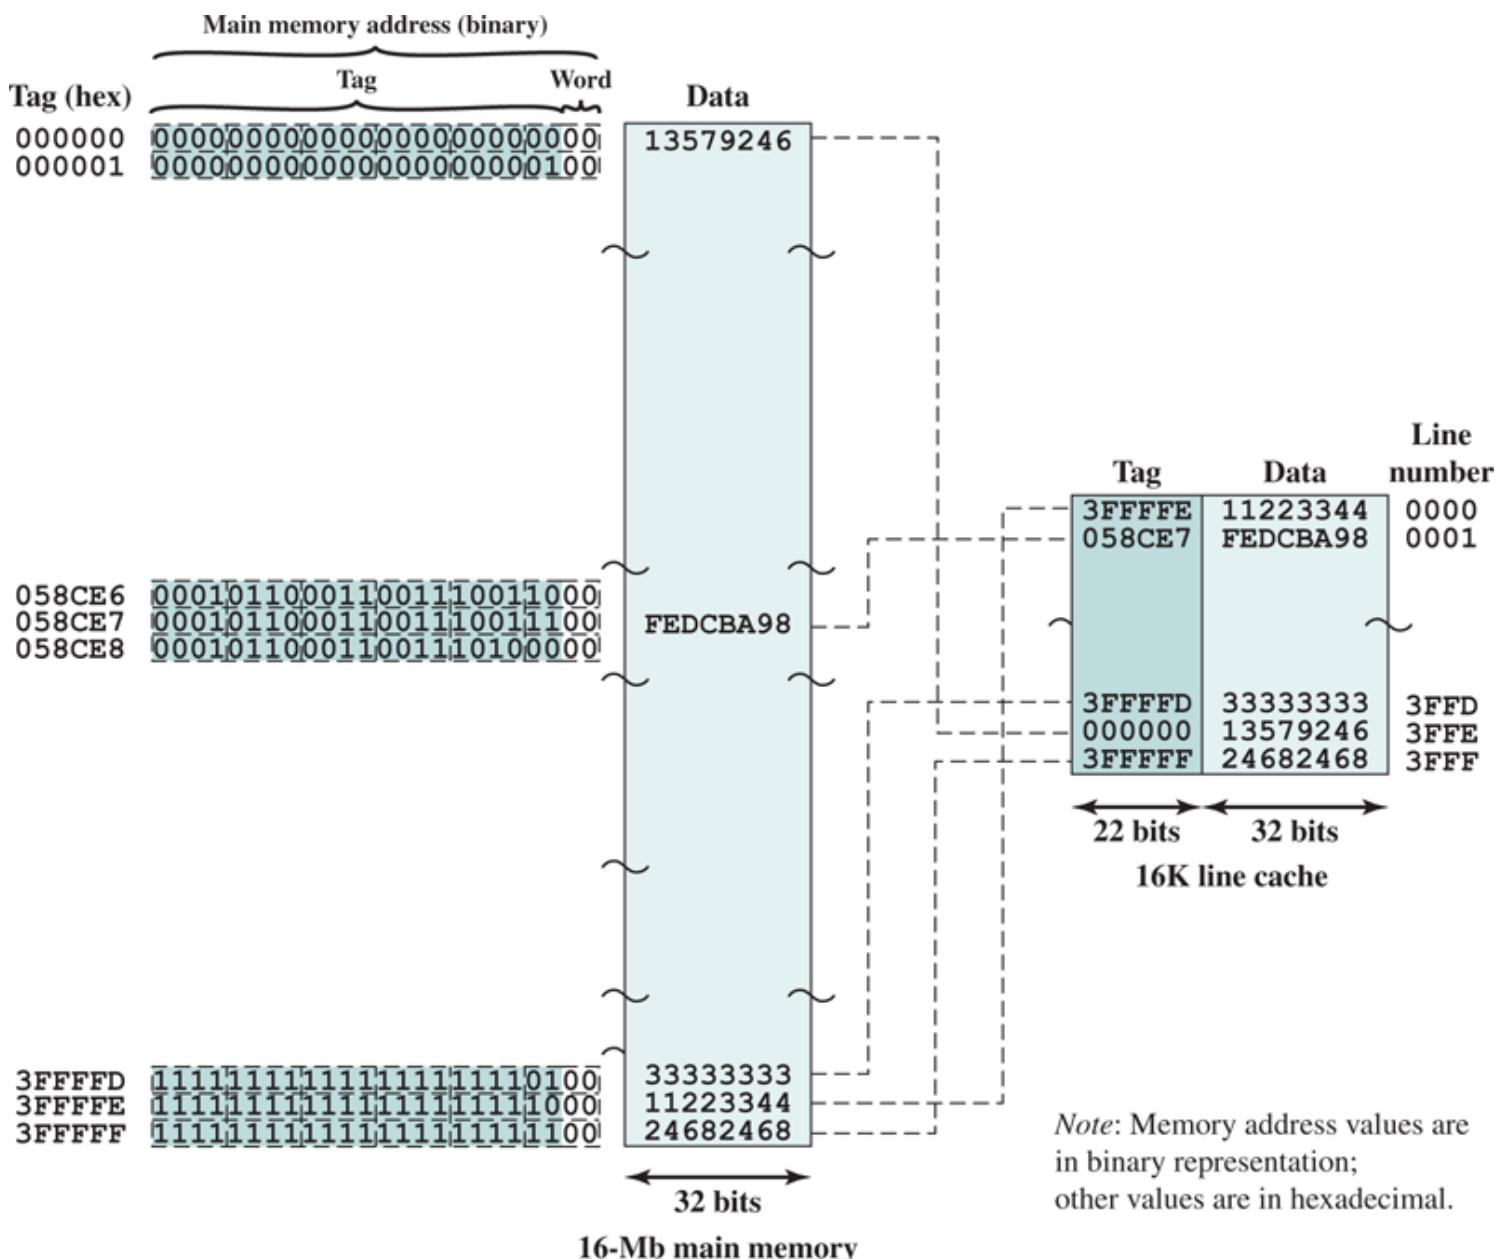

Figure 5.11 Associative Mapping Example

With associative mapping, there is flexibility as to which block to replace when a new block is read into the cache. Replacement algorithms, discussed later in this section, are designed to maximize the hit ratio. The principal disadvantage of associative mapping is the complex circuitry required to examine the tags of all cache lines in parallel.

Aleksandr Lukin/123RF

Cache Time Analysis Simulator

SET-ASSOCIATIVE MAPPING

Set-associative mapping is a compromise that exhibits the strengths of both the direct and associative approaches while reducing their disadvantages.

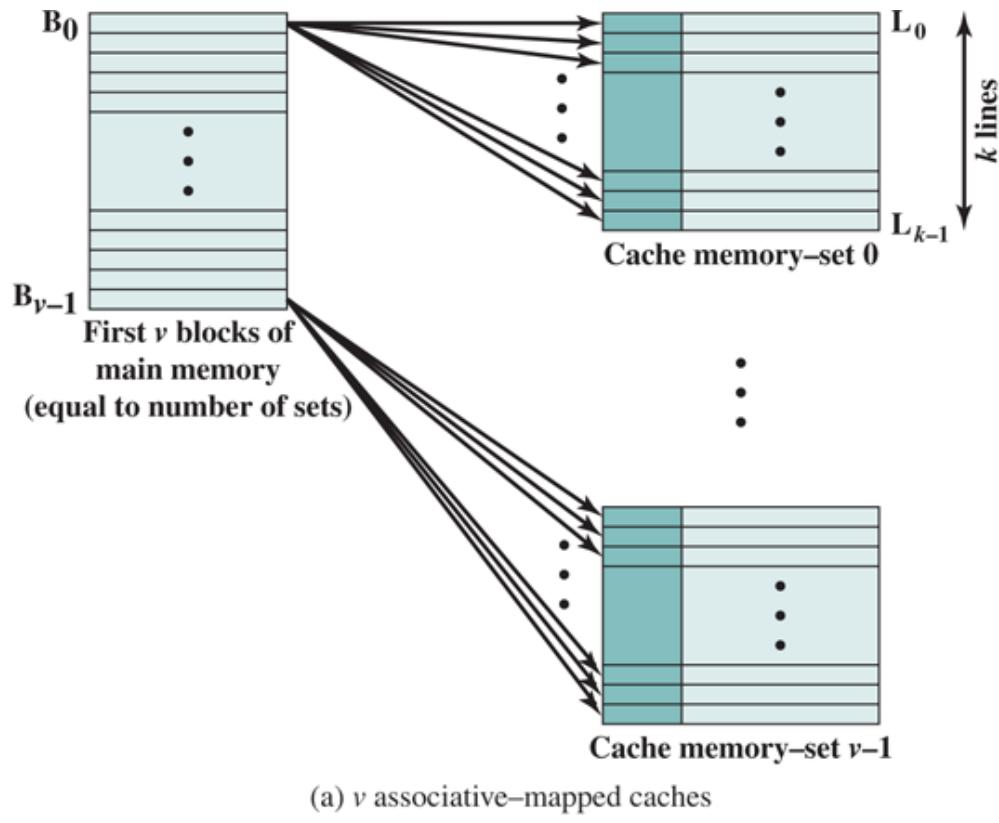

In this case, the cache consists of number sets, each of which consists of a number of lines. The relationships are

$$\begin{aligned}m &= v \times k \\i &= j \text{ modulo } v\end{aligned}$$

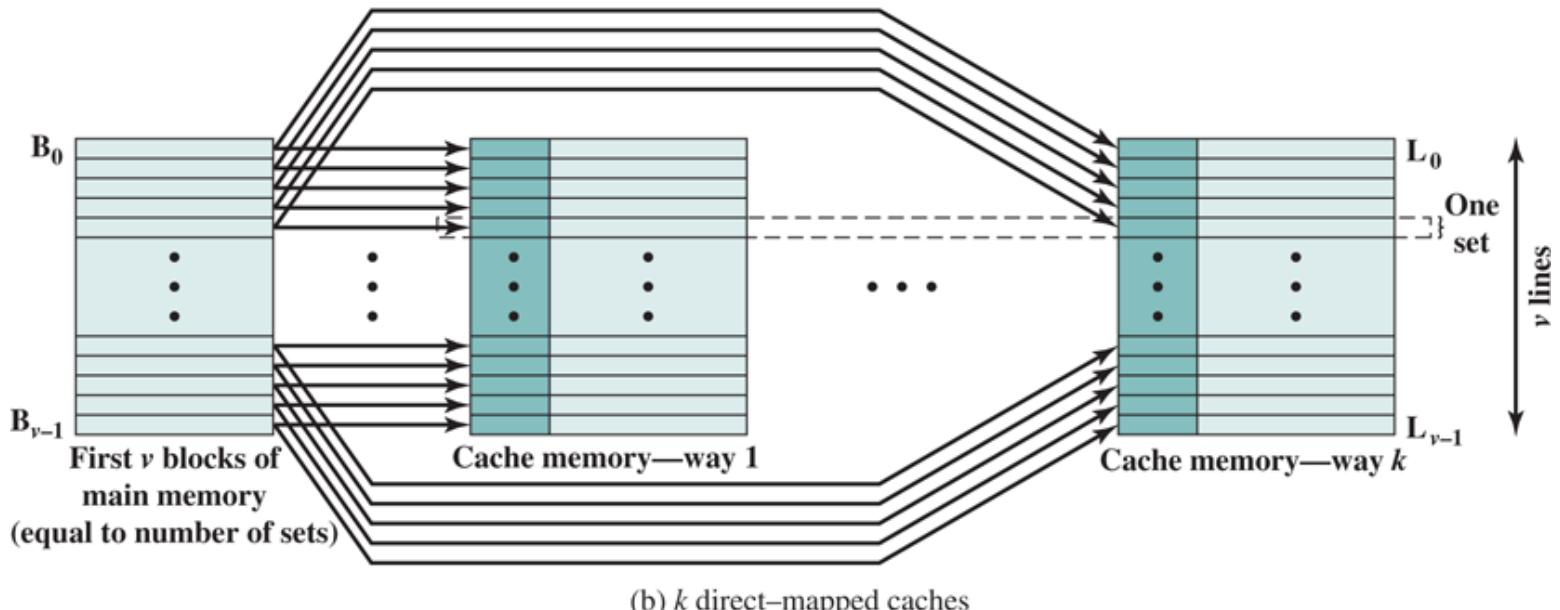

where

- i = cache set number
- j = main memory block number
- m = number of lines in the cache
- v = number of sets
- k = number of lines in each set

This is referred to as k -way set-associative mapping. With set-associative mapping, block B_j can be mapped into any of the lines of set j . [Figure 5.12a](#) illustrates this mapping for the first v blocks of main memory. As with associative mapping, each word maps into multiple cache lines. For set-associative mapping, each word maps into all the cache lines in a specific set, so that main memory block B_0 maps into set 0, and so on. Thus, the set-associative cache can be physically implemented as v associative caches, typically implemented as v CAM memories. It is also possible to implement the set-associative cache as k direct mapping caches, as shown in [Figure 5.12b](#). Each direct-mapped cache is referred to as a way, consisting of v lines. The first v lines of main memory are direct mapped into the v lines of each way; the next group of v lines of main memory are similarly mapped, and so on. The direct-mapped implementation is typically used for small degrees of associativity (small values of k) while the associative-mapped implementation is typically used for higher degrees of associativity [JACO08].

(a) v associative-mapped caches

(b) k direct-mapped caches

Figure 5.12 Mapping from Main Memory to Cache: k -Way Set Associative

For set-associative mapping, the cache control logic interprets a memory address as three fields: Tag, Set, and Word. The d set bits specify one of $v = 2^d$ sets. The s bits of the Tag and Set fields specify one of the 2^s blocks of main memory. [Figure 5.13](#) illustrates the cache control logic. With fully associative mapping, the tag in a memory address is quite large and must be compared to the tag of every line in the cache. With k -way set-associative mapping, the tag in a memory address is much smaller and is only compared to the k tags within a single set. As shown in [Figure 5.12](#), if there is match of tags on any of the lines in the set, the corresponding select function is enabled and retrieves the desired word. If all comparisons report a miss, then the desired word is retrieved from main memory.

To summarize,

- Address length = $(s + w)$ bits
- Number of addressable units = 2^{s+w} words or bytes
- Block size = line size = 2^w words or bytes
- Number of blocks in main memory = $\frac{2^{s+w}}{2^w} = 2^s$
- Number of lines in set = k
- Number of sets = $v = 2^d$
- Number of lines in cache = $m = kv = k \times 2^d$
- Size of cache = $k \times 2^{d+w}$ words or bytes
- Size of tag = $(s - d)$ bits

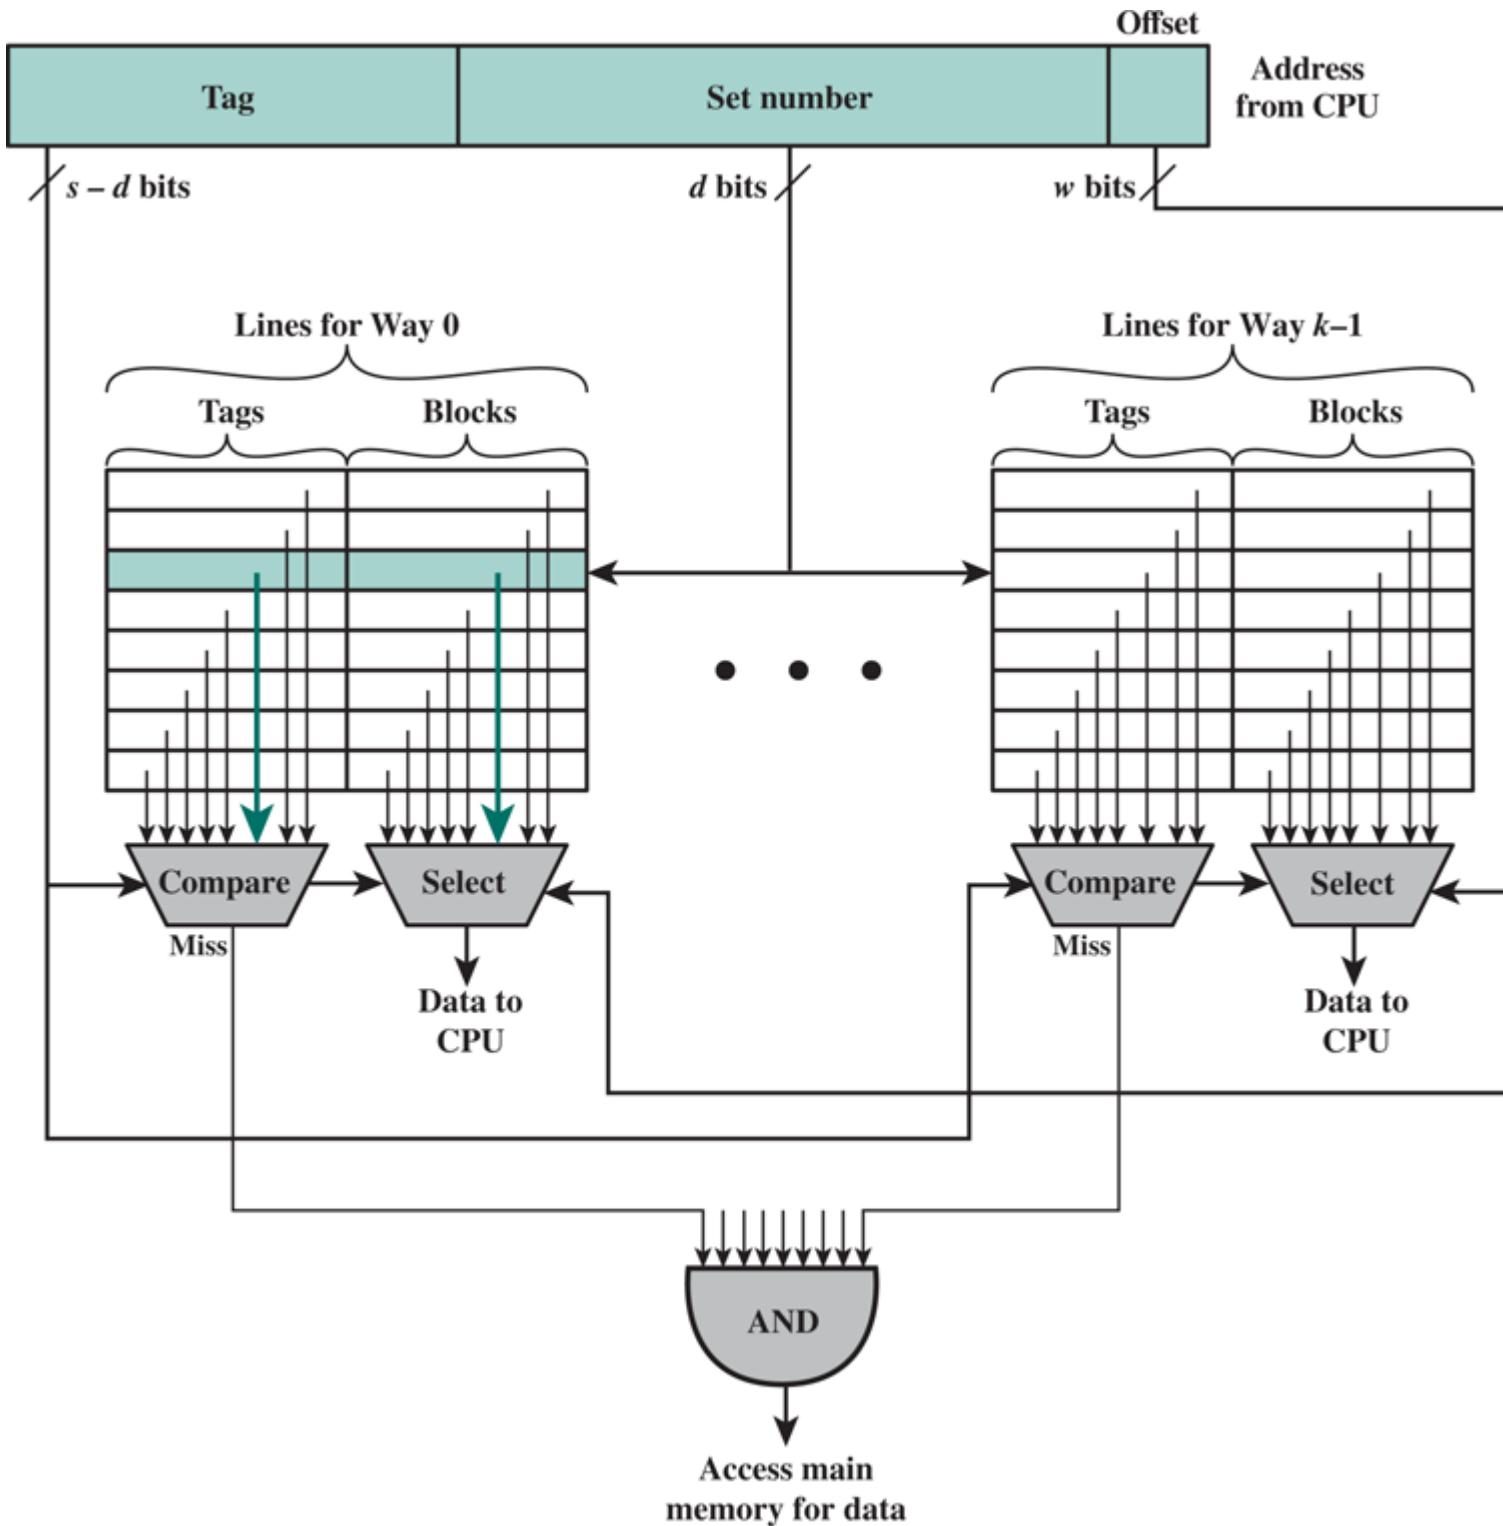

Figure 5.13 k -Way Set Associative Cache Organization

Example 5.1c

Figure 5.14 shows our example using two-way set-associative mapping with two lines in each set. The 13-bit set number identifies a unique set of two lines within the cache. It also gives the number of the block in main memory, modulo 2^{13} . This determines the mapping of blocks into lines. Thus, blocks 000000, 008000, ..., FF8000 of main memory map into **cache set 0**. Any of those blocks can be loaded into either of the two lines in the set. Note that no two blocks that map into the same cache set have the same tag number. For a read operation, the 13-bit set number is used to determine which set of two lines is to be examined. Both lines in the set are examined for a match with the tag number of the address to be accessed.

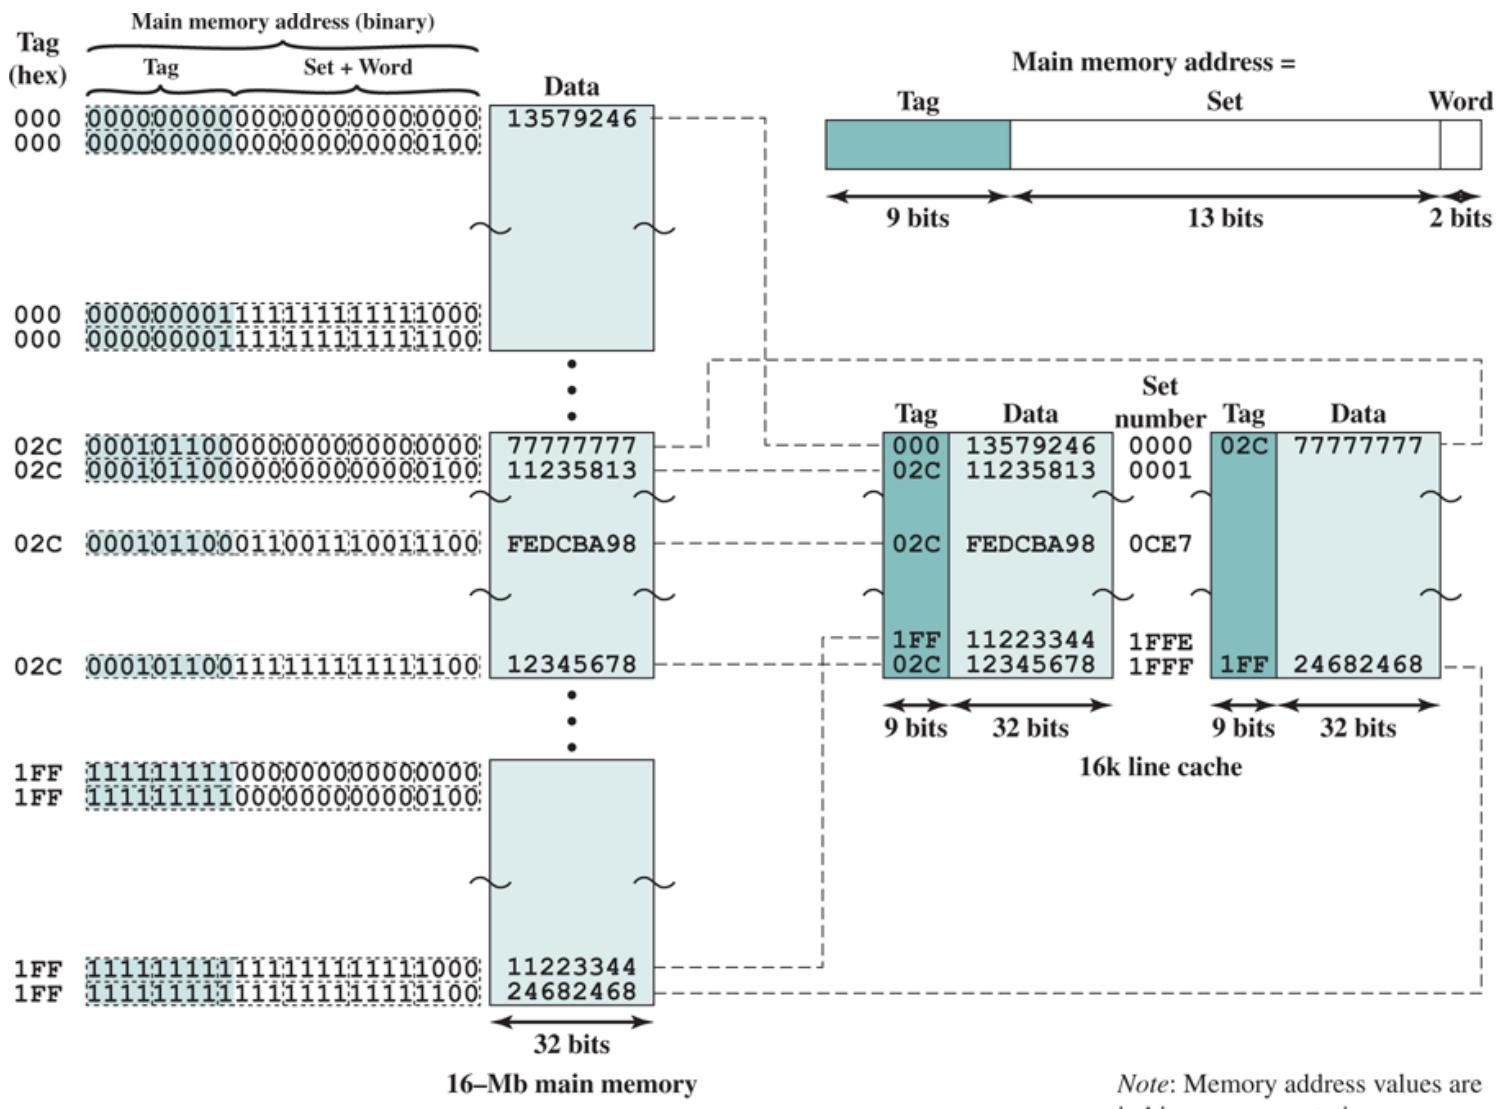

Figure 5.14 Two-Way Set-Associative Mapping Example

In the extreme case of $v = m, k = 1$, the set-associative technique reduces to direct mapping, and for $v = 1, k = m$, it reduces to associative mapping. The use of two lines per set ($v = m/2, k = 2$) is the most common set-associative organization. It significantly improves the hit ratio over direct mapping. Four-way set associative ($v = m/4, k = 4$) makes a modest additional improvement for a relatively small additional cost [MAYB84, HILL89]. Further increases in the number of lines per set have little effect.

Figure 5.15 shows the results of one simulation study of set-associative cache performance as a function of cache size [GENU04]. The difference in performance between direct and two-way set associative is significant up to at least a cache size of 64 kB. Note also that the difference between two-way and four-way at 4 kB is much less than the difference in going from 4 kB to 8 kB in cache size. The complexity of the cache increases in proportion to the associativity, and in this case would not be justifiable against increasing cache size to 8 or even 16 kB. A final point to note is that beyond about 32 kB, increase in cache size brings no significant increase in performance.

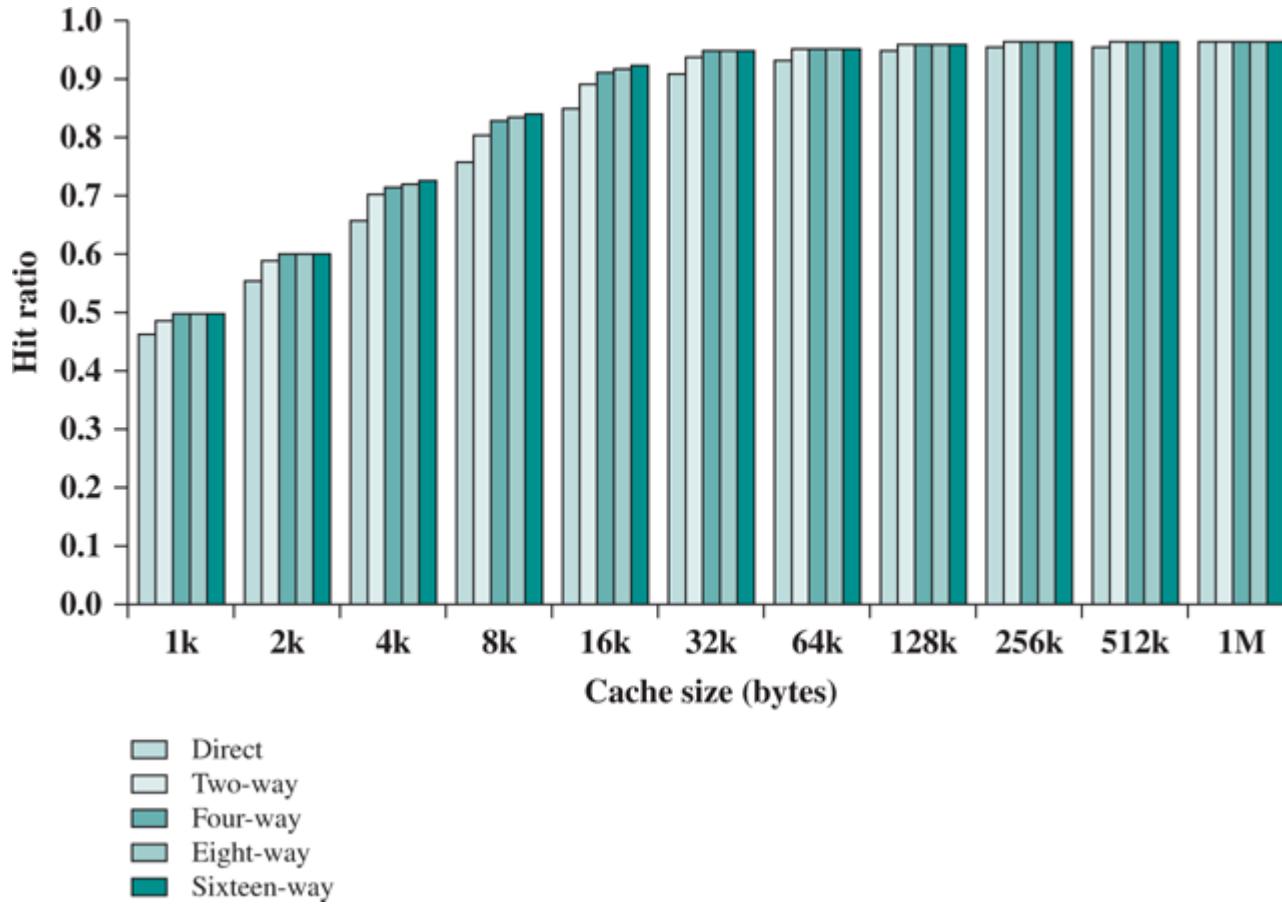

Figure 5.15 Varying Associativity over Cache Size

The results of [Figure 5.15](#) are based on simulating the execution of a GCC compiler. Different applications may yield different results. For example, [CANT01] reports on the results for cache performance using many of the CPU2000 SPEC benchmarks. The results of [CANT01] in comparing hit ratio to cache size follow the same pattern as [Figure 5.15](#), but the specific values are somewhat different.

For both associative and set-associative caches, there is an additional time element for comparing tag fields. One way to reduce this time penalty in a set-associative cache is with way prediction. Way prediction allows the data array and tag array to be accessed in parallel. If the predicted way was correct (determined by a tag match), no penalty occurs. If the prediction was incorrect, additional cycles are needed to find the data. The way predictor is a table that guesses which “way” a given address should access, based on recent history. An implementation reported in [POWE01], using a number of SPEC CPU benchmark programs, found prediction rates that ranged from 50% to over 90% for a 4-way set associative cache. Another study [TSEN09] on a 4-way set associative cache using SPEC CPU programs resulted in prediction rates ranging from 85% to 95%.

Cache Simulator

Multitask Cache Simulator

Replacement Algorithms

Once the cache has been filled, when a new block is brought into the cache, one of the existing blocks must be replaced. For direct mapping, there is only one possible line for any particular block, and no choice is possible. For the associative and set-associative techniques, a replacement algorithm is needed. To achieve high speed, such an algorithm must be implemented in hardware. A number of algorithms have been tried. We mention four of the most common. Probably the most effective is **least recently used (LRU)**: Replace that block in the set that has been in the cache longest with no reference to it. For two-way set associative, this is easily implemented. Each line includes a USE bit. When a line is referenced, its USE bit is set to 1 and the USE bit of the other line in that set is set to 0. When a block is to be read into the set, the line whose USE bit is 0 is used. Because we are assuming that more recently used memory locations are more likely to be referenced, LRU should give the best hit ratio. LRU is also relatively easy to implement for a fully associative cache. The cache mechanism maintains a separate list of indexes to all the lines in the cache. When a line is referenced, it moves to the front of the list. For replacement, the line at the back of the list is used. Because of its simplicity of implementation, LRU is the most popular replacement algorithm.

Another possibility is first-in-first-out (FIFO): Replace that block in the set that has been in the cache longest. FIFO is easily implemented as a round-robin or circular buffer technique. Still another possibility is least frequently used (LFU): Replace that block in the set that has experienced the fewest references. LFU could be implemented by associating a counter with each line. A technique not based on usage (i.e., not LRU, LFU, FIFO, or some variant) is to pick a line at random from among the candidate lines. Simulation studies have shown that random replacement provides only slightly inferior performance to an algorithm based on usage [SMIT82].

Write Policy

When a block that is resident in the cache is to be replaced, there are two cases to consider. If the old block in the cache has not been altered, then it may be overwritten with a new block without first writing out the old block. If at least one write operation has been performed on a word in that line of the cache, then main memory must be updated by writing the line of cache out to the block of memory before bringing in the new block. A variety of write policies, with performance and economic trade-offs, is possible. There are two problems to contend with. First, more than one device may have access to main memory. For example, an I/O module may be able to read-write directly to memory. If a word has been altered only in the cache, then the corresponding memory word is invalid. Further, if the I/O device has altered main memory, then the cache word is invalid. A more complex problem occurs when multiple processors are attached to the same bus and each processor has its own local cache. Then, if a word is altered in one cache, it could conceivably invalidate a word in other caches.

The simplest technique is called **write through**. Using this technique, all write operations are made to main memory as well as to the cache, ensuring that main memory is always valid. Any other processor–cache module can monitor traffic to main memory to maintain consistency within its own cache. The main disadvantage of this technique is that it generates substantial memory traffic and may create a bottleneck. An alternative technique, known as **write back**, minimizes memory writes. With write back, updates are made only in the cache. When an update occurs, a **dirty bit**, or **use bit**, associated with the line is set. Then, when a block is replaced, it is written back to main memory if and only if the dirty bit is set. The problem with write back is that portions of main memory are invalid, and hence accesses by I/O modules can be allowed only through the cache. This makes for complex circuitry and a potential bottleneck. Experience has shown that the percentage of memory references that are writes is on the order of 15% [SMIT82]. However, for HPC applications, this number may approach 33% (vector-vector multiplication) and can go as high as 50% (matrix transposition).

Example 5.2

Consider a cache with a line size of 32 bytes and a main memory that requires 30 ns to transfer a 4-byte word. For any line that is written at least once before being swapped out of the cache, what is the average number of times that the line must be written before being swapped out for a write-back cache to be more efficient than a write-through cache?

For the write-back case, each dirty line is written back once, at swap-out time, taking $8 \times 30 = 240$ ns. For the write-through case, each update of the line requires that one word be written out to main memory, taking 30 ns. Therefore, if the average line that gets written at least once gets written more than 8 times before swap out, then write back is more efficient.

There is another dimension to the write policy when a miss occurs at a cache level. There are two alternatives in the event of a write miss:

- **Write Allocate:** The block containing the word to be written is fetched from main memory (or next level cache) into the cache and the processor proceeds with the write cycle.
- **No Write Allocate:** The block containing the word to be written is modified in the main memory and not loaded into the cache.

Either of these policies can be used with either write through or write back. Most commonly, no write allocate is used with write through. The reasoning is that even if locality holds and a write will be made to the same block in the near future, the write-through policy will generate a write to main memory anyway, so bringing the block into the cache does not seem efficient. For example, the ARM Cortex processors can be configured to use write allocate or no write allocate with write back, but only no write allocate with write through.

With write back, write allocate is most commonly used, although some systems, such as the ARM Cortex, also allow no write allocate. The reasoning for using write allocate is that subsequent writes to the same block, if the block originally caused a miss, will hit in the cache next time, setting the dirty bit for the block. That will eliminate extra memory accesses and result in efficient execution. The write back, no write allocate option eliminates the time spent in bringing a block into the cache. Depending on locality patterns for reads and writes, there may be some advantage to this technique.

In a bus organization in which more than one device (typically a processor) has a cache and main memory is shared, a new problem is introduced. If data in one cache are altered, this invalidates not only the corresponding word in main memory, but also that same word in other caches (if any other cache happens to have that same word). Even if a write-through policy is used, the other caches may contain invalid data. A system that prevents this problem is said to maintain cache coherency.

Possible approaches to cache coherency include the following:

- **Bus watching with write through:** Each cache controller monitors the address lines to detect write operations to memory by other bus masters. If another master writes to a location in shared memory that also resides in the cache memory, the cache controller invalidates that cache entry. This strategy depends on the use of a write-through policy by all cache controllers.
- **Hardware transparency:** Additional hardware is used to ensure that all updates to main memory via cache are reflected in all caches. Thus, if one processor modifies a word in its cache, this update is written to main memory. In addition, any matching words in other caches are similarly updated.
- **Noncacheable memory:** Only a portion of main memory is shared by more than one processor, and this is designated as noncacheable. In such a system, all accesses to shared memory are cache misses, because the shared memory is never copied into the cache. The noncacheable memory can be identified using chip-select logic or high-address bits.

Cache coherency is an active field of research. This topic is explored further in Part Five.

Line Size

Another design element is the line size. When a block of data is retrieved and placed in the cache, not only the desired word but also some number of adjacent words are retrieved. As the block size increases from very small to larger sizes, the hit ratio will at first increase because of the principle of **locality**, which states that data in the vicinity of a referenced word are likely to be referenced in the near future. As the block size increases, more useful data are brought into the cache. The hit ratio will begin to decrease, however, as the block becomes even bigger and the probability of using the newly fetched information becomes less than the probability of reusing the information that has to be replaced. Two specific effects come into play:

- Larger blocks reduce the number of blocks that fit into a cache. Because each block fetch overwrites older cache contents, a small number of blocks results in data being overwritten shortly after they are fetched.
- As a block becomes larger, each additional word is farther from the requested word and therefore less likely to be needed in the near future.

The relationship between block size and hit ratio is complex, depending on the locality characteristics of a particular program, and no definitive optimum value has been found. A size of from 8 to 64 bytes seems reasonably close to optimum [SMIT87, PRZY88, PRZY90, HAND98]. For HPC systems, 64- and 128-byte cache line sizes are most frequently used.

Number of Caches

When caches were originally introduced, the typical system had a single cache. More recently, the use of multiple caches has become the norm. Two aspects of this design issue concern the number of levels of caches and the use of unified versus split caches.

MULTILEVEL CACHES

As logic density has increased, it has become possible to have a cache on the same chip as the processor: the on-chip cache. Compared with a cache reachable via an external bus, the on-chip cache reduces the processor's external bus activity and therefore speeds up execution times and increases overall system performance. When the requested instruction or data is found in the on-chip cache, the bus access is eliminated. Because of the short data paths internal to the processor, compared with bus lengths, on-chip cache accesses will complete appreciably faster than would even zero-wait state bus cycles. Furthermore, during this period the bus is free to support other transfers.

The inclusion of an on-chip cache leaves open the question of whether an off-chip, or external, cache is still desirable. Typically, the answer is yes, and most contemporary designs include both on-chip and external caches. The simplest such organization is known as a two-level cache, with the internal level 1 (L1) and the external cache designated as level 2 (L2). The reason for including an L2 cache is the following: If there is no L2 cache and the processor makes an access request for a memory location not in the L1 cache, then the processor must access DRAM or ROM memory across the bus. Due to the typically slow bus speed and slow memory access time, this results in poor performance. On the other hand, if an L2 SRAM (static RAM) cache is used, then frequently the missing information can be quickly retrieved. If the SRAM is fast enough to match the bus speed, then the data can be accessed using a zero-wait state transaction, the fastest type of bus transfer.

Two features of contemporary cache design for multilevel caches are noteworthy. First, for an off-chip L2 cache, many designs do not use the system bus as the path for transfer between the L2 cache and the processor, but use a separate data path, so as to reduce the burden on the system bus. Second,

with the continued shrinkage of processor components, a number of processors now incorporate the L2 cache on the processor chip, improving performance.

The potential savings due to the use of an L2 cache depends on the hit rates in both the L1 and L2 caches. Several studies have shown that, in general, the use of a second-level cache does improve performance (e.g., see [AZIM92], [NOVI93], [HAND98]). However, the use of multilevel caches does complicate all of the design issues related to caches, including size, replacement algorithm, and write policy; see [HAND98] and [PEIR99] for discussions.

Figure 5.16 shows the results of one simulation study of two-level cache performance as a function of cache size [GENU04]. The figure assumes that both caches have the same line size and shows the total hit ratio. That is, a **hit** is counted if the desired data appears in either the L1 or the L2 cache. The figure shows the impact of L2 on total hits with respect to L1 size. L2 has little effect on the total number of cache hits until it is at least double the L1 cache size. Note that the steepest part of the slope for an L1 cache of 8 kB is for an L2 cache of 16 kB. Again for an L1 cache of 16 kB, the steepest part of the curve is for an L2 cache size of 32 kB. Prior to that point, the L2 cache has little, if any, impact on total cache performance. The need for the L2 cache to be larger than the L1 cache to affect performance makes sense. If the L2 cache has the same line size and capacity as the L1 cache, its contents will more or less mirror those of the L1 cache.

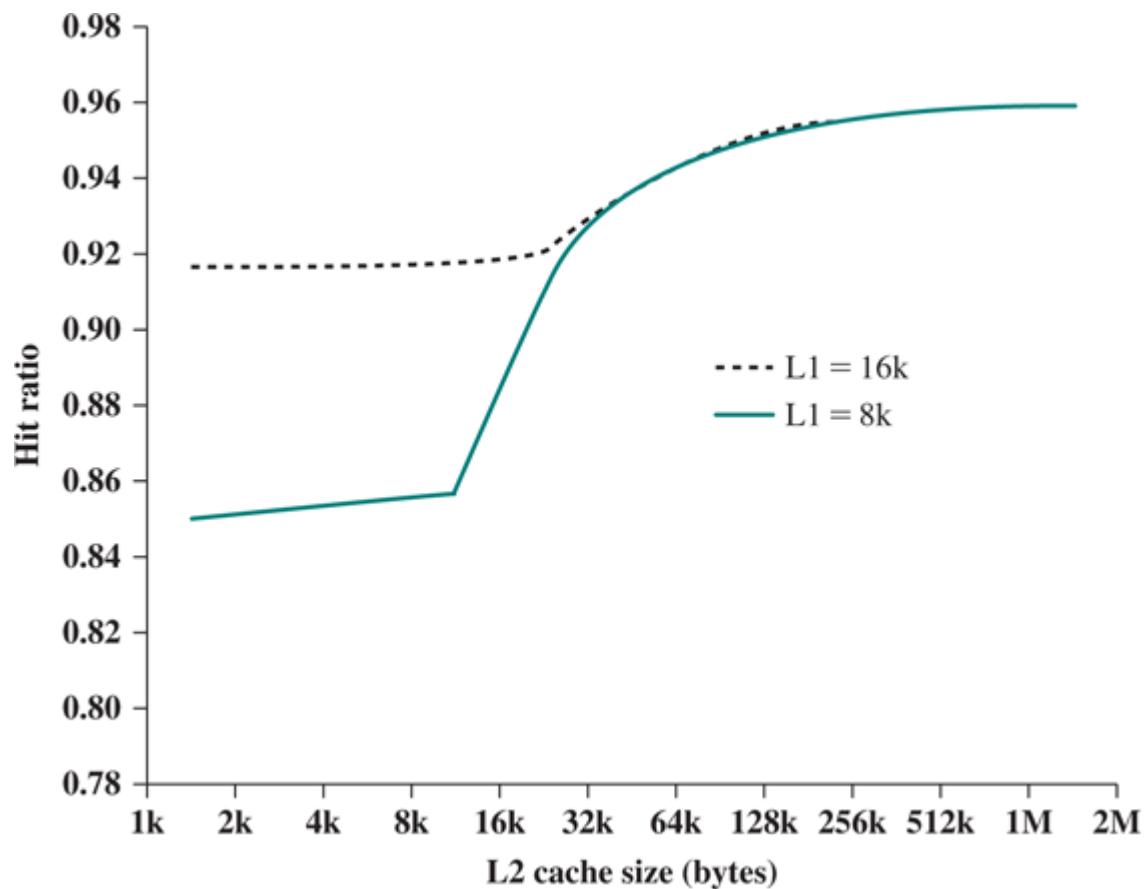

Figure 5.16 Total Hit Ratio (L1 and L2) for 8-kB and 16-kB L1

With the increasing availability of on-chip area available for cache, most contemporary microprocessors have moved the L2 cache onto the processor chip and added an L3 cache. Originally, the L3 cache was accessible over the external bus. More recently, most microprocessors have incorporated an on-chip L3 cache. In either case, there appears to be a performance advantage to adding the third level (e.g., see [GHAI98]). Further, large systems, such as the IBM mainframe zEnterprise systems, incorporate 3 on-chip cache levels and a fourth level of cache shared across multiple chips [BART15].

UNIFIED VERSUS SPLIT CACHES

When the on-chip cache first made an appearance, many of the designs consisted of a single cache used to store references to both data and instructions. More recently, it has become common to split the cache into two: one dedicated to instructions and one dedicated to data. These two caches both exist at the same level, typically as two L1 caches. When the processor attempts to fetch an instruction from main memory, it first consults the instruction L1 cache, and when the processor attempts to fetch data from main memory, it first consults the data L1 cache.

There are two potential advantages of a **unified cache**:

- For a given cache size, a unified cache has a higher hit rate than **split caches** because it balances the load between instruction and data fetches automatically. That is, if an execution pattern involves many more instruction fetches than data fetches, then the cache will tend to fill up with instructions, and if an execution pattern involves relatively more data fetches, the opposite will occur.
- Only one cache needs to be designed and implemented.

The trend is toward split caches at the L1 and unified caches for higher levels, particularly for superscalar machines, which emphasize parallel instruction execution and the prefetching of predicted future instructions. The key advantage of the split cache design is that it eliminates contention for the cache between the instruction fetch/decode unit and the execution unit. This is important in any design that relies on the pipelining of instructions. Typically, the processor will fetch instructions ahead of time and fill a buffer, or pipeline, with instructions to be executed. Suppose now that we have a unified instruction/**data cache**. When the execution unit performs a memory access to load and store data, the request is submitted to the unified cache. If, at the same time, the instruction prefetcher issues a read request to the cache for an instruction, that request will be temporarily blocked so that the cache can service the execution unit first, enabling it to complete the currently executing instruction. This cache contention can degrade performance by interfering with efficient use of the instruction pipeline. The split cache structure overcomes this difficulty.

Inclusion Policy

Recall from Chapter 4 that we defined the inclusion principle for memory hierarchies as follows: All information items are originally stored in level M_n , where n is the level most remote from the processor (lowest level). During the processing, subsets of M_n are copied into M_{n-1} . Similarly, subsets of M_{n-1} are copied into M_{n-2} , and so on. This is expressed concisely as $M_i \rightarrow M_{i+1}$. Thus, if a word is found in M_i , then copies of the same word also exist in all lower layers $M_{i+1}, M_{i+2}, \dots, M_n$. In a multilevel cache environment, in which there may be multiple caches at one level that share the same cache at the next lower level, inclusion between these two levels may not always be desirable. Three inclusion policies are found in contemporary cache systems:

The **inclusive policy** dictates that a piece of data in one cache is guaranteed to be also found in all lower levels of caches. The advantage of the inclusive policy is that it simplifies searching for data when there are multiple processors in the computing system. For example, if one processor wants to know whether another processor has the data it needs, it does not need to search all levels of caches of that other processor but only the lowest-level cache. This property is useful in enforcing cache coherence, which is discussed in [Chapter 20](#).

The **exclusive policy** dictates that a piece of data in one cache is guaranteed *not* to be found in all lower levels of caches. The advantage of the exclusive policy is that it does not waste cache capacity since it does not store multiple copies of the same data in all of the caches. The disadvantage is the

need to search multiple cache levels when invalidating or updating a block. To minimize the search time, the higher-level tag sets are typically duplicated at the lowest cache level to centralize searching.

With the **noninclusive policy**, a piece of data in one cache may or may not be found in lower levels of caches. This can be contrasted with the other two policies with the following examples. Suppose that the L2 line size is a multiple of the L1 line size. For the inclusive policy, if a block is evicted from the L2 cache, the corresponding multiple blocks will be evicted from the L1 cache. In contrast, with a noninclusive policy, the L1 cache may retain portions of a block recently evicted from the L2 cache. For the same difference in block size, if a portion of a block is promoted from the L2 cache to the L1 cache, the exclusive policy requires the entire L2 block be evicted. In contrast, the noninclusive policy does not require this eviction. As with the exclusive policy, a noninclusive policy will generally maintain all higher-level cache sets at the lowest cache level.

5.3 Intel x86 Cache Organization

The evolution of cache organization is seen clearly in the evolution of Intel microprocessors ([Table 5.4](#)). The 80386 does not include an on-chip cache. The 80486 includes a single on-chip cache of 8 kB, using a line size of 16 bytes and a four-way set-associative organization. All of the Pentium processors include two on-chip L1 caches, one for data and one for instructions. For the Pentium 4, the L1 data cache is 16 kB, using a line size of 64 bytes and a four-way set-associative organization. The Pentium 4 **instruction cache** is described subsequently. The Pentium II also includes an L2 cache that feeds both of the L1 caches. The L2 cache is eight-way set associative with a size of 512 kB and a line size of 128 bytes. An L3 cache was added for the Pentium III and became on-chip with high-end versions of the Pentium 4.

Table 5.4 Intel Cache Evolution

Problem	Solution	Processor on Which Feature First Appears
External memory slower than the system bus.	Add external cache using faster memory technology.	386
Increased processor speed results in external bus becoming a bottleneck for cache access.	Move external cache on-chip, operating at the same speed as the processor.	486
Internal cache is rather small, due to limited space on chip.	Add external L2 cache using faster technology than main memory.	486
Contention occurs when both the Instruction Prefetcher and the Execution Unit simultaneously require access to the cache. In that case, the Prefetcher is stalled while the Execution Unit's data access takes place.	Create separate data and instruction caches.	Pentium
Increased processor speed results in external bus becoming a bottleneck for L2 cache access.	Create separate back-side bus that runs at higher speed than the main (front-side) external bus. The BSB is dedicated to the L2 cache.	Pentium Pro
	Move L2 cache on to the processor chip.	Pentium II

Some applications deal with massive databases and must have rapid access to large amounts of data. The on-chip caches are too small.	Add external L3 cache.	Pentium III
	Move L3 cache on-chip.	Pentium 4

Figure 5.17 provides a simplified view of the Pentium 4 organization, highlighting the placement of the three caches. This cache architecture is similar to those of more modern x86 systems. The processor core consists of four major components:

- **Fetch/decode unit:** Fetches program instructions in order from the L2 cache, decodes these into a series of micro-operations, and stores the results in the L1 instruction cache.
- **Out-of-order execution logic:** Schedules execution of the micro-operations subject to data dependencies and resource availability; thus, micro-operations may be scheduled for execution in a different order than they were fetched from the instruction stream. As time permits, this unit schedules speculative execution of micro-operations that may be required in the future.
- **Execution units:** These units execute micro-operations, fetching the required data from the L1 data cache and temporarily storing results in registers.
- **Memory subsystem:** This unit includes the L2 and L3 caches and the system bus, which is used to access main memory when the L1 and L2 caches have a cache miss and to access the system I/O resources.

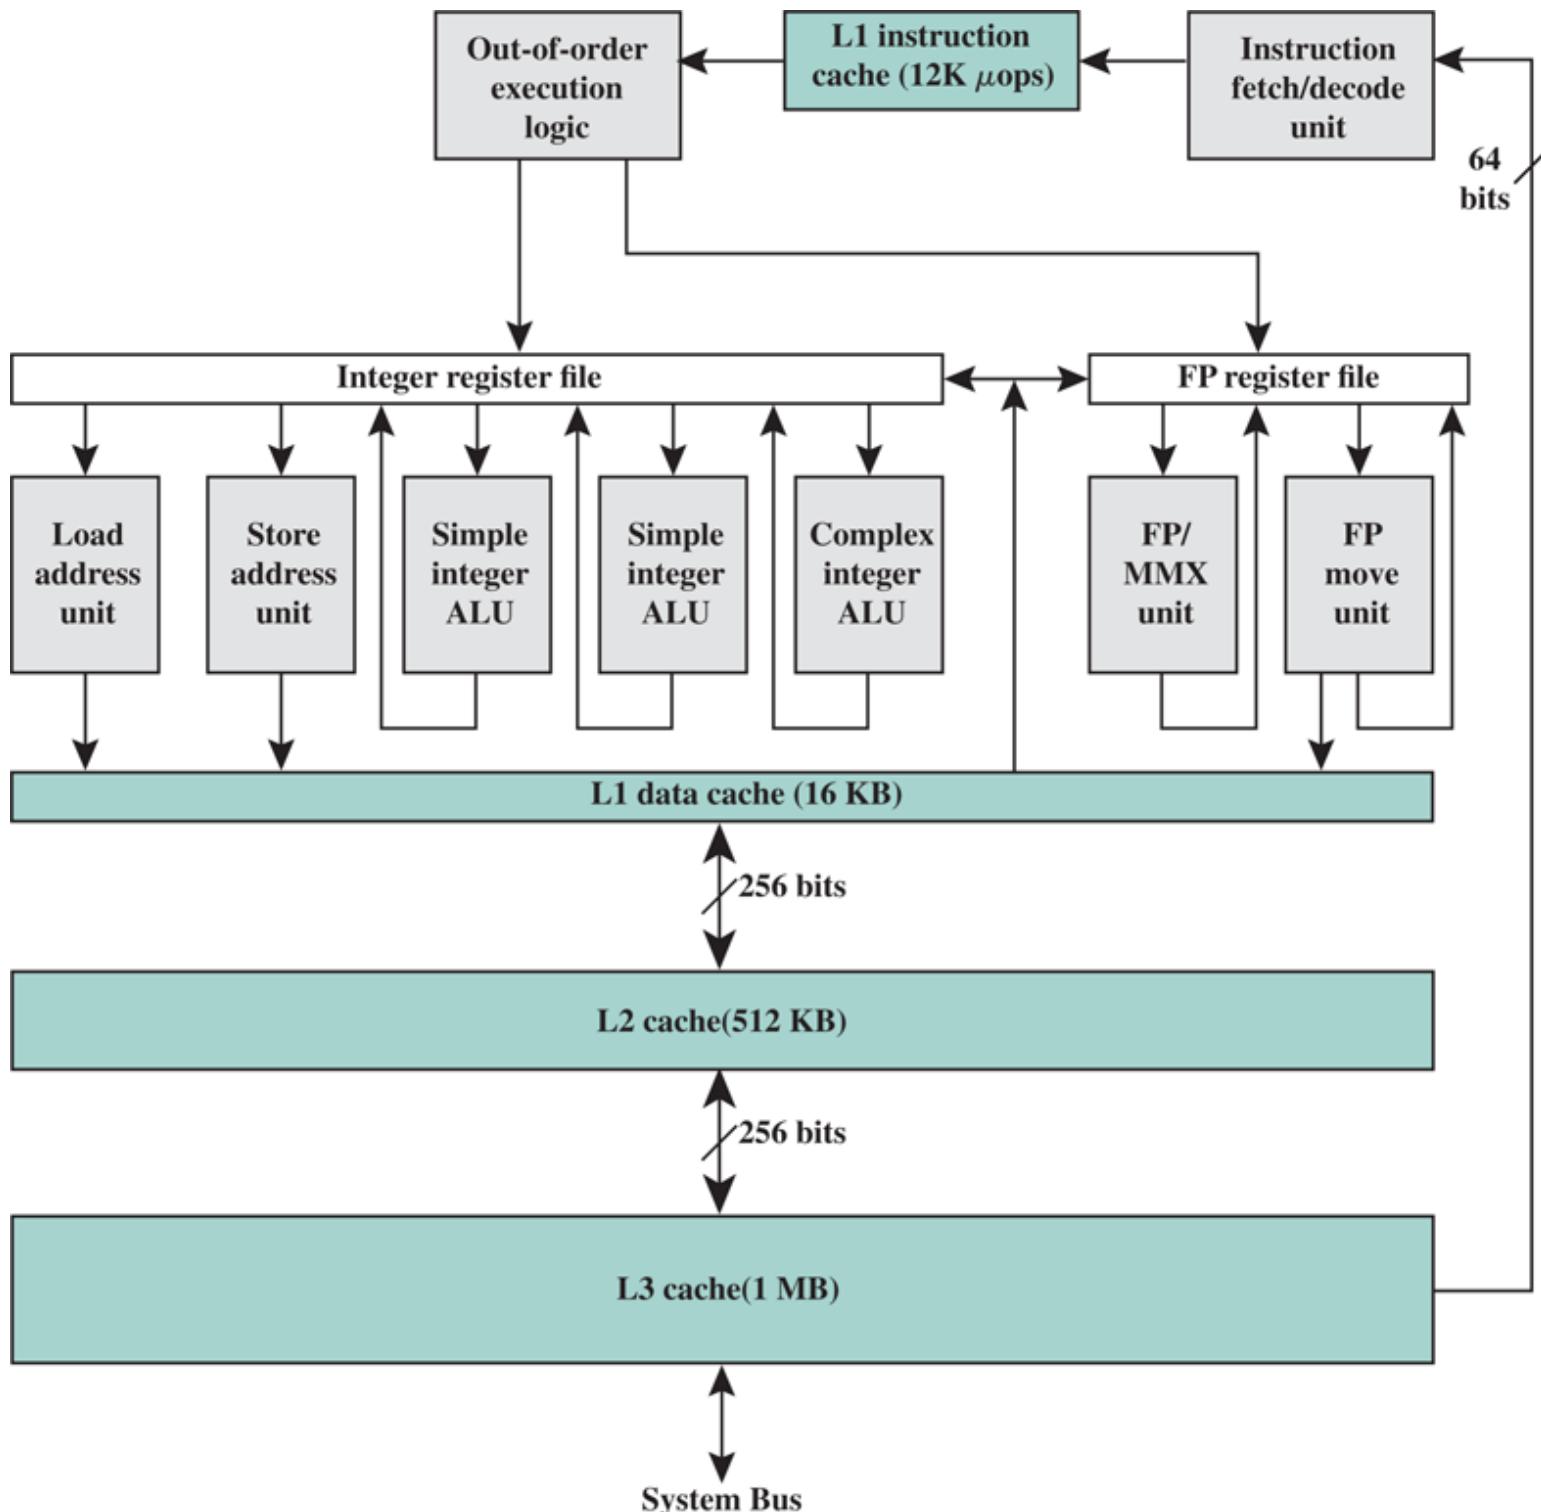

Figure 5.17 Pentium 4 Block Diagram

Unlike the organization used in all previous Pentium models, and in most other processors, the Pentium 4 instruction cache sits between the instruction decode logic and the execution core. The reasoning behind this design decision is as follows: As discussed more fully in Chapter 18, the Pentium processor decodes, or translates, Pentium machine instructions into simple RISC-like instructions called micro-operations. The use of simple, fixed-length micro-operations enables the use of superscalar pipelining and scheduling techniques that enhance performance. However, the Pentium machine instructions are cumbersome to decode; they have a variable number of bytes and many different options. It turns out that performance is enhanced if this decoding is done independently of the scheduling and pipelining logic. We return to this topic in [Chapter 18](#).

The data cache employs a write-back policy: Data are written to main memory only when they are

removed from the cache and there has been an update. The Pentium 4 processor can be dynamically configured to support write-through caching.

The L1 data cache is controlled by two bits in one of the control registers, labeled the CD (cache disable) and NW (not write-through) bits ([Table 5.5](#)). There are also two Pentium 4 instructions that can be used to control the data cache: INVD invalidates (flushes) the internal cache memory and signals the external cache (if any) to invalidate. WBINVD writes back and invalidates internal cache and then writes back and invalidates external cache.

Table 5.5 Pentium 4 Cache Operating Modes

Note: CD = 0 ; NW = 1 is an invalid combination.

Control Bits		Operating Mode		
CD	NW	Cache Fills	Write Throughs	Invalidates
0	0	Enabled	Enabled	Enabled
1	0	Disabled	Enabled	Enabled
1	1	Disabled	Disabled	Disabled

Both the L2 and L3 caches are eight-way set-associative with a line size of 128 bytes.

5.4 The IBM z13 Cache Organization

The IBM z13 cache organization was introduced in [Chapter 5](#). This section provides more detail.

[Figure 5.18](#) illustrates the logical interconnections of the z13 cache system, showing the structure of a single processor drawer. A maximum system, called a central processing complex (CPC) consists of four drawers. Each drawer consists of two processor nodes, with each node containing 3 processor unit (PU) chips and one storage control (SC) chip. Each PU includes up to 8 cores. The L1, L2, and L3 caches are contained on each PU chip, and a separate SC chip holds the L4 cache for a processor node. Thus a maximum configuration contains 192 cores. Some key characteristics of each level are as follows:

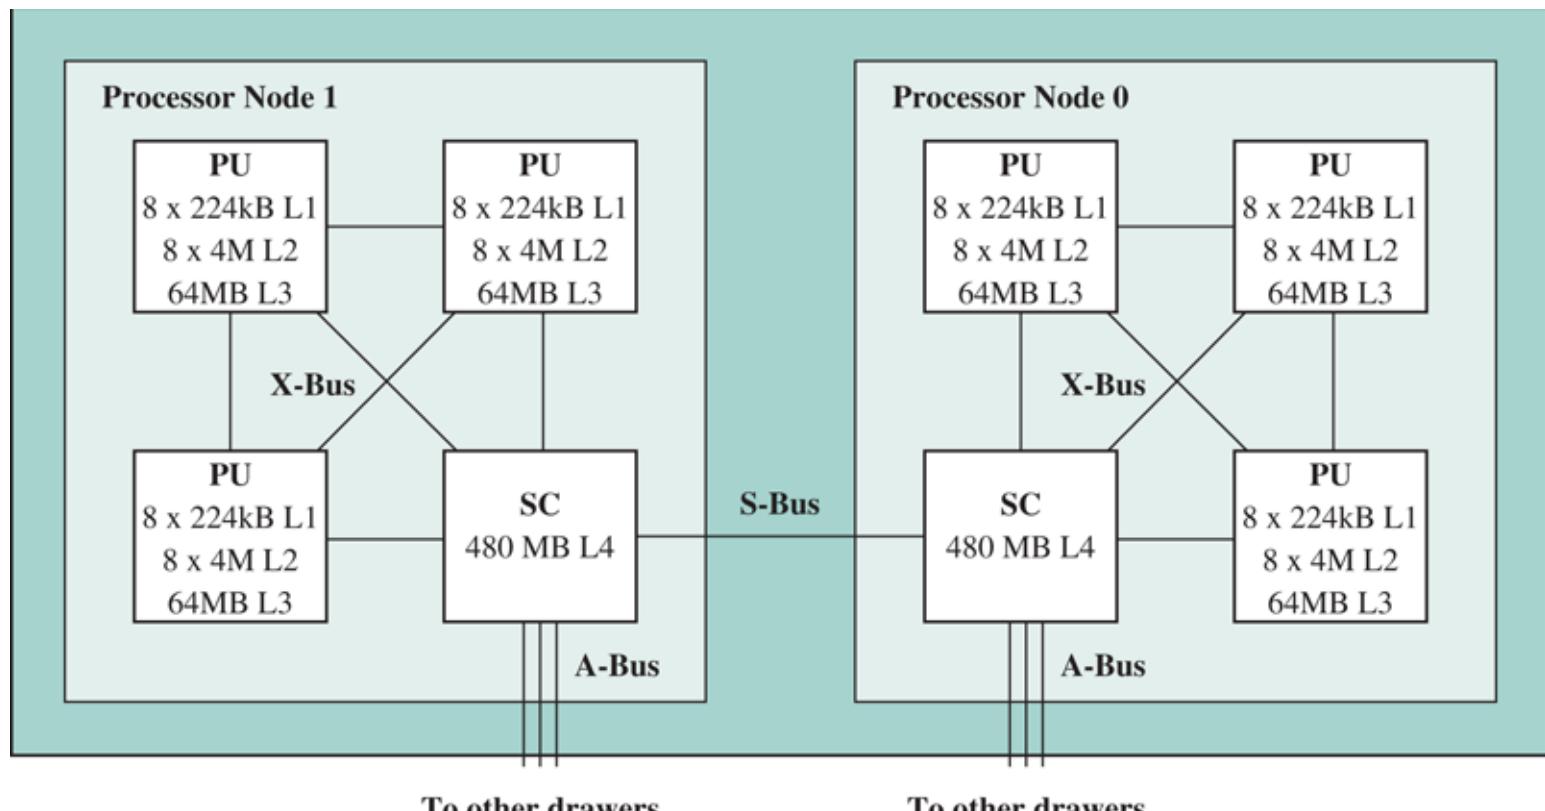

Figure 5.18 IBM z13 CPC Drawer Logical Structure

- **L1 cache:** Each core contains a 96-kB L1 I-cache and a 128-kB D-cache, for a maximum total of 18 MB of L1 I-cache and 24 MB of L1 D-cache. The L1 caches are designed as write-through caches.
- **L2 cache:** Each core contains a 2-MB L2 I-cache and a 2-MB L2 D-cache, for a maximum total of 384 MB of L2 I-cache and 384 MB of L2 D-cache. The L2 caches are designed as write-through caches.
- **L3 cache:** Each PU chip contains a 64-MB L3 cache, for a maximum total of 1.5 GB of L3 cache. The L3 cache is 16-way set associative and uses a line size of 256 bytes. The L3 cache uses the write-back policy.
- **L4 cache:** Each processor node contains a 480-MB L4 cache for a maximum total of 3.75 GB of L4 cache. The L4 cache is organized as a 30-way set-associative cache. The L4 cache uses the write-back policy.

The use of an L3 cache that is shared by 8 cores on a chip facilitates low-latency cross-processor cache line sharing and provides cache efficiency effects by elimination of redundant lines (single copy, multiple users), which is not possible with private caches. Thus, there are efficiency gains by devoting a substantial portion of each PU chip to a shared L3 cache as opposed to either increasing the size of

the L2 caches or providing private L3 caches for each core.

There are also efficiency benefits from providing an L4 cache chip on the same processor node, or motherboard, as the PU chips. The L4 cache enables smooth scaling from a single processor chip to a maximum system configuration by providing a significant buffer before main memory.

The interconnection design contributes to the overall efficiency of this arrangement. Within each PU chip, 160-GB/s bus bandwidth is used between L1/L2 and L2/L3 cache boundaries. The 80-GB/s XBus provides tightly coupled interconnection within a node at the L3/L4 cache boundary. The high-speed S-Bus connects via L4 between the nodes of a drawer, and A-Bus connections are provided to other drawers.

The cache write policy is tailored to the configuration. The L1 and L2 caches are write-through, taking advantage of the high-speed on-chip connection to the next cache level. Further, the L3 cache is most efficiently used if it always maintains the most recent version of any L2 cache line. Going from L3 to L4 is a lower speed, off-chip transmission and here a write-back policy is preferred to minimize traffic. Similarly, write-back is preferred going from L4 to main memory.

5.5 Cache Performance Models⁶

⁶ Used with permission from Professor Roger Kieckhafer of Michigan Technological University.

This section looks first at the cache timing of the different cache access organizations, then at a model of design options for improving performance.

Cache Timing Model

We can derive some insight into the timing differences between the different cache access models by developing equations that show the different time delays. The following parameters are needed:

t_{ct} = time needed to compare the tag field of an address with the tag value in a cache line.

t_{rl} = time needed to read a line from the cache to retrieve the data block in the cache.

t_{xb} = time needed to transmit byte or word to the processor; this includes extracting the desired bytes from the fetched line and gating these bytes onto the bus to the processor.

t_{hit} = time expended at this cache level in the event of a hit.

t_{miss} = time expended at this cache level in the event of a miss.

First consider direct-mapped cache access. The first operation is checking the Tag field of an address against the tag value in the line designated by the Line field. If there is not a match (miss), then the operation is complete. If there is a match (hit), then the cache hardware reads the data block from the line in the cache and then fetches the byte or word indicated by the Offset field of the address. The timing equations therefore are:

$$t_{hit} = t_{rl} + t_{xb} + t_{ct} \quad t_{miss} = t_{rl} + t_{ct} \quad (5.1)$$

One of the advantages of a direct-mapped cache is that it allows simple and fast speculation. Once the address has been computed, the one cache line that might have a copy of that location in memory is known. That cache entry can be read, and the processor can continue to work with that data before it finishes checking that the tag actually matches the requested address. Thus checking and fetching are performed in parallel. Assuming the fetch time is larger, the timing equations become:

$$t_{hit} = t_{rl} + t_{xb} \quad t_{miss} = t_{rl} + t_{ct} \quad (5.2)$$

Next, consider a fully associative cache. In this case, the line number is not known until the tag comparison is completed. So the hit time is the same as for direct-mapped. Because this is a content-addressable memory, the miss time is simply the tag comparison time. That is, the tag comparison is made without the need to read a line of data from the cache, but is made in parallel to all of the lines of the cache internally to the cache. The equations in this case:

$$t_{hit} = t_{rl} + t_{xb} + t_{ct} \quad t_{miss} = t_{ct} \quad (5.3)$$

With set associative, it is not possible to transmit bytes and compare tags in parallel as can be done with direct-mapped with speculative access. However, the circuitry can be designed so that the data block from each line in a set can be loaded and then transmitted once the tag check is made. This yields the equation pair of [Equation 5.1](#).

If set associative is augmented with way prediction, then the following equations hold:

$$t_{\text{hit}} = t_{\text{rl}} + t_{\text{xb}} + (1 - F_p) t_{\text{ct}} \quad t_{\text{miss}} = t_{\text{rl}} + t_{\text{ct}} \quad (5.4)$$

where F_p is the fraction of time that the way prediction succeeds. Note that for $F_p = 1$, set associative with way prediction reduces to the same equations as direct-mapped with speculative access, which is the best case. For $F_p = 0$, the results are the same as without way prediction, which is the worst case. The prediction scheme typically used is to predict that the requested data is contained in the last block used from this set. If there is a high degree of spatial locality, then F_p will be close to 1.

Table 5.6 summarizes the cache timing equations.

Table 5.6 Cache Timing Equations

	Time for hit	Time for miss
Direct-Mapped	$t_{\text{hit}} = t_{\text{rl}} + t_{\text{xb}} + t_{\text{ct}}$	$t_{\text{miss}} = t_{\text{rl}} + t_{\text{ct}}$
Direct-Mapped with Speculation	$t_{\text{hit}} = t_{\text{rl}} + t_{\text{xb}}$	$t_{\text{miss}} = t_{\text{rl}} + t_{\text{ct}}$
Fully Associative	$t_{\text{hit}} = t_{\text{rl}} + t_{\text{xb}} + t_{\text{ct}}$	$t_{\text{miss}} = t_{\text{ct}}$
Set-Associative	$t_{\text{hit}} = t_{\text{rl}} + t_{\text{xb}} + t_{\text{ct}}$	$t_{\text{miss}} = t_{\text{rl}} + t_{\text{ct}}$
Set-Associative with Way Prediction	$t_{\text{hit}} = t_{\text{rl}} + t_{\text{xb}} + (1 - F_p) t_{\text{ct}}$	$t_{\text{miss}} = t_{\text{rl}} + t_{\text{ct}}$

Design Option for Improving Performance

Equation 4.5 expressed the mean time to access data in a memory hierarchy as follows:

$$\begin{aligned} T_s &= \sum_{\text{all paths}} [\text{Probability of taking a path} \times \text{Duration of that a path}] \\ &= \sum_{\text{all paths}} \prod (\text{All probabilities in the path}) \times \sum (\text{All times in that path}) \\ &= \sum_{i=1}^n \prod_{j=0}^{i-1} (1 - h_j) h_i \times t_I \end{aligned}$$

where

n = Number of levels of memory.

t_i = Total time needed to access data in level M_i

= The sum of all times in the path to a hit in level M_i

h_i = Hit ratio of level M_i

= Conditional probability that the data for a memory access is resident in level M_i given that it is not resident in M_{i-1}

T_S = Mean time needed to access data

This can be rearranged to show the contribution of level M_1 explicitly:

$$\begin{aligned}
 T_s &= \\
 h_1 \times t_1 + (1 - h_1) \sum_{i=2}^I \prod_{j=2}^i (1 - h_j) h_1 \times t_i & \\
 &= h_1 \times t_1 + (1 - h_1)t_{\text{penalty}}
 \end{aligned} \tag{5.3}$$

where t_{penalty} is the mean time to access data if there is a miss at level M_1 . Note that t_1 is the same quantity as t_{hit} defined at the beginning of this section, because we are referring to level M_1 .

Equation 5.3 provides insight into the approaches that can be taken to improve performance by showing three distinct parameters that can be altered. The value of T_s can be reduced by one of the following methods: reduce the hit time t_1 , reduce the miss rate $(1 - h_1)$, and reduce the miss penalty t_{penalty} . The following is a list of widely used techniques that can be used to reduce one of these parameters (**Table 5.7**):

Table 5.7 Cache Performance Improvement Techniques

Technique	Reduce t_1	Reduce $(1 - h_1)$	Reduce t_{penalty}
Way Prediction			
Cache Capacity	Small	Large	
Line Size	Small	Large	
Degree of Associativity	Decrease	Increase	
More Flexible Replacement Policies			
Cache Unity	Split I-cache and D-cache	Unified cache	
Prefetching			
Write Through		Write allocate	No write allocate
Critical Word First			
Victim Cache			
Wider Busses			

- For a set-associative cache, the use of way prediction reduces t_{hit} (**Table 5.6**).
- The access time for a smaller, more compact cache is less than for a larger cache, reducing t_{hit} . On the other hand, in general, the larger the cache, the smaller the miss rate.
- Increasing the line size can decrease the miss rate because of spatial locality. However, a larger line size means that more time is spent bringing in a line on a miss. But the chance that the additional data brought into the cache by the larger line size will be used goes down with the increased distance between addresses in the line. At some point, the amount of time spent fetching data that is not used into the cache becomes greater than the time saved through increasing the hit rate.
- The direct-mapped cache with speculation has the smallest value of t_{hit} , and the fully associative cache has the largest (**Table 5.6**). On the other hand, increasing the associativity of a cache can reduce its miss rate by reducing the number of conflict misses—misses that occur because more lines compete for a set in the cache than can fit in the set.
- If a cache is split between I-cache and D-cache, each cache is smaller, therefore reducing t_{hit} . But for the overall miss rate including instructions and data, a unified cache is likely to provide a reduced miss rate.
- The prefetching of blocks whose access is predicted for the near future can reduce t_{hit} .
- If write through is used with write allocate, the miss rate should be lower than write through, no write allocate. This is because the block that caused the cache miss is now in the cache and it is likely that future writes or perhaps reads will be to the same block. But, if no write allocate is used, then the time to complete the operation is less, reducing t_{penalty} .
- The use of the critical word first policy reduces the miss penalty by getting the request word to the processor as quickly as possible, not waiting for a cache line to be filled.
- As discussed in **Section 5.2**, a victim cache can be used to reduce the miss penalty.

A wider memory bus enables the transmission of more words in parallel between main memory and the cache, reducing the number of transfers required to load an entire cache block. This reduces the miss penalty time.

5.6 Key Terms, Review Questions, and Problems

Key Terms

Review Questions

- 5.1 What are the differences among direct mapping, associative mapping, and set-associative mapping?
- 5.2 What is the difference between associative cache memory and content-addressable memory?
- 5.3 For a direct-mapped cache, a main memory address is viewed as consisting of three fields. List and define the three fields.
- 5.4 For an associative cache, a main memory address is viewed as consisting of two fields. List and define the two fields.
- 5.5 For a set-associative cache, a main memory address is viewed as consisting of three fields. List and define the three fields.
- 5.6 What is the distinction between spatial locality and temporal locality?
- 5.7 In general, what are the strategies for exploiting spatial locality and temporal locality?

Problems

- 5.1 A cache has a line size of 64 bytes. To determine which byte within a cache line an address points to, how many bits are in the Offset field?
- 5.2 A set-associative cache consists of 64 lines, or slots, divided into four-line sets. Main memory contains 4K blocks of 128 words each. Show the format of main memory addresses.
- 5.3 A two-way set-associative cache has lines of 16 bytes and a total size of 8 kB. The 64-MB main memory is byte addressable. Show the format of main memory addresses.
- 5.4 For the hexadecimal main memory addresses 111111, 666666, BBBB, show the following information, in hexadecimal format:
 - a. Tag, Line, and Word values for a direct-mapped cache, using the format of [Figure 5.7](#)
 - b. Tag and Word values for an associative cache, using the format of [Figure 5.10](#)
 - c. Tag, Set, and Word values for a two-way set-associative cache, using the format of [Figure 5.13](#)
- 5.5 List the following values:
 - a. For the direct cache example of [Figure 5.7](#) : address length, number of addressable units, block size, number of blocks in main memory, number of lines in cache, size of tag
 - b. For the associative cache example of [Figure 5.10](#) : address length, number of addressable units, block size, number of blocks in main memory, number of lines in cache, size of tag
 - c. For the two-way set-associative cache example of [Figure 5.13](#) : address length, number of addressable units, block size, number of blocks in main memory, number of lines in set, number of sets, number of lines in cache, size of tag

- 5.6 Consider a 32-bit microprocessor that has an on-chip 16-kB four-way set-associative cache. Assume that the cache has a line size of four 32-bit words. Draw a block diagram of this cache showing its organization and how the different address fields are used to determine a cache hit/miss. Where in the cache is the word from memory location ABCDE8F8 mapped?
- 5.7 Given the following specifications for an external cache memory: four-way set associative; line size of two 16-bit words; able to accommodate a total of 4K 32-bit words from main memory; used with a 16-bit processor that issues 24-bit addresses. Design the cache structure

with all pertinent information and show how it interprets the processor's addresses.

5.8 The Intel 80486 has an on-chip, unified cache. It contains 8 kB and has a four-way set-associative organization and a block length of four 32-bit words. The cache is organized into 128 sets. There is a single "line valid bit" and three bits, B0, B1, and B2 (the "LRU" bits), per line. On a cache miss, the 80486 reads a 16-byte line from main memory in a bus memory read burst. Draw a simplified diagram of the cache and show how the different fields of the address are interpreted.

5.9 Consider a machine with a byte addressable main memory of 2^{16} bytes and block size of 8 bytes. Assume that a direct mapped cache consisting of 32 lines is used with this machine.

- How is a 16-bit memory address divided into tag, line number, and byte number?
- Into what line would bytes with each of the following addresses be stored?

0001	0001	0001	1011
1100	0011	0011	0100
1101	0000	0001	1101
1010	1010	1010	1010

- Suppose the byte with address 0001 1010 0001 1010 is stored in the cache. What are the addresses of the other bytes stored along with it?
- How many total bytes of memory can be stored in the cache?
- Why is the tag also stored in the cache?

5.10 For its on-chip cache, the Intel 80486 uses a replacement algorithm referred to as **pseudo least recently used**. Associated with each of the 128 sets of four lines (labeled L0, L1, L2, L3) are three bits B0, B1, and B2. The replacement algorithm works as follows: When a line must be replaced, the cache will first determine whether the most recent use was from L0 and L1 or L2 and L3. Then the cache will determine which of the pair of blocks was least recently used and mark it for replacement. [Figure 5.19](#) illustrates the logic.

- Specify how the bits B0, B1, and B2 are set and then describe in words how they are used in the replacement algorithm depicted in [Figure 5.19](#).
- Show that the 80486 algorithm approximates a true LRU algorithm. *Hint:* Consider the case in which the most recent order of usage is L0, L2, L3, L1.
- Demonstrate that a true LRU algorithm would require 6 bits per set.

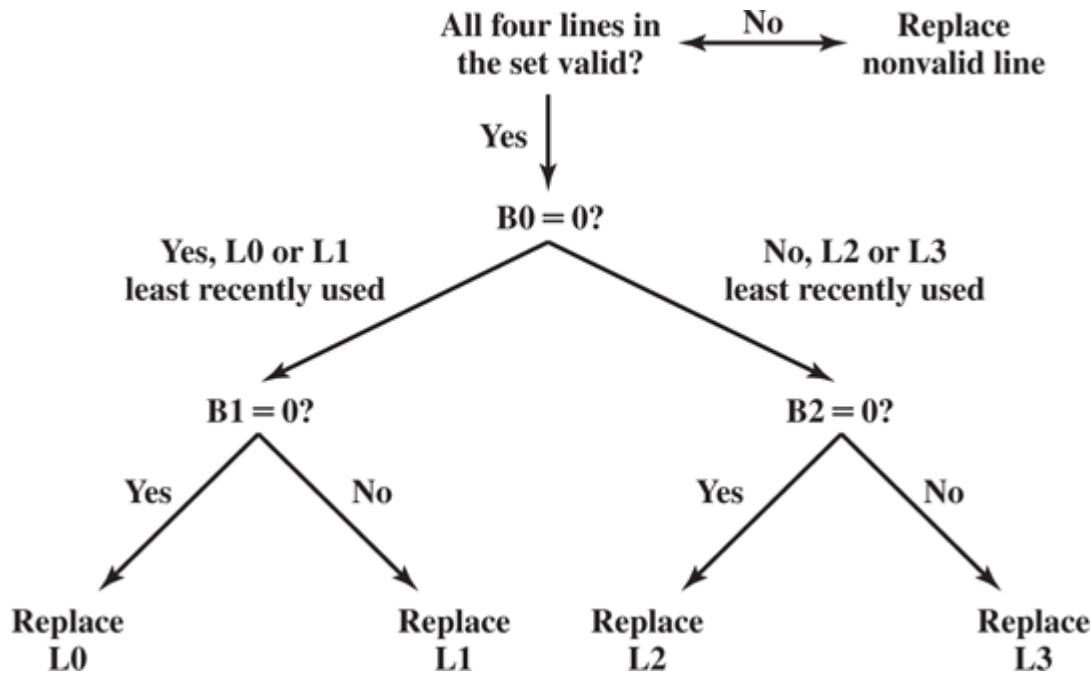

Figure 5.19 Intel 80486 On-Chip Cache Replacement Strategy

5.11 A set-associative cache has a block size of four 16-bit words and a set size of 2. The cache can accommodate a total of 4096 words. The main memory size that is cacheable is $64K \times 32$ bits. Design the cache structure and show how the processor's addresses are interpreted.

5.12 Consider a memory system that uses a 32-bit address to address at the byte level, plus a cache that uses a 64-byte line size.

- Assume a direct mapped cache with a tag field in the address of 20 bits. Show the address format and determine the following parameters: number of addressable units, number of blocks in main memory, number of lines in cache, size of tag.
- Assume an associative cache. Show the address format and determine the following parameters: number of addressable units, number of blocks in main memory, number of lines in cache, size of tag.
- Assume a four-way set-associative cache with a tag field in the address of 9 bits. Show the address format and determine the following parameters: number of addressable units, number of blocks in main memory, number of lines in set, number of sets in cache, number of lines in cache, size of tag.

5.13 Consider a computer with the following characteristics: total of 1 MB of main memory; word size of 1 byte; block size of 16 bytes; and cache size of 64 kB.

- For the main memory addresses of F0010, 01234, and CABBE, give the corresponding tag, cache line address, and word offsets for a direct-mapped cache.
- Give any two main memory addresses with different tags that map to the same cache slot for a direct-mapped cache.
- For the main memory addresses of F0010 and CABBE, give the corresponding tag and offset values for a fully-associative cache.
- For the main memory addresses of F0010 and CABBE, give the corresponding tag, cache set, and offset values for a two-way set-associative cache.

5.14 Describe a simple technique for implementing an LRU replacement algorithm in a four-way set-associative cache.

5.15 Consider again **Example 5.2**. How does the answer change if the main memory uses a block transfer capability that has a first-word access time of 30 ns and an access time of 5 ns for each word thereafter?

A computer system contains a main memory of 32K 16-bit words. It also has a 4K word cache divided into four-line sets with 64 words per line. Assume that the cache is initially empty. The processor fetches words from locations 0, 1, 2, . . . , 4351 in that order. It then repeats this fetch sequence nine more times. The cache is 10 times faster than main memory. Estimate the improvement resulting from the use of the cache. Assume an LRU policy for block replacement.

5.16 Consider a cache of 4 lines of 16 bytes each. Main memory is divided into blocks of 16 bytes each. That is, block 0 has bytes with addresses 0 through 15, and so on. Now consider a program that accesses memory in the following sequence of addresses:

Once: 63 through 70.

Loop ten times: 15 through 32; 80 through 95.

- a. Suppose the cache is organized as direct mapped. Memory blocks 0, 4, and so on are assigned to line 1; blocks 1, 5, and so on to line 2; and so on. Compute the hit ratio.
- b. Suppose the cache is organized as two-way set associative, with two sets of two lines each. Even-numbered blocks are assigned to set 0 and odd-numbered blocks are assigned to set 1. Compute the hit ratio for the two-way set-associative cache using the least recently used replacement scheme.

5.17 Consider a cache with a line size of 64 bytes. Assume that on average 30% of the lines in the cache are dirty. A word consists of 8 bytes.

- a. Assume there is a 3% miss rate (0.97 hit ratio). Compute the amount of main memory traffic, in terms of bytes per instruction for both write-through and write-back policies. Memory is read into cache one line at a time. However, for write back, a single word can be written from cache to main memory.
- b. Repeat part a for a 5% rate.
- c. Repeat part a for a 7% rate.
- d. What conclusion can you draw from these results?

5.18 The level below a cache in the memory hierarchy requires 60 ns to read or write a word of data. If the cache line size is 8 words, how many times does the average line have to be written (counting only lines that are written at least once) before a write-back cache is more efficient than a write-through cache?

6.7 Key Terms, Review Questions, and Problems

Learning Objectives

After studying this chapter, you should be able to:

- Present an overview of the principle types of semiconductor main memory.
- Understand the operation of a basic code that can detect and correct single-bit errors in 8-bit words.
- Summarize the properties of contemporary **DDR DRAM** organizations.
- Understand the difference between **NOR** and **NAND** flash memory.
- Present an overview of the newer nonvolatile solid-state memory technologies.

We begin this chapter with a survey of semiconductor main memory subsystems,

including ROM, DRAM, and SRAM memories. Then we look at error control techniques used to enhance memory reliability. Following this, we look at more advanced DRAM architectures.

6.1 Semiconductor Main Memory

In earlier computers, the most common form of random-access storage for computer main memory employed an array of doughnut-shaped ferromagnetic loops referred to as *cores*. Hence, main memory was often referred to as *core*, a term that persists to this day. The advent of, and advantages of, microelectronics has long since vanquished the magnetic core memory. Today, the use of semiconductor chips for main memory is almost universal. Key aspects of this technology are explored in this section.

Organization

The basic element of a **semiconductor memory** is the memory cell. Although a variety of electronic technologies are used, all semiconductor memory cells share certain properties:

- They exhibit two stable (or semistable) states, which can be used to represent binary 1 and 0.
- They are capable of being written into (at least once), to set the state.
- They are capable of being read to sense the state.

Figure 6.1 depicts the operation of a memory cell. Most commonly, the cell has three functional terminals capable of carrying an electrical signal. The select terminal, as the name suggests, selects a memory cell for a read or write operation. The control terminal indicates read or write. For writing, the other terminal provides an electrical signal that sets the state of the cell to 1 or 0. For reading, that terminal is used for output of the cell's state. The details of the internal organization, functioning, and timing of the memory cell depend on the specific integrated circuit technology used and are beyond the scope of this book, except for a brief summary. For our purposes, we will take it as given that individual cells can be selected for reading and writing operations.

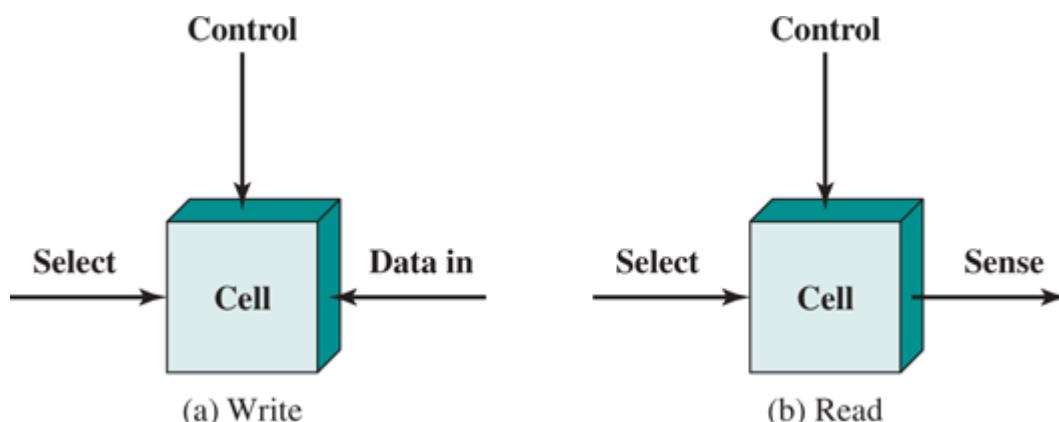

Figure 6.1 Memory Cell Operation

DRAM and SRAM

All of the memory types that we will explore in this chapter are random access. That is, individual words of memory are directly accessed through wired-in addressing logic.

Table 6.1 lists the major types of semiconductor memory. The most common is referred to as **random-access memory (RAM)**. This is, in fact, a misuse of the term, because all of the types listed in the table are random access. One distinguishing characteristic of memory that is designated as RAM is that it is possible both to read data from the memory and to write new data into the memory easily and rapidly. Both the reading and writing are accomplished through the use of electrical signals.

Table 6.1 Semiconductor Memory Types

Memory Type	Category	Erasure	Write Mechanism	Volatility
Random-access memory (RAM)	Read-write memory	Electrically, byte-level	Electrically	Volatile
Read-only memory (ROM)	Read-only memory	Not possible	Masks	Nonvolatile
Programmable ROM (PROM)			Electrically	
Erasable PROM (EPROM)		UV light, chip-level		
Electrically Erasable PROM (EEPROM)	Read-mostly memory	Electrically, byte-level		
Flash memory		Electrically, block-level		

The other distinguishing characteristic of traditional RAM is that it is volatile. A RAM must be provided with a constant power supply. If the power is interrupted, then the data are lost. Thus, RAM can be used only as temporary storage. The two traditional forms of RAM used in computers are DRAM and SRAM. Newer forms of RAM, discussed in Section 6.5, are nonvolatile.

DYNAMIC RAM

RAM technology is divided into two technologies: dynamic and static. A **dynamic RAM (DRAM)** is made with cells that store data as charge on capacitors. The presence or absence of charge in a capacitor is interpreted as a binary 1 or 0. Because capacitors have a natural tendency to discharge, dynamic

RAMs require periodic charge refreshing to maintain data storage. The term *dynamic* refers to this tendency of the stored charge to leak away, even with power continuously applied.

Figure 6.2a is a typical DRAM structure for an individual cell that stores one bit. The address line is activated when the bit value from this cell is to be read or written. The transistor acts as a switch that is closed (allowing current to flow) if a voltage is applied to the address line and open (no current flows) if no voltage is present on the address line.

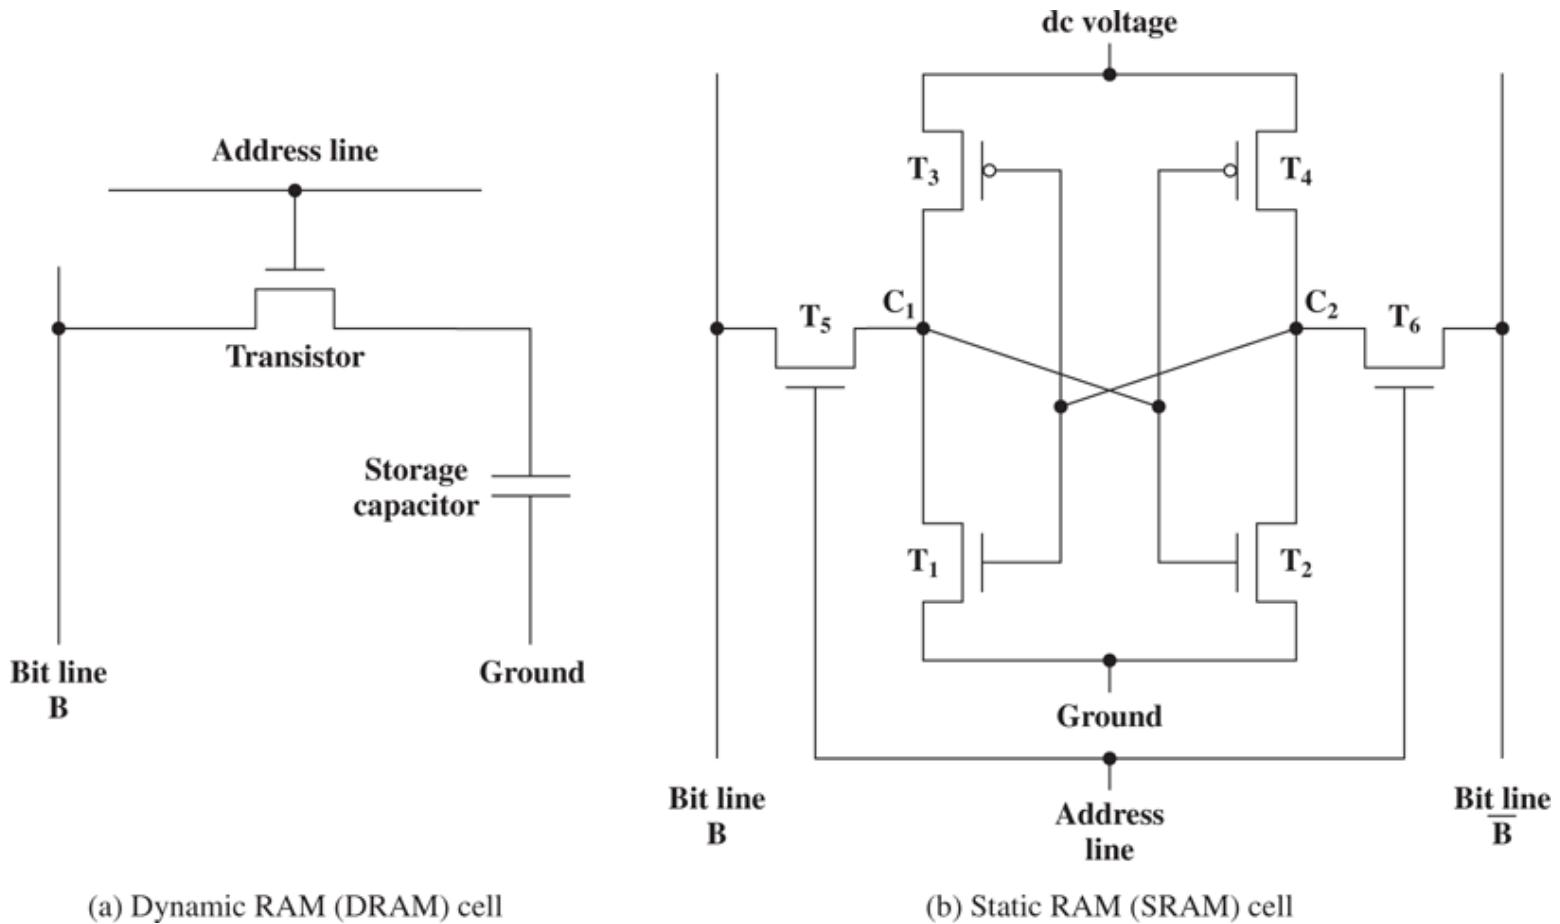

Figure 6.2 Typical Memory Cell Structures

For the write operation, a voltage signal is applied to the bit line; a high voltage represents 1, and a low voltage represents 0. A signal is then applied to the address line, allowing a charge to be transferred to the capacitor.

For the read operation, when the address line is selected, the transistor turns on and the charge stored on the capacitor is fed out onto a bit line and to a sense amplifier. The sense amplifier compares the capacitor voltage to a reference value and determines if the cell contains a logic 1 or a logic 0. The readout from the cell discharges the capacitor, which must be restored to complete the operation.

Although the DRAM cell is used to store a single bit (0 or 1), it is essentially an analog device. The capacitor can store any charge value within a range; a threshold value determines whether the charge is interpreted as 1 or 0.

STATIC RAM

In contrast, a **static RAM (SRAM)** is a digital device that uses the same logic elements used in the processor. In a SRAM, binary values are stored using traditional flip-flop logic-gate configurations (see [Chapter 12](#) for a description of flip-flops). A static RAM will hold its data as long as power is supplied to it.

[Figure 6.2b](#) is a typical SRAM structure for an individual cell. Four transistors (T_1, T_2, T_3, T_4) are cross connected in an arrangement that produces a stable logic state. In logic state 1, point C_1 is high and point C_2 is low; in this state, T_1 and T_4 are off and T_2 and T_3 are on.¹ In logic state 0, point C_1 is low and point C_2 is high; in this state, T_1 and T_4 are on and T_2 and T_3 are off. Both states are stable

as long as the direct current (dc) voltage is applied. Unlike the DRAM, no refresh is needed to retain data.

¹ The circles associated with T_3 and T_4 in **Figure 6.2b** indicate signal negation.

As in the DRAM, the SRAM address line is used to open or close a switch. The address line controls two transistors (T_5 and T_6). When a signal is applied to this line, the two transistors are switched on, allowing a read or write operation. For a write operation, the desired bit value is applied to line B, while its complement is applied to line \bar{B} . This forces the four transistors (T_1, T_2, T_3, T_4) into the proper state. For a read operation, the bit value is read from line B.

SRAM VERSUS DRAM

Both static and dynamic RAMs are volatile; that is, power must be continuously supplied to the memory to preserve the bit values. A dynamic memory cell is simpler and smaller than a static memory cell. Thus, a DRAM is more dense (smaller cells = more cells per unit area) and less expensive than a corresponding SRAM. On the other hand, a DRAM requires the supporting refresh circuitry. For larger memories, the fixed cost of the refresh circuitry is more than compensated for by the smaller variable cost of DRAM cells. Thus, DRAMs tend to be favored for large memory requirements. A final point is that SRAMs are somewhat faster than DRAMs. Because of these relative characteristics, SRAM is used for cache memory (both on and off chip), and DRAM is used for main memory.

Types of ROM

As the name suggests, a **read-only memory (ROM)** contains a permanent pattern of data that cannot be changed. A ROM is nonvolatile; that is, no power source is required to maintain the bit values in memory. While it is possible to read a ROM, it is not possible to write new data into it. An important application of ROMs is microprogramming, discussed in Part Four. Other potential applications include

- Library subroutines for frequently wanted functions
- System programs
- Function tables

For a modest-sized requirement, the advantage of ROM is that the data or program is permanently in main memory and need never be loaded from a secondary storage device.

A ROM is created like any other integrated circuit chip, with the data actually wired into the chip as part of the fabrication process. This presents two problems:

- The data insertion step includes a relatively large fixed cost, whether one or thousands of copies of a particular ROM are fabricated.
- There is no room for error. If one bit is wrong, the whole batch of ROMs must be thrown out.

When only a small number of ROMs with a particular memory content is needed, a less expensive alternative is the **programmable ROM (PROM)**. Like the ROM, the PROM is **nonvolatile** and may be written into only once. For the PROM, the writing process is performed electrically and may be performed by a supplier or customer at a time later than the original chip fabrication. Special equipment is required for the writing or “programming” process. PROMs provide flexibility and convenience. The ROM remains attractive for high-volume production runs.

Another variation on read-only memory is the **read-mostly memory**, which is useful for applications in

which read operations are far more frequent than write operations but for which nonvolatile storage is required. There are three common forms of read-mostly memory: EPROM, EEPROM, and flash memory.

The optically **erasable programmable read-only memory (EPROM)** is read and written electrically, as with PROM. However, before a write operation, all the storage cells must be erased to the same initial state by exposure of the packaged chip to ultraviolet radiation. Erasure is performed by shining an intense ultraviolet light through a window that is designed into the memory chip. This erasure process can be performed repeatedly; each erasure can take as much as 20 minutes to perform. Thus, the EPROM can be altered multiple times and, like the ROM and PROM, holds its data virtually indefinitely. For comparable amounts of storage, the EPROM is more expensive than PROM, but it has the advantage of the multiple update capability.

A more attractive form of read-mostly memory is **electrically erasable programmable read-only memory (EEPROM)**. This is a read-mostly memory that can be written into at any time without erasing prior contents; only the byte or bytes addressed are updated. The write operation takes considerably longer than the read operation, on the order of several hundred microseconds per byte. The EEPROM combines the advantage of nonvolatility with the flexibility of being updatable in place, using ordinary bus control, address, and data lines. EEPROM is more expensive than EPROM and also is less dense, supporting fewer bits per chip.

Another form of semiconductor memory is **flash memory** (so named because of the speed with which it can be reprogrammed). First introduced in the mid-1980s, flash memory is intermediate between EPROM and EEPROM in both cost and functionality. Like EEPROM, flash memory uses an electrical erasing technology. An entire flash memory can be erased in one or a few seconds, which is much faster than EPROM. In addition, it is possible to erase just blocks of memory rather than an entire chip. Flash memory gets its name because the microchip is organized so that a section of memory cells are erased in a single action or “flash.” However, flash memory does not provide byte-level erasure. Like EPROM, flash memory uses only one transistor per bit, and so achieves the high density (compared with EEPROM) of EPROM.

Chip Logic

As with other integrated circuit products, semiconductor memory comes in packaged chips (**Figure 1.10**). Each chip contains an array of memory cells.

In the memory hierarchy as a whole, we saw that there are trade-offs among speed, density, and cost. These trade-offs also exist when we consider the organization of memory cells and functional logic on a chip. For semiconductor memories, one of the key design issues is the number of bits of data that may be read/written at a time. At one extreme is an organization in which the physical arrangement of cells in the array is the same as the logical arrangement (as perceived by the processor) of words in memory. The array is organized into W words of B bits each. For example, a 16-Mbit chip could be organized as 1M 16-bit words. At the other extreme is the so-called 1-bit-per-chip organization, in which data are read/written one bit at a time. We will illustrate memory chip organization with a DRAM; ROM organization is similar, though simpler.

Figure 6.3 shows a typical organization of a 16-Mbit DRAM. In this case, 4 bits are read or written at a time. Logically, the memory array is organized as four square arrays of 2048 by 2048 elements. Various physical arrangements are possible. In any case, the elements of the array are connected by both horizontal (row) and vertical (column) lines. Each horizontal line connects to the Select terminal of each cell in its row; each vertical line connects to the Data-In/Sense terminal of each cell in its column.

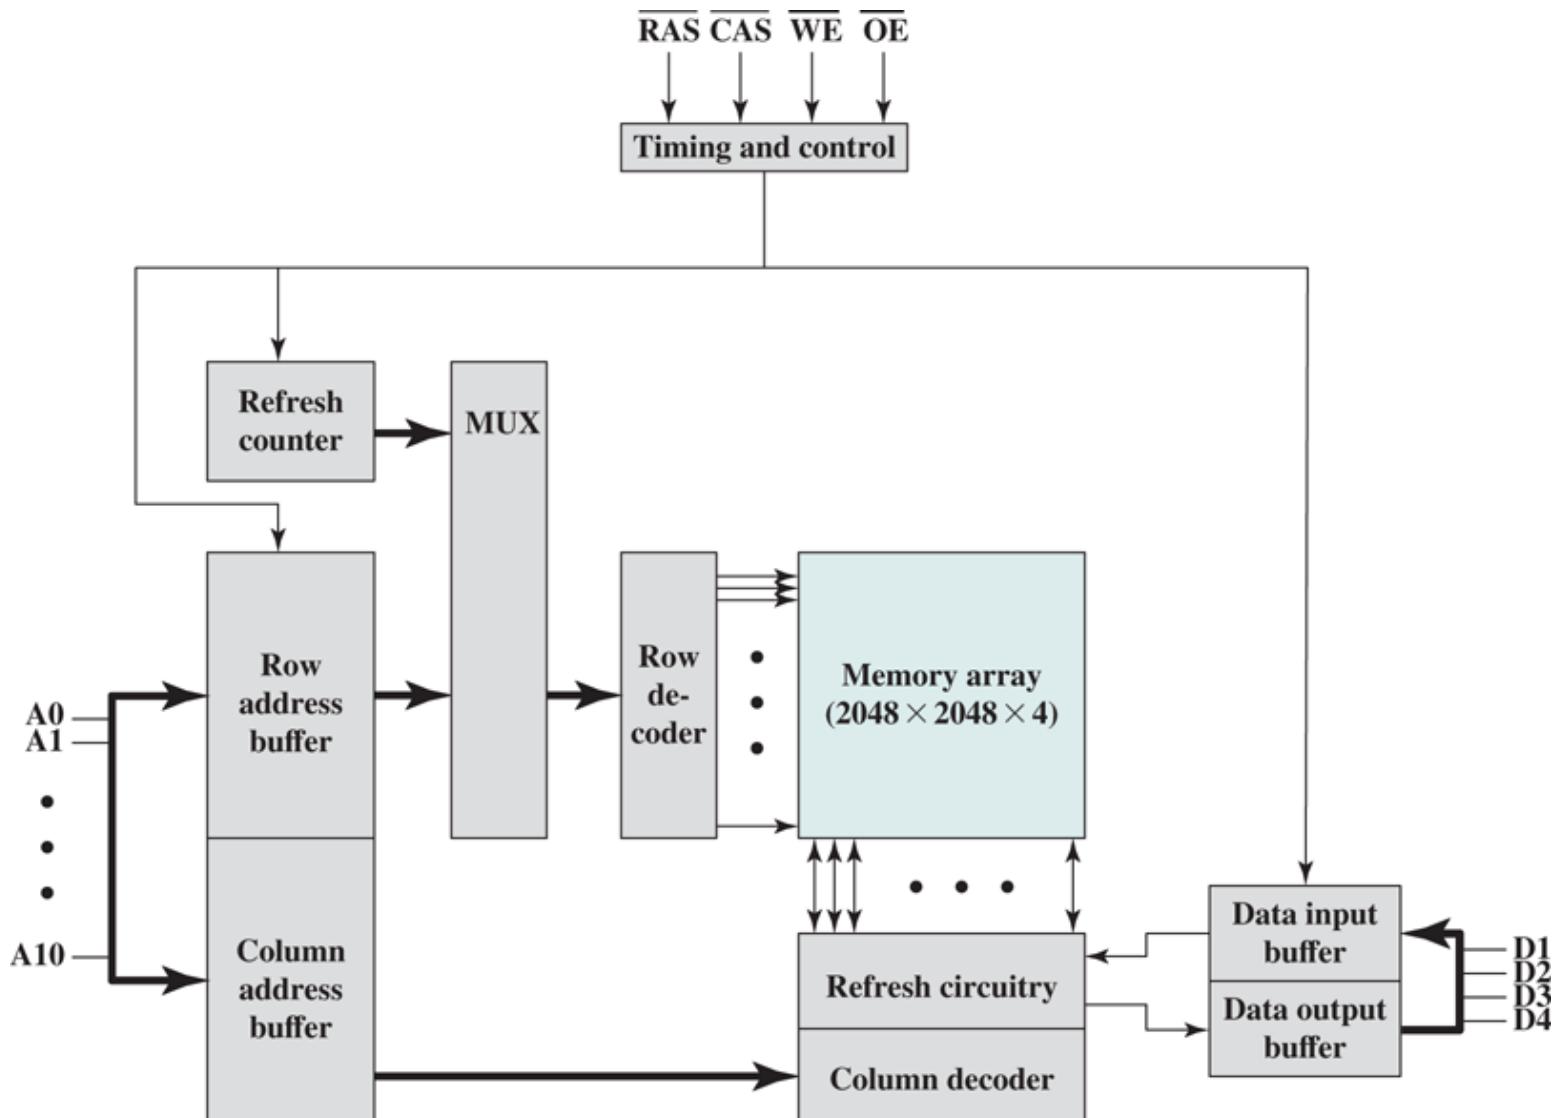

Figure 6.3 Typical 16-Mbit DRAM (4M × 4)

Address lines supply the address of the word to be selected. A total of $\log_2 W$ lines are needed. In our example, 11 address lines are needed to select one of 2048 rows. These 11 lines are fed into a row decoder, which has 11 lines of input and 2048 lines for output. The logic of the decoder activates a single one of the 2048 outputs depending on the bit pattern on the 11 input lines ($2^{11} = 2048$).

An additional 11 address lines select one of 2048 columns of 4 bits per column. Four data lines are used for the input and output of 4 bits to and from a data buffer. On input (write), the bit driver of each bit line is activated for a 1 or 0 according to the value of the corresponding data line. On output (read), the value of each bit line is passed through a sense amplifier and presented to the data lines. The row line selects which row of cells is used for reading or writing.

Because only 4 bits are read/written to this DRAM, there must be multiple DRAMs connected to the memory controller to read/write a word of data to the bus.

Note that there are only 11 address lines (A0–A10), half the number you would expect for a 2048×2048 array. This is done to save on the number of pins. The 22 required address lines are passed through select logic external to the chip and multiplexed onto the 11 address lines. First, 11 address signals are passed to the chip to define the row address of the array, and then the other 11 address signals are presented for the column address. These signals are accompanied by row address select (RAS) and column address select (CAS) signals to provide timing to the chip.

The write enable (WE) and output enable (OE) pins determine whether a write or read operation is performed. Two other pins, not shown in **Figure 6.3**, are ground (V_{ss}) and a voltage source (V_{cc}).

As an aside, multiplexed addressing plus the use of square arrays result in a quadrupling of memory size with each new generation of memory chips. One more pin devoted to addressing doubles the number of rows and columns, and so the size of the chip memory grows by a factor of 4.

Figure 6.3 also indicates the inclusion of refresh circuitry. All DRAMs require a refresh operation. A simple technique for refreshing is, in effect, to disable the DRAM chip while all data cells are refreshed. The refresh counter steps through all of the row values. For each row, the output lines from the refresh counter are supplied to the row decoder and the RAS line is activated. The data are read out and written back into the same location. This causes each cell in the row to be refreshed.

Chip Packaging

As was mentioned in **Chapter 2**, an integrated circuit is mounted on a package that contains pins for connection to the outside world.

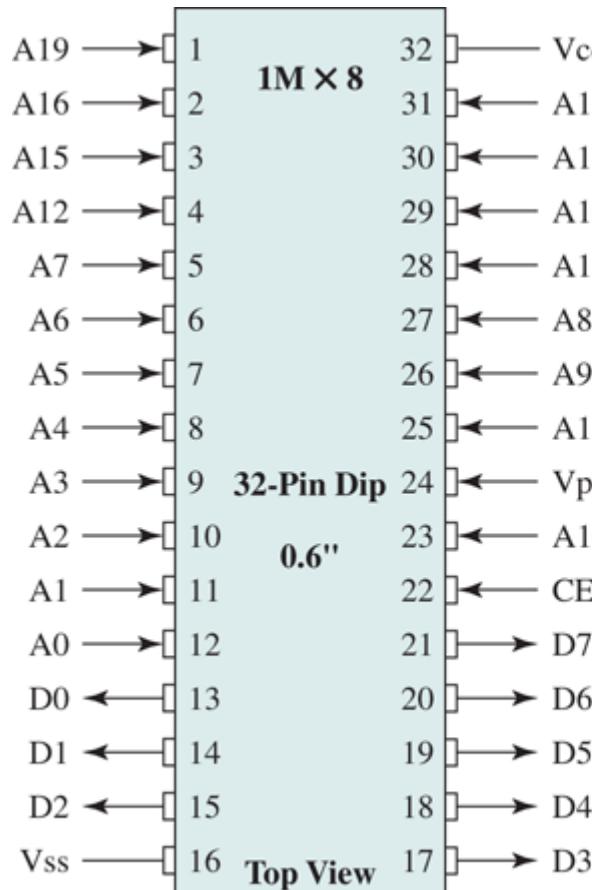

Figure 6.4a shows an example EPROM package, which is an 8-Mbit chip organized as 1M × 8. In this case, the organization is treated as a one-word-per-chip package. The package includes 32 pins, which is one of the standard chip package sizes. The pins support the following signal lines:

- The address of the word being accessed. For 1M words, a total of $20 (2^{20} = 1M)$ pins are needed (A₀–A₁₉).
- The data to be read out, consisting of 8 lines (D₀–D₇).
- The power supply to the chip (V_{cc}) .
- A ground pin (V_{ss}) .
- A chip enable (CE) pin. Because there may be more than one memory chip, each of which is connected to the same address bus, the CE pin is used to indicate whether or not the address is valid for this chip. The CE pin is activated by logic connected to the higher-order bits of the address bus (i.e., address bits above A₁₉). The use of this signal is illustrated presently.
- A program voltage (V_{pp}) that is supplied during programming (write operations).

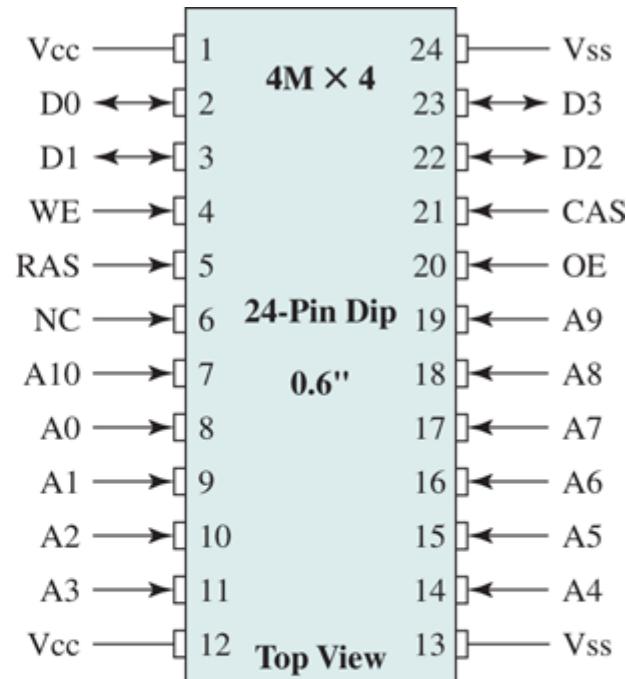

A typical DRAM pin configuration is shown in **Figure 6.4b**, for a 16-Mbit chip organized as 4M × 4.

There are several differences from a ROM chip. Because a RAM can be updated, the data pins are input/output. The write enable (WE) and output enable (OE) pins indicate whether this is a write or read operation. Because the DRAM is accessed by row and column, and the address is multiplexed, only 11 address pins are needed to specify the 4M row/column combinations ($2^{11} \times 2^{11} = 2^{22} = 4M$).

The functions of the row address select (RAS) and column address select (CAS) pins were discussed previously. Finally, the no connect (NC) pin is provided so that there are an even number of pins.

(a) 8-Mbit EPROM

(b) 16-Mbit DRAM

Figure 6.4 Typical Memory Package Pins and Signals

Module Organization

If a RAM chip contains only one bit per word, then clearly we will need at least a number of chips equal to the number of bits per word. As an example, [Figure 6.5](#) shows how a memory module consisting of 256K 8-bit words could be organized. For 256K words, an 18-bit address is needed and is supplied to the module from some external source (e.g., the address lines of a bus to which the module is attached). The address is presented to 8256K \times 1-bit chips, each of which provides the input/output of one bit.

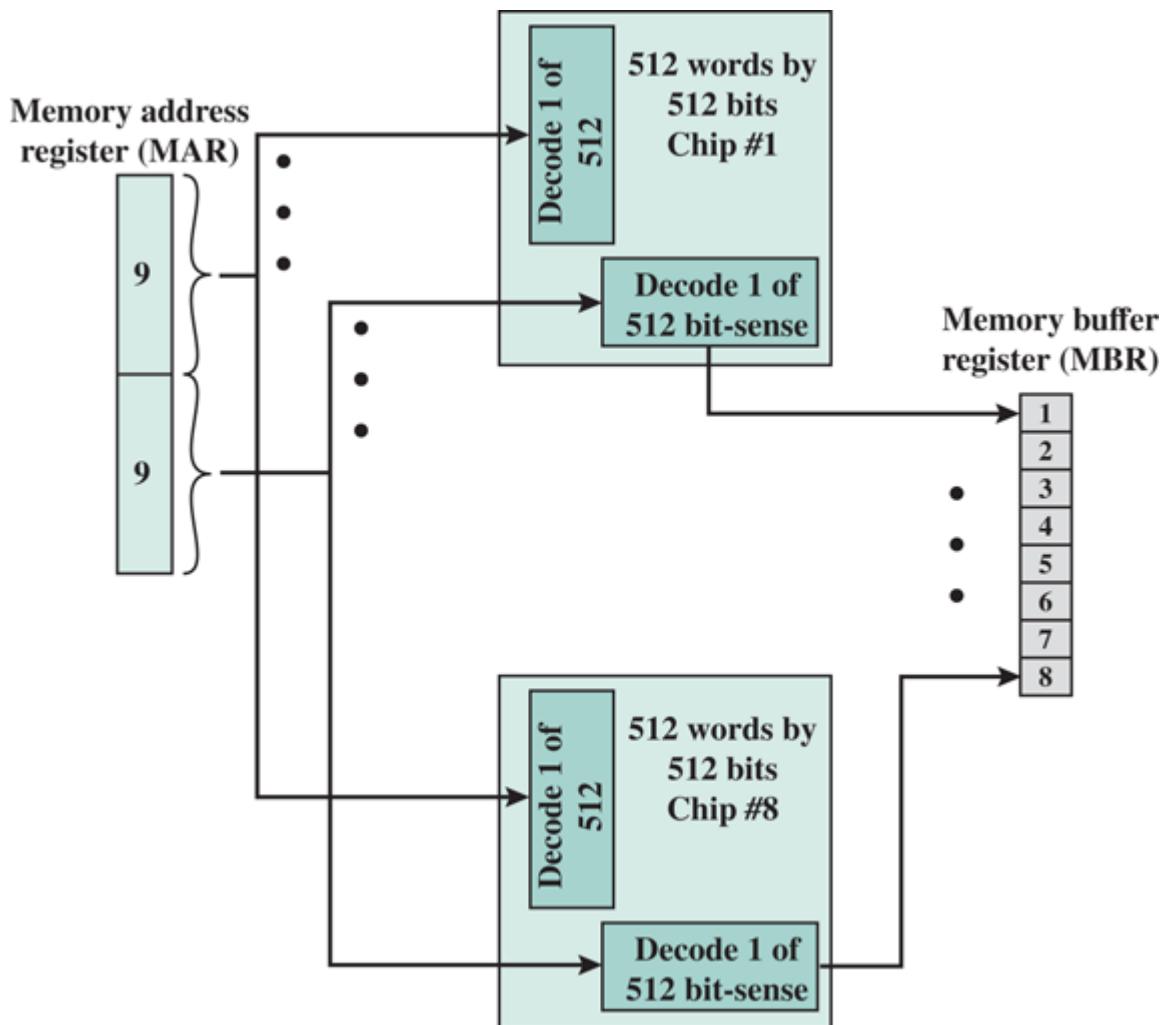

Figure 6.5 256-KByte Memory Organization

This organization works as long as the size of memory in words equals the number of bits per chip. In the case in which larger memory is required, an array of chips is needed. [Figure 6.6](#) shows the possible organization of a memory consisting of 1M word by 8 bits per word. In this case, we have four columns of chips, each column containing 256K words arranged as in [Figure 6.5](#). For 1M word, 20 address lines are needed. The 18 least significant bits are routed to all 32 modules. The high-order 2 bits are input to a group select logic module that sends a chip enable signal to one of the four columns of modules.

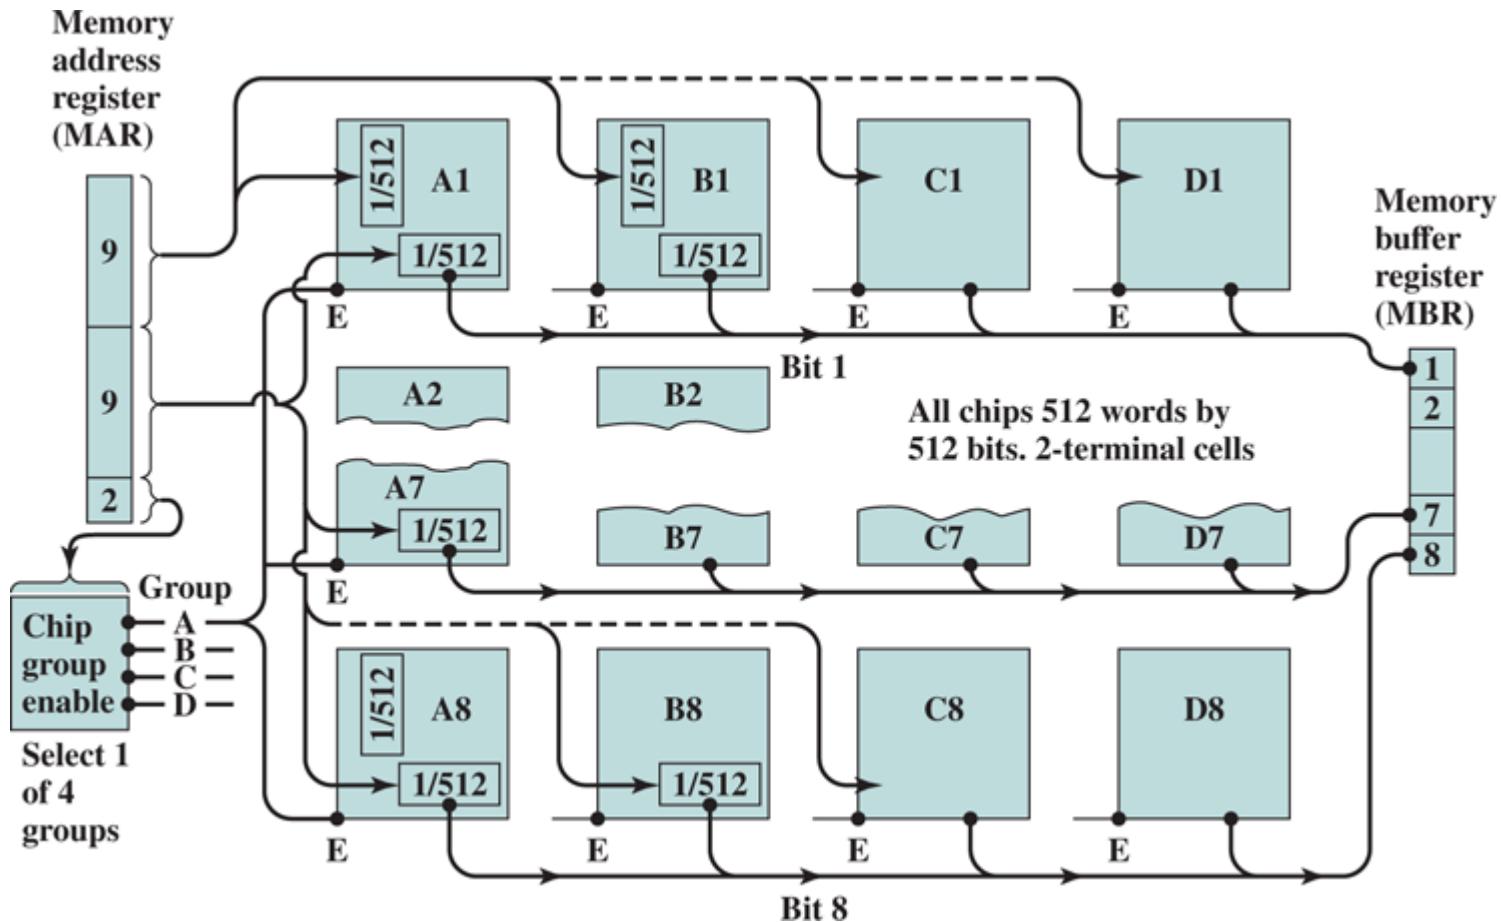

Figure 6.6 1-MB Memory Organization

Interleaved Memory

Main memory is composed of a collection of DRAM memory chips. A number of chips can be grouped together to form a *memory bank*. It is possible to organize the memory banks in a way known as interleaved memory. Each bank is independently able to service a memory read or write request, so that a system with K banks can service K requests simultaneously, increasing memory read or write rates by a factor of K . If consecutive words of memory are stored in different banks, then the transfer of a block of memory is speeded up. Appendix C explores the topic of interleaved memory.

Aleksandr Lukin/123RF

Interleaved Memory Simulator

6.2 Error Correction

A semiconductor memory system is subject to errors. These can be categorized as hard failures and soft errors. A **hard failure** is a permanent physical defect so that the memory cell or cells affected cannot reliably store data but become stuck at 0 or 1 or switch erratically between 0 and 1. Hard errors can be caused by harsh environmental abuse, manufacturing defects, and wear. A **soft error** is a random, nondestructive event that alters the contents of one or more memory cells without damaging the memory. Soft errors can be caused by power supply problems or alpha particles. These particles result from radioactive decay and are distressingly common because radioactive nuclei are found in small quantities in nearly all materials. Both hard and soft errors are clearly undesirable, and most modern main memory systems include logic for both detecting and correcting errors.

Figure 6.7 illustrates in general terms how the process is carried out. When data are to be written into memory, a calculation, depicted as a function f , is performed on the data to produce a code. Both the code and the data are stored. Thus, if an M -bit word of data is to be stored and the code is of length K bits, then the actual size of the stored word is $M + K$ bits.

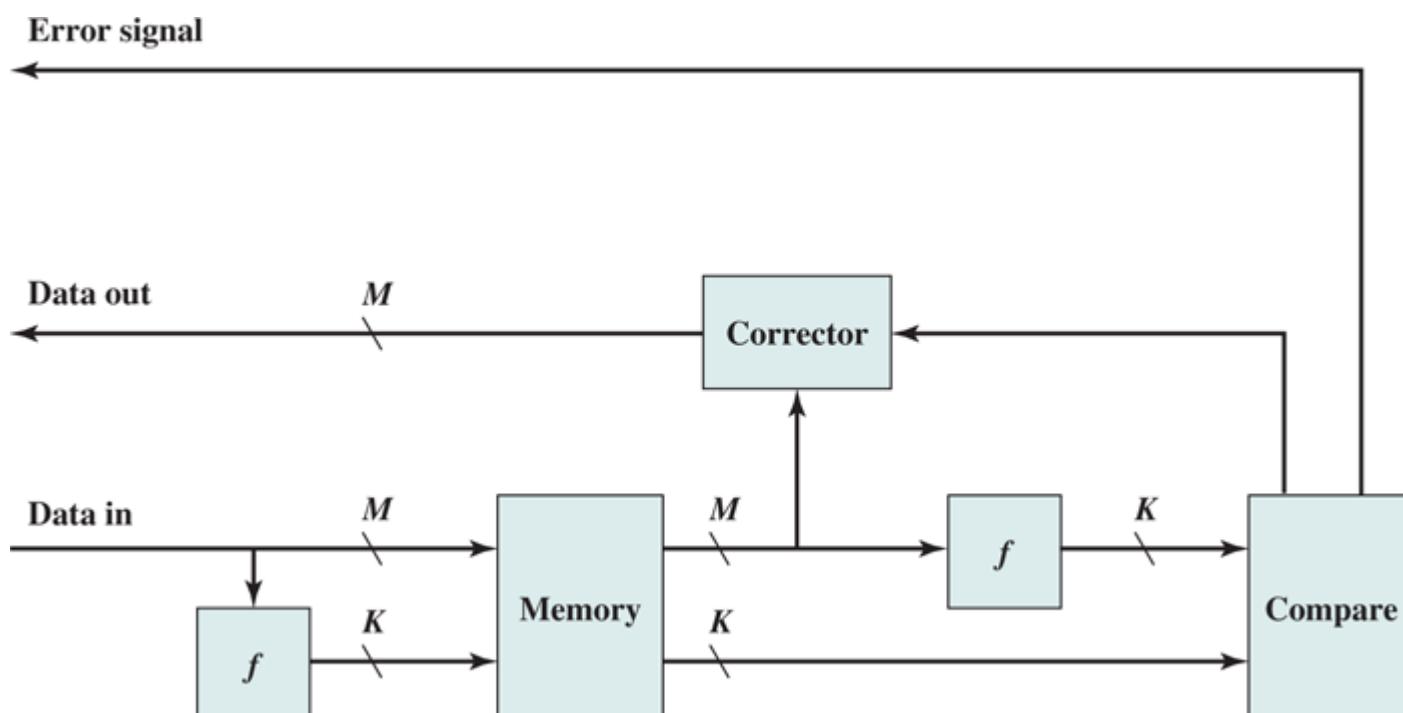

Figure 6.7 Error-Correcting Code Function

When the previously stored word is read out, the code is used to detect and possibly correct errors. A new set of K code bits is generated from the M data bits and compared with the fetched code bits. The comparison yields one of three results:

- No errors are detected. The fetched data bits are sent out.
- An error is detected, and it is possible to correct the error. The data bits plus **error correction** bits are fed into a corrector, which produces a corrected set of M bits to be sent out.
- An error is detected, but it is not possible to correct it. This condition is reported.

Codes that operate in this fashion are referred to as **error-correcting codes**. A code is characterized by the number of bit errors in a word that it can correct and detect.

The simplest of the error-correcting codes is the **Hamming code** devised by Richard Hamming at Bell Laboratories. **Figure 6.8** uses Venn diagrams to illustrate the use of this code on 4-bit words ($M = 4$).

With three intersecting circles, there are seven compartments. We assign the 4 data bits to the inner compartments (**Figure 6.8a**). The remaining compartments are filled with what are called *parity bits*. Each parity bit is chosen so that the total number of 1s in its circle is even (**Figure 6.8b**). Thus, because circle A includes three data 1s, the parity bit in that circle is set to 1. Now, if an error changes one of the data bits (**Figure 6.8c**), it is easily found. By checking the parity bits, discrepancies are found in circle A and circle C but not in circle B. Only one of the seven compartments is in A and C but not B (Figure 6.8d). The error can therefore be corrected by changing that bit.

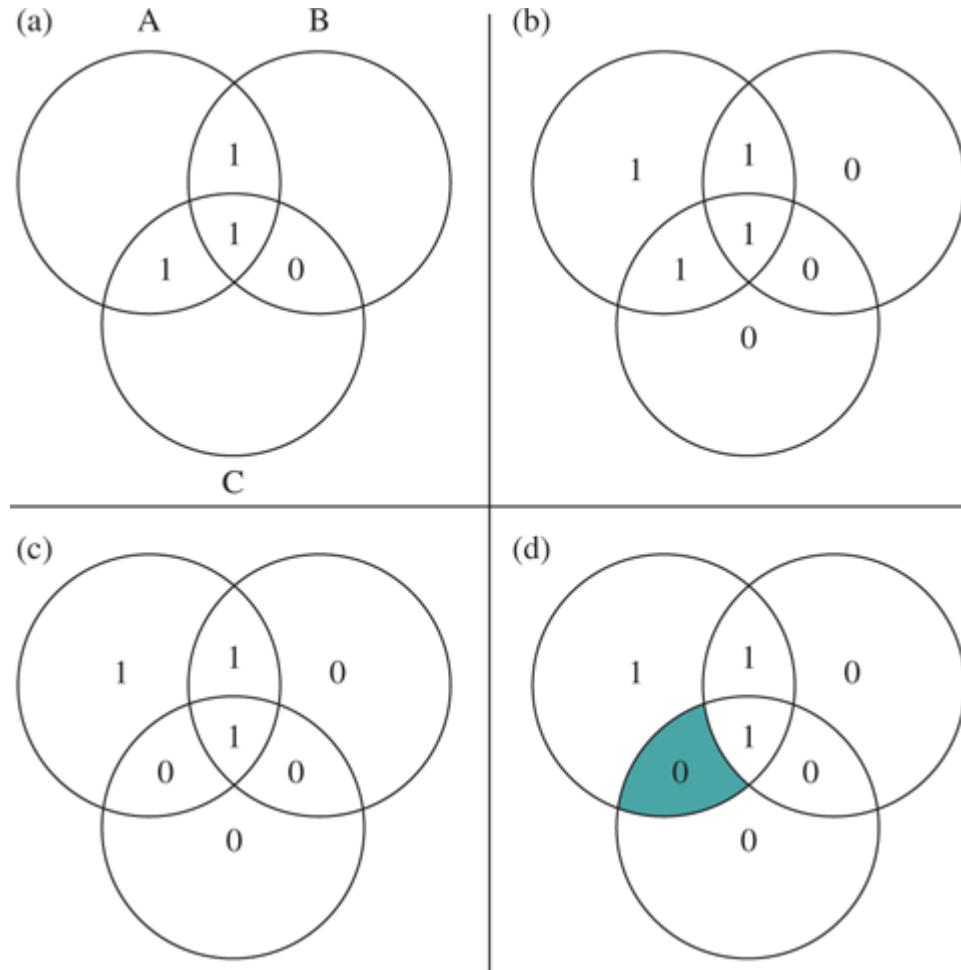

Figure 6.8 Hamming Error-Correcting Code

To clarify the concepts involved, we will develop a code that can detect and correct single-bit errors in 8-bit words.

To start, let us determine how long the code must be. Referring to **Figure 6.7**, the comparison logic receives as input two K -bit values. A bit-by-bit comparison is done by taking the exclusive-OR of the two inputs. The result is called the *syndrome word*. Thus, each bit of the **syndrome** is 0 or 1 according to if there is or is not a match in that bit position for the two inputs.

The syndrome word is therefore K bits wide and has a range between 0 and $2^K - 1$. The value 0 indicates that no error was detected, leaving $2^K - 1$ values to indicate, if there is an error, which bit was in error. Now, because an error could occur on any of the M data bits or K check bits, we must have

$$2^K - 1 \geq M + K$$

This inequality gives the number of bits needed to correct a single bit error in a word containing M

data bits. For example, for a word of 8 data bits ($M = 8$), we have

- $K = 3 : 2^3 - 1 < 8 + 3$
- $K = 4 : 2^4 - 1 > 8 + 4$

Thus, eight data bits require four check bits. The first three columns of **Table 6.2** lists the number of check bits required for various data word lengths.

Table 6.2 Increase in Word Length with Error Correction

Single-Error Correction			Single-Error Correction/ Double-Error Detection	
Data Bits	Check Bits	% Increase	Check Bits	% Increase
8	4	50.0	5	62.5
16	5	31.25	6	37.5
32	6	18.75	7	21.875
64	7	10.94	8	12.5
128	8	6.25	9	7.03
256	9	3.52	10	3.91

For convenience, we would like to generate a 4-bit syndrome for an 8-bit data word with the following characteristics:

- If the syndrome contains all 0s, no error has been detected.
- If the syndrome contains one and only one bit set to 1, then an error has occurred in one of the 4 check bits. No correction is needed.
- If the syndrome contains more than one bit set to 1, then the numerical value of the syndrome indicates the position of the data bit in error. This data bit is inverted for correction.

To achieve these characteristics, the data and check bits are arranged into a 12-bit word as depicted in **Figure 6.9**. The bit positions are numbered from 1 to 12. Those bit positions whose position numbers are powers of 2 are designated as check bits. The check bits are calculated as follows, where the symbol \oplus designates the exclusive-OR operation:

$$\begin{aligned}
 C_1 &= D_1 \oplus D_2 \oplus D_4 \oplus D_5 \oplus D_7 \\
 C_2 &= D_1 \oplus D_3 \oplus D_4 \oplus D_6 \oplus D_7 \\
 C_4 &= D_2 \oplus D_3 \oplus D_4 \oplus D_8 \\
 C_8 &= D_5 \oplus D_6 \oplus D_7 \oplus D_8
 \end{aligned}$$

Each check bit operates on every data bit whose position number contains a 1 in the same bit position as the position number of that check bit. Thus, data bit positions 3, 5, 7, 9, and 11 (D_1, D_2, D_4, D_5, D_7) all contain a 1 in the least significant bit of their position number as does C_1 ; bit positions 3, 6, 7, 10, and 11 all contain a 1 in the second bit position, as does C_2 ; and so on. Looked at another way, bit position n is checked by those bits C such that $\sum i = n$. For example, position 7 is checked by bits

i *i*
in position 4, 2, and 1; and $7 = 4 + 2 + 1$.

Bit position	12	11	10	9	8	7	6	5	4	3	2	1
Position number	1100	1011	1010	1001	1000	0111	0110	0101	0100	0011	0010	0001
Data bit	D8	D7	D6	D5		D4	D3	D2		D1		
Check bit					C8				C4		C2	C1

Figure 6.9 Layout of Data Bits and Check Bits

Let us verify that this scheme works with an example. Assume that the 8-bit input word is 00111001, with data bit D1 in the rightmost position. The calculations are as follows:

$$\begin{aligned} C1 &= 1 \oplus 0 \oplus 1 \oplus 1 \oplus 0 = 1 \\ C2 &= 1 \oplus 0 \oplus 1 \oplus 1 \oplus 0 = 1 \\ C4 &= 0 \oplus 0 \oplus 1 \oplus 0 = 1 \\ C8 &= 1 \oplus 1 \oplus 0 \oplus 0 = 0 \end{aligned}$$

Suppose now that data bit 3 sustains an error and is changed from 0 to 1. When the check bits are recalculated, we have

$$\begin{aligned} C1 &= 1 \oplus 0 \oplus 1 \oplus 1 \oplus 0 = 1 \\ C2 &= 1 \oplus 1 \oplus 1 \oplus 1 \oplus 0 = 0 \\ C4 &= 0 \oplus 1 \oplus 1 \oplus 0 = 0 \\ C8 &= 1 \oplus 1 \oplus 0 \oplus 0 = 0 \end{aligned}$$

When the new check bits are compared with the old check bits, the syndrome word is formed:

$$\begin{array}{cccc} C8 & C4 & C2 & C1 \\ 0 & 1 & 1 & 1 \\ \oplus & 0 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{array}$$

The result is 0110, indicating that bit position 6, which contains data bit 3, is in error.

Figure 6.10 illustrates the preceding calculation. The data and check bits are positioned properly in the 12-bit word. Four of the data bits have a value 1 (shaded in the table), and their bit position values are XORed to produce the Hamming code 0111, which forms the four check digits. The entire block that is stored is 001101001111. Suppose now that data bit 3, in bit position 6, sustains an error and is changed from 0 to 1. The resulting block is 001101101111, with a Hamming code of 0001. An XOR of the Hamming code and all of the bit position values for nonzero data bits results in 0110. The nonzero result detects an error and indicates that the error is in bit position 6.

Bit position	12	11	10	9	8	7	6	5	4	3	2	1
Position number	1100	1011	1010	1001	1000	0111	0110	0101	0100	0011	0010	0001
Data bit	D8	D7	D6	D5		D4	D3	D2		D1		
Check bit					C8				C4		C2	C1
Word stored as	0	0	1	1	0	1	0	0	1	1	1	1
Word fetched as	0	0	1	1	0	1	1	0	1	1	1	1
Position number	1100	1011	1010	1001	1000	0111	0110	0101	0100	0011	0010	0001
Check bit					0				0		0	1

Figure 6.10 Check Bit Calculation

The code just described is known as a **single-error-correcting (SEC) code**. More commonly, semiconductor memory is equipped with a **single-error-correcting, double-error-detecting (SEC-DED) code**. As **Table 6.2** shows, such codes require one additional bit compared with SEC codes.

Figure 6.11 illustrates how such a code works, again with a 4-bit data word. The sequence shows that if two errors occur (**Figure 6.11c**), the checking procedure goes astray (d) and worsens the problem by creating a third error (e). To overcome the problem, an eighth bit is added that is set so that the total number of 1s in the diagram is even. The extra parity bit catches the error (f).

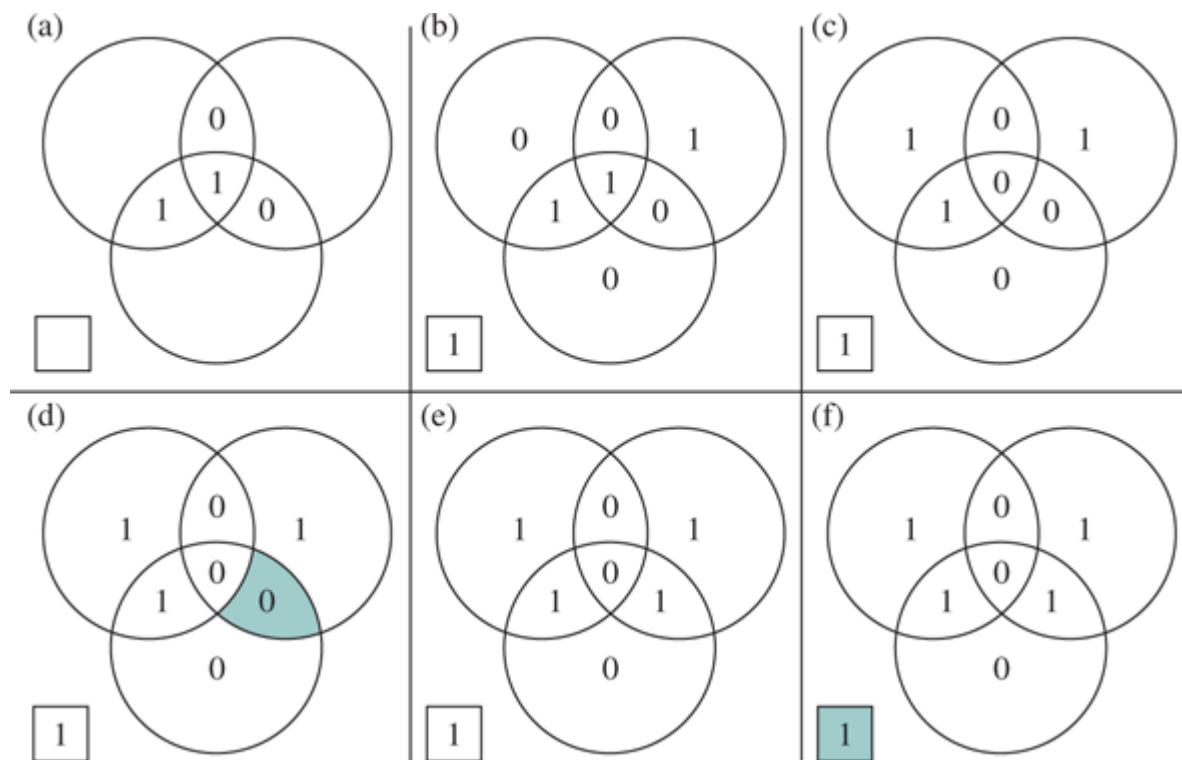

Figure 6.11 Hamming SEC-DEC Code

An error-correcting code enhances the reliability of the memory at the cost of added complexity. With a 1-bit-per-chip organization, an SEC-DED code is generally considered adequate. For example, the IBM 30xx implementations used an 8-bit SEC-DED code for each 64 bits of data in main memory. Thus, the size of main memory is actually about 12% larger than is apparent to the user. The VAX computers used a 7-bit SEC-DED for each 32 bits of memory, for a 22% overhead. Contemporary

DRAM systems may have anywhere from 7% to 20% overhead [SHAR03].

6.3 DDR DRAM

As discussed in [Chapter 1](#), one of the most critical system bottlenecks when using high-performance processors is the interface to internal main memory. This interface is the most important pathway in the entire computer system. The basic building block of main memory remains the DRAM chip, as it has for decades; until recently, there had been no significant changes in DRAM architecture since the early 1970s. The traditional DRAM chip is constrained both by its internal architecture and by its interface to the processor's memory bus.

We have seen that one attack on the performance problem of DRAM main memory has been to insert one or more levels of high-speed SRAM cache between the DRAM main memory and the processor. But SRAM is much costlier than DRAM, and expanding cache size beyond a certain point yields diminishing returns.

In recent years, a number of enhancements to the basic DRAM architecture have been explored. The schemes that currently dominate the market are SDRAM and DDR-DRAM. We examine each of these in turn.

Synchronous DRAM

One of the most widely used forms of DRAM is the [synchronous DRAM \(SDRAM\)](#). Unlike the traditional DRAM, which is asynchronous, the SDRAM exchanges data with the processor synchronized to an external clock signal and running at the full speed of the processor/memory bus without imposing wait states.

In a typical DRAM, the processor presents addresses and control levels to the memory, indicating that a set of data at a particular location in memory should be either read from or written into the DRAM. After a delay, the access time, the DRAM either writes or reads the data. During the access-time delay, the DRAM performs various internal functions, such as activating the high capacitance of the row and column lines, sensing the data, and routing the data out through the output buffers. The processor must simply wait through this delay, slowing system performance.

With synchronous access, the DRAM moves data in and out under control of the system clock. The processor or other master issues the instruction and address information, which is latched by the DRAM. The DRAM then responds after a set number of clock cycles. Meanwhile, the master can safely do other tasks while the SDRAM is processing the request.

[Figure 6.12](#) shows the internal logic of a typical 256-Mb SDRAM typical of SDRAM organization, and [Table 6.3](#) defines the various pin assignments. The SDRAM employs a burst mode to eliminate the address setup time and row and column line precharge time after the first access. In burst mode, a series of data bits can be clocked out rapidly after the first bit has been accessed. This mode is useful when all the bits to be accessed are in sequence and in the same row of the array as the initial access. In addition, the SDRAM has a multiple-bank internal architecture that improves opportunities for on-chip parallelism.

Table 6.3 SDRAM Pin Assignments

A0 to A13	Address inputs
BA0, BA1	Bank address lines

CLK	Clock input
CKE	Clock enable
CS	Chip select
RAS	Row address strobe
CAS	Column address strobe
WE	Write enable
DQ0 to DQ7	Data input/output
DQM	Data mask

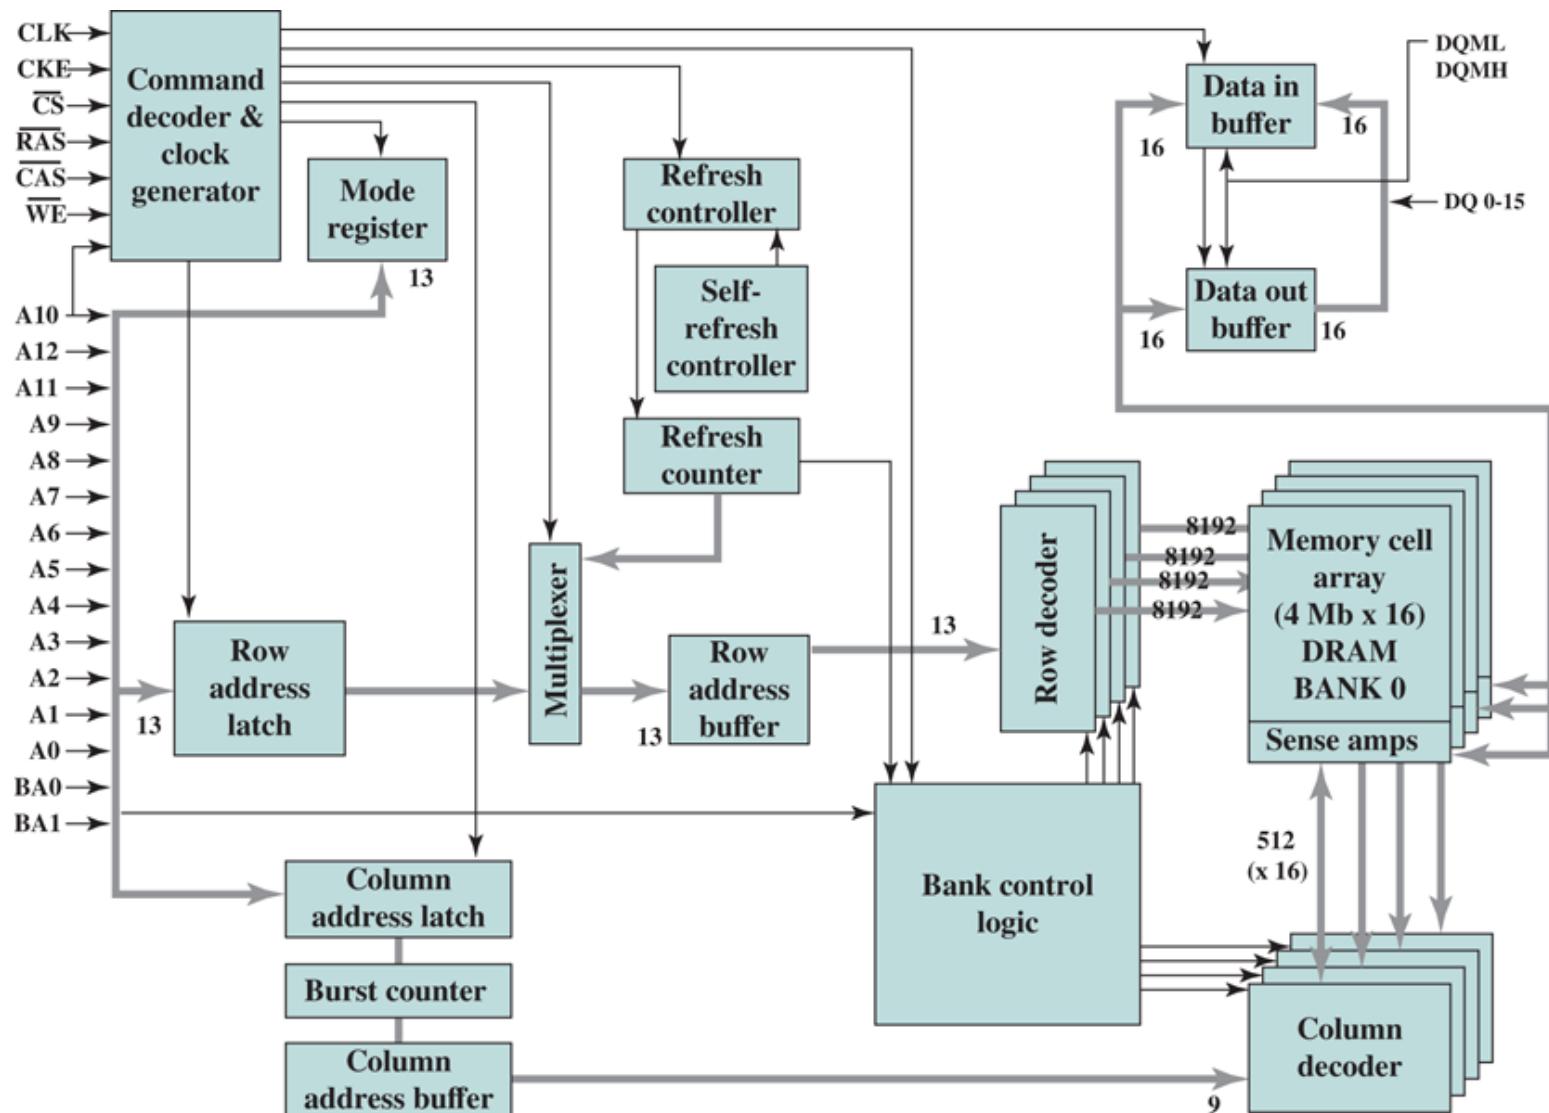

Figure 6.12 256-Mb Synchronous Dynamic RAM (SDRAM)

The mode register and associated control logic is another key feature differentiating SDRAMs from conventional DRAMs. It provides a mechanism to customize the SDRAM to suit specific system requirements.

needs. The mode register specifies the burst length, which is the number of separate units of data synchronously fed onto the bus. The register also allows the programmer to adjust the latency between receipt of a read request and the beginning of data transfer.

The SDRAM performs best when it is transferring large blocks of data sequentially, such as for applications like word processing, spreadsheets, and multimedia.

Figure 6.13 shows an example of SDRAM operation, using a **timing diagram**. A timing diagram shows the signal level on a line as a function of time. By convention, the binary 1 signal level is depicted as a higher level than that of binary 0. Usually, binary 0 is the default value. That is, if no data or other signal is being transmitted, then the level on a line is that which represents binary 0. A signal transition from 0 to 1 is frequently referred to as the signal's *leading edge*; a transition from 1 to 0 is referred to as a *trailing edge*. Such transitions are not instantaneous, but this transition time is usually small compared with the duration of a signal level. For clarity, the transition is usually depicted as an angled line that exaggerates the relative amount of time that the transition takes. Signals are sometimes represented in groups, shown as shaded areas in **Figure 6.13**. For example, if data are transferred a byte at a time, then eight lines are required. Generally, it is not important to know the exact value being transferred on such a group, but rather whether signals are present or not.

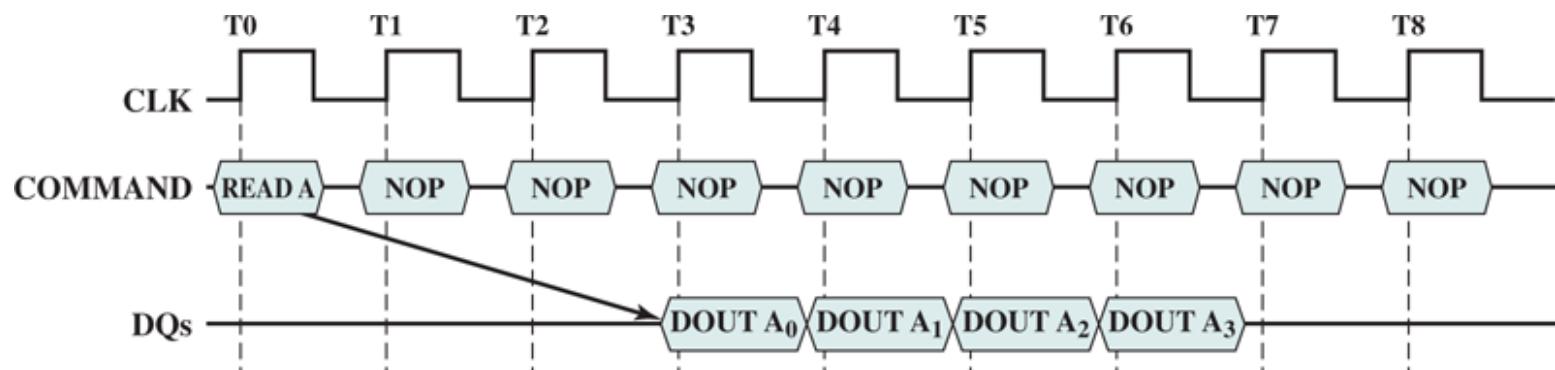

Figure 6.13 SDRAM Read Timing (burstlength = 4 , CASlatency = 2)

For the SDRAM operation in **Figure 6.13**, the burst length is 4 and the latency is 2. The burst read command is initiated by having CS and CAS low while holding RAS and WE high at the rising edge of the clock. The address inputs determine the starting column address for the burst, and the mode register sets the type of burst (sequential or interleave) and the burst length (1, 2, 4, 8, full page). The delay from the start of the command to when the data from the first cell appears on the outputs is equal to the value of the CAS latency that is set in the mode register.

DDR SDRAM

Although SDRAM is a significant improvement on asynchronous RAM, it still has shortcomings that unnecessarily limit the I/O data rate that can be achieved. To address these shortcomings a newer version of SDRAM, referred to as double-data-rate DRAM (DDR DRAM) provides several features that dramatically increase the data rate. DDR DRAM was developed by the JEDEC Solid State Technology Association, the Electronic Industries Alliance's semiconductor-engineering-standardization body. Numerous companies make DDR chips, which are widely used in desktop computers and servers.

DDR achieves higher data rates in three ways. First, the data transfer is synchronized to both the rising and falling edge of the clock, rather than just the rising edge. This doubles the data rate; hence

the term *double data rate*. Second, DDR uses higher clock rate on the bus to increase the transfer rate. Third, a buffering scheme is used, as explained subsequently.

JEDEC has thus far defined four generations of the DDR technology (**Table 6.4**). The initial DDR version makes use of a 2-bit prefetch buffer. The prefetch buffer is a memory cache located on the SDRAM chip. It enables the SDRAM chip to preposition bits to be placed on the data bus as rapidly as possible. The DDR I/O bus uses the same clock rate as the memory chip, but because it can handle two bits per cycle, it achieves a data rate that is double the clock rate. The 2-bit prefetch buffer enables the SDRAM chip to keep up with the I/O bus.

Table 6.4 DDR Characteristics

	DDR1	DDR2	DDR3	DDR4
Prefetch buffer (bits)	2	4	8	8
Voltage level (V)	2.5	1.8	1.5	1.2
Front side bus data rates (Mbps)	200—400	400—1066	800—2133	2133—4266

To understand the operation of the prefetch buffer, we need to look at it from the point of view of a word transfer. The prefetch buffer size determines how many words of data are fetched (across multiple SDRAM chips) every time a column command is performed with DDR memories. Because the core of the DRAM is much slower than the interface, the difference is bridged by accessing information in parallel and then serializing it out the interface through a multiplexor (MUX). Thus, DDR prefetches two words, which means that every time a read or a write operation is performed, it is performed on two words of data, and bursts out of, or into, the SDRAM over one clock cycle on both clock edges for a total of two consecutive operations. As a result, the DDR I/O interface is twice as fast as the SDRAM core.

Although each new generation of SDRAM results in much greater capacity, the core speed of the SDRAM has not changed significantly from generation to generation. To achieve greater data rates than those afforded by the rather modest increases in SDRAM clock rate, JEDEC increased the buffer size. For DDR2, a 4-bit buffer is used, allowing for words to be transferred in parallel, increasing the effective data rate by a factor of 4. For DDR3, an 8-bit buffer is used and a factor of 8 speedup is achieved (**Figure 6.14**).

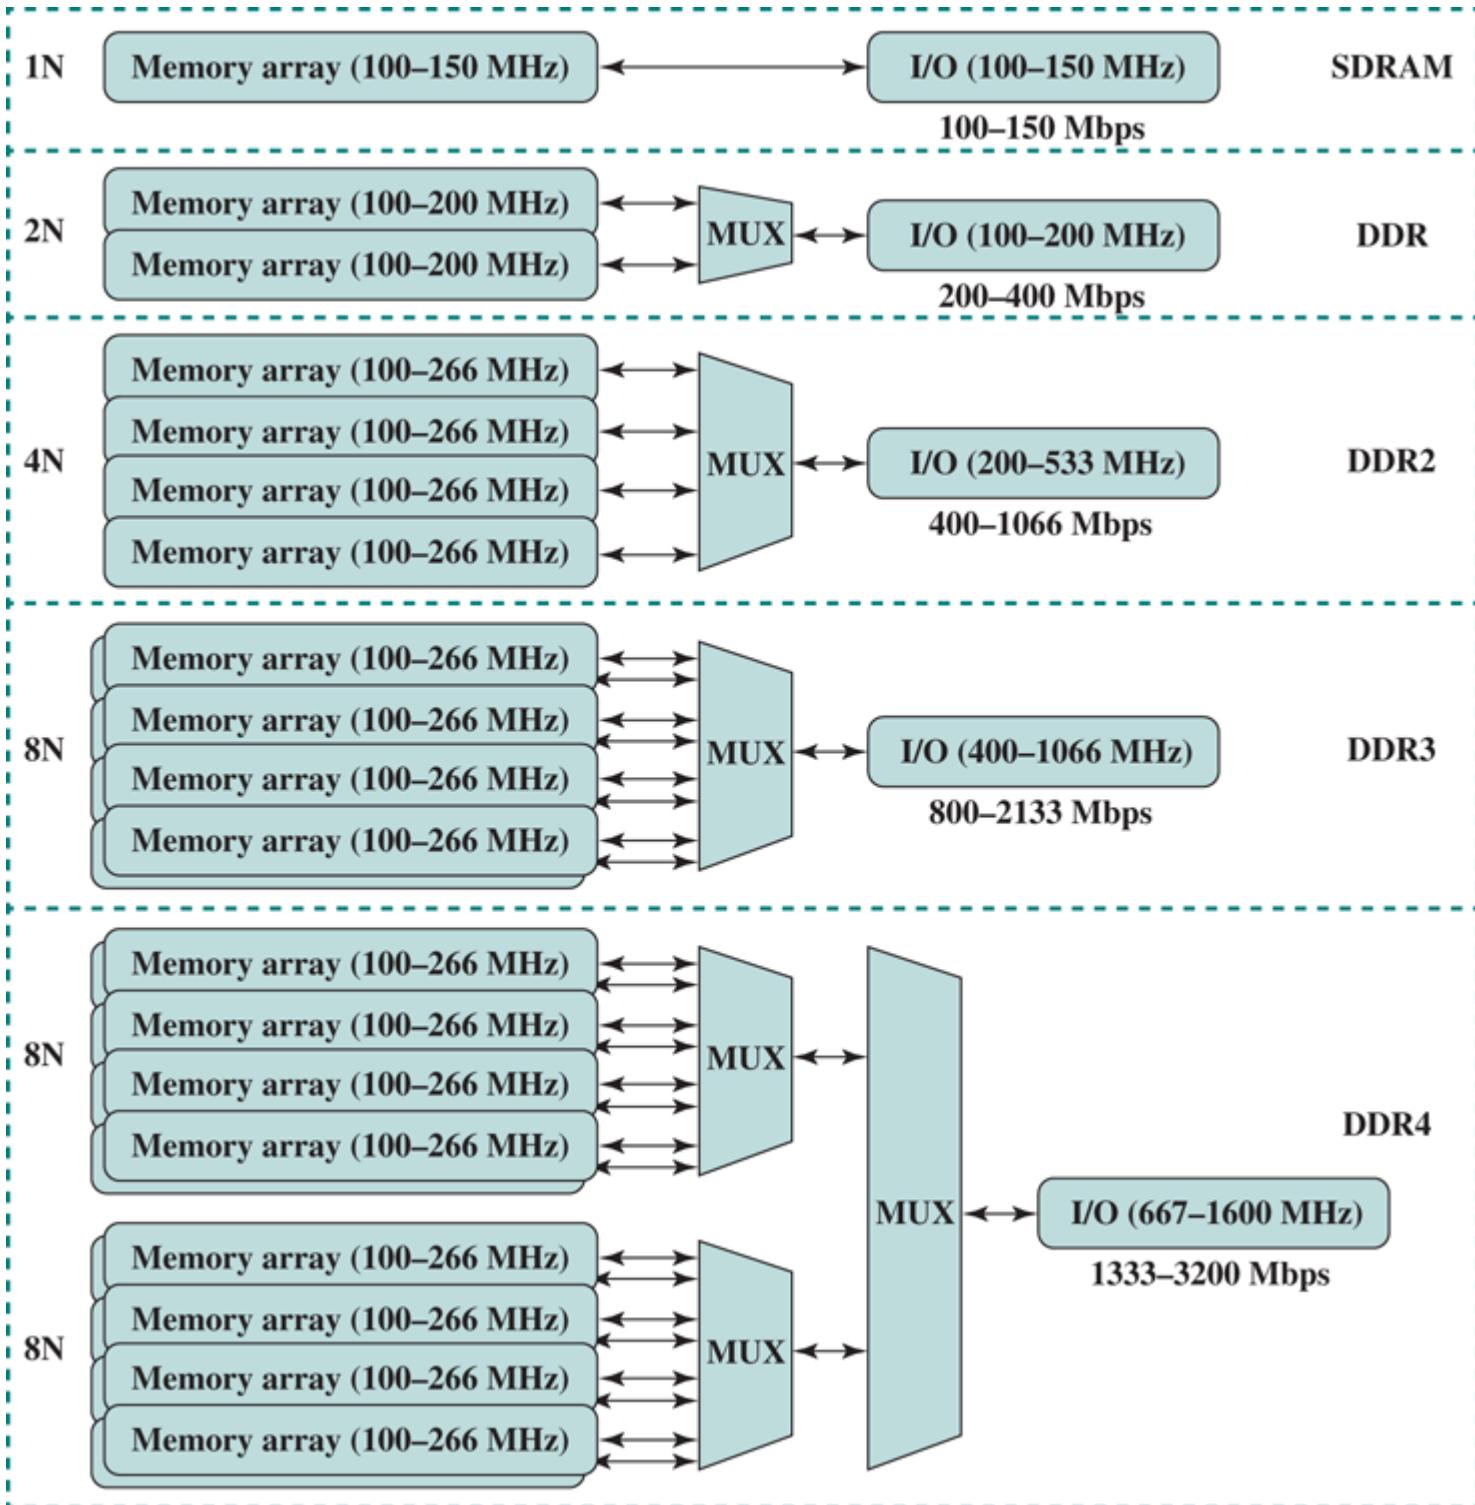

Figure 6.14 DDR Generations

The downside to the prefetch is that it effectively determines the minimum burst length for the SDRAMs. For example, it is very difficult to have an efficient burst length of four words with DDR3's prefetch of eight. Accordingly, the JEDEC designers chose not to increase the buffer size to 16 bits for DDR4, but rather to introduce the concept of a **bank group** [ALLA13]. Bank groups are separate entities such that they allow a column cycle to complete within a bank group, but that column cycle does not impact what is happening in another bank group. Thus, two prefetches of eight can be operating in parallel in the two bank groups. This arrangement keeps the prefetch buffer size the same as for DDR3, while increasing performance as if the prefetch is larger.

Figure 6.14 shows a configuration with two bank groups. With DDR4, up to 4 bank groups can be used.

6.4 Edram

An increasingly widespread technology used in the memory hierarchy is the embedded DRAM (eDRAM). eDRAM is a DRAM integrated on the same chip or MCM of an application-specific integrated circuit (ASIC) or microprocessor. For a number of metrics, eDRAM is intermediate between on-chip SRAM and off-chip DRAM:

- For the same surface area, eDRAM provides a larger size memory than SRAM but smaller than off-chip DRAM.
- eDRAM's cost-per-bit is higher when compared to equivalent stand-alone DRAM chips used as external memory, but it has a lower cost-per-bit than SRAM.
- Access time to eDRAM is greater than SRAM but, because of its proximity and the ability to use wider busses, eDRAM provides faster access than DRAM.

A variety of technologies are used in fabricating eDRAMs, but fundamentally they use the same designs and architectures as DRAM.

[JACO08] lists the following as trends that have led to increasing use of eDRAM:

- For larger systems and high-end applications, the spatial locality curves have become flatter and wider, meaning that the likely area of memory for upcoming references is larger. This makes DRAM-based caches attractive due to their bit density.
- On-chip or on-MCM eDRAM matches the performance of off-chip SRAM, so that greater cache size can be achieved by replacing some on-chip area that would otherwise be dedicated to SRAM with DRAM, avoiding or reducing the need for off-chip SRAM or DRAM.
- eDRAM generally dissipates less power than SRAM.

IBM z13 eDRAM Cache Structure

The IBM z13 system uses eDRAM at two levels of the cache hierarchy (see [Figure 4.10](#)). Each processor unit (PU) chip, with up to eight cores, has a shared 64-MB eDRAM L3 cache. This is an example of an eDRAM integrated on the same chip as the microprocessors. Three PU chips share a 480-MB eDRAM L4 cache (see [Figure 5.18](#)). The L4 cache is on a separate storage control (SC) chip. This is an example of an eDRAM integrated on the same chip with other memory-related logic. The L4 cache on each SC chip has 480 MB of noninclusive cache and a 224-MB Non-data Inclusive Coherent (NIC) directory. The NIC directory consists of tags that point to L3-owned lines that have not been included in L4 cache.

[Figure 6.15](#) shows the physical layout of an SC chip. About 60% of the surface area of the SC chip is devoted to the L4 cache and the NIC directory. The remainder of the chip includes L4 cache controller logic and I/O logic.

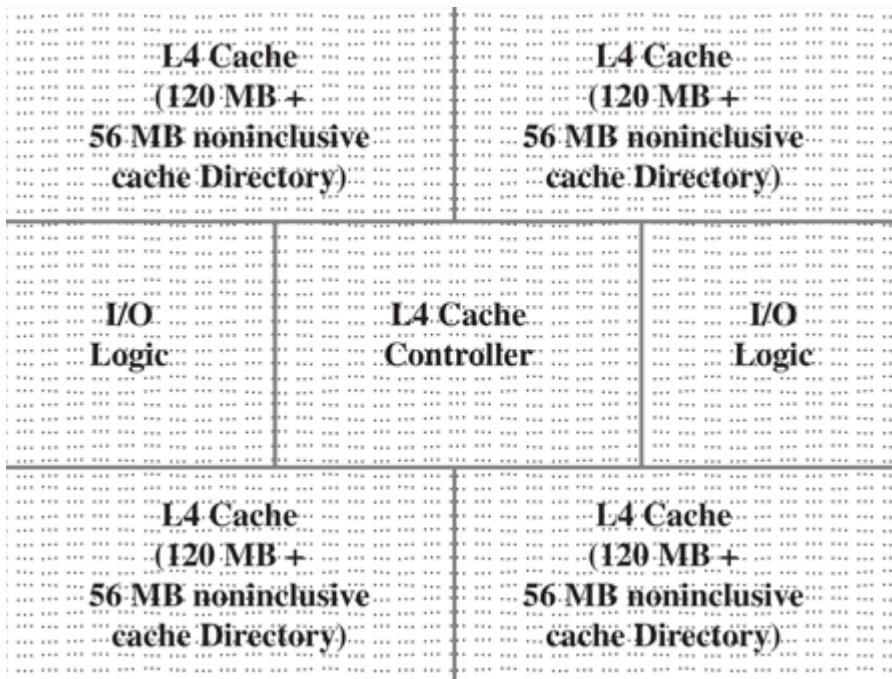

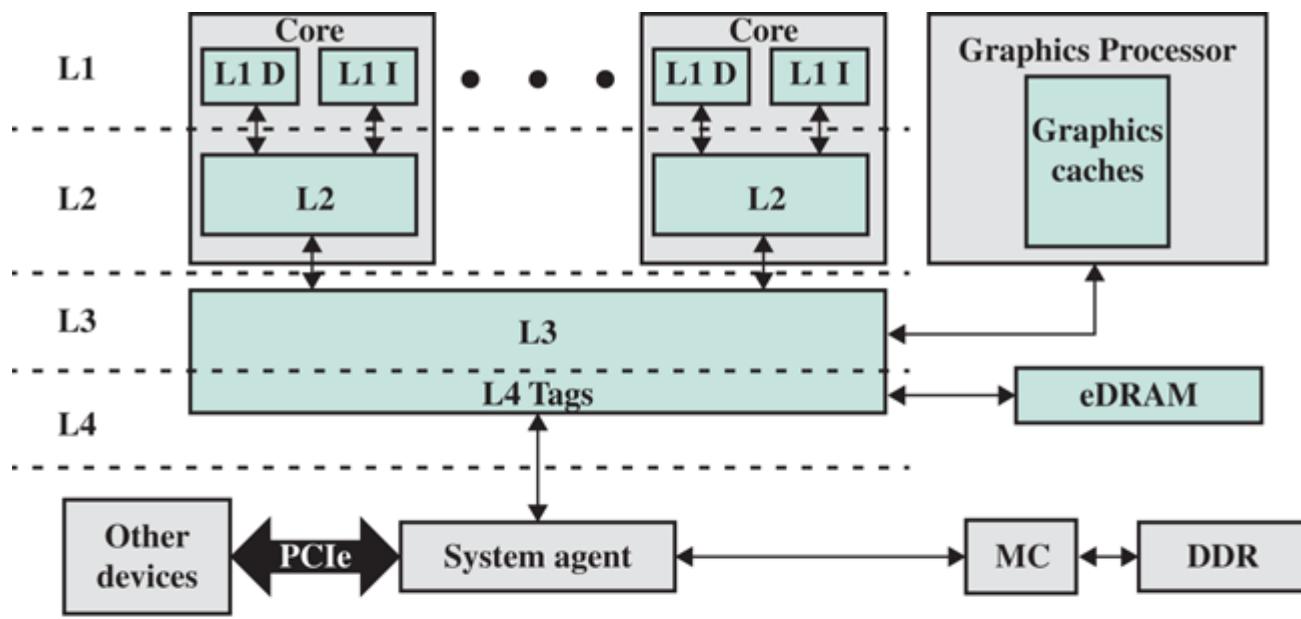

Figure 6.15 IBM z13 Storage Control (SC) Chip Layout

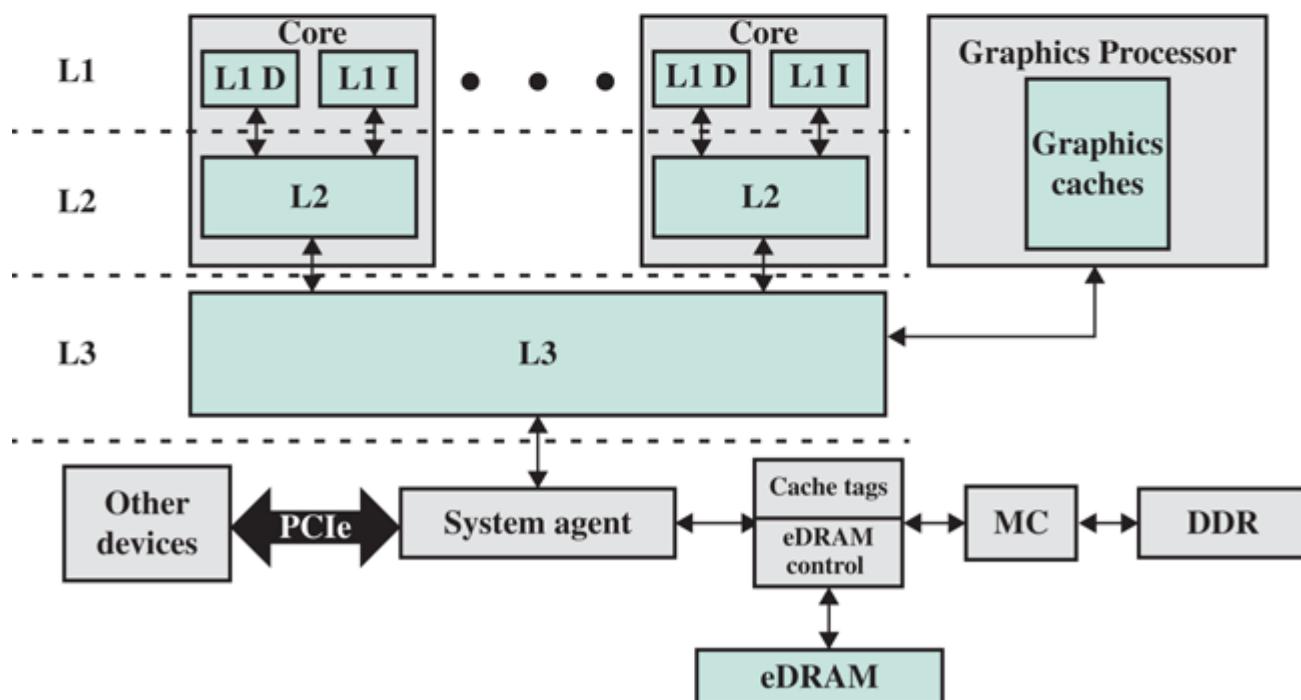

Intel Core System Cache Structure

Intel has shipped a number of products with an eDRAM positioned as an L4 cache. [Figure 6.16a](#) shows this arrangement. The eDRAM is accessed by a store of L4 tags contained within the L3 cache of each core, and as a result acts more as a victim cache to the L3 rather than as a DRAM implementation. Any instructions or hardware that requires data from the eDRAM has to go through the L3 and do the L4 tag conversion, limiting its potential.

In more recent products, Intel removed the eDRAM from its position as an L4 cache, as shown in [Figure 6.16b](#). This removed an undesired dependency between the capacity of the eDRAM and the number of cores. In this new arrangement, the eDRAM is effectively no longer a true L4 cache but rather a memory side cache. This has a number of benefits such that each and every memory access that goes through the memory controller gets looked up in the eDRAM. On a satisfied hit, the value is obtained from there. On a miss, a value gets allocated and stored in the eDRAM. Thus, rather than acting as a pseudo-L4 cache, the eDRAM becomes a DRAM buffer and automatically transparent to any software (CPU or IGP) that requires DRAM access. As a result, other hardware that communicates through the system agent (such as PCIe devices or data from the chipset) and requires information in DRAM does not need to navigate through the L3 cache on the processor.

MC = memory controller

Figure 6.16 Use of eDRAM in Intel Core Systems

6.5 Flash Memory

Another form of semiconductor memory is flash memory. Flash memory is used both for internal memory and external memory applications. Here, we provide a technical overview and look at its use for internal memory.

First introduced in the mid-1980s, flash memory is intermediate between EPROM and EEPROM in both cost and functionality. Like EEPROM, flash memory uses an electrical erasing technology. An entire flash memory can be erased in one or a few seconds, which is much faster than EPROM. In addition, it is possible to erase just blocks of memory, rather than an entire chip. Flash memory gets its name because the microchip is organized so that a section of memory cells are erased in a single action or “flash.” However, flash memory does not provide byte-level erasure. Like EPROM, flash memory uses only one transistor per bit, and so achieves the high density (compared with EEPROM) of EPROM.

Operation

Figure 6.17 illustrates the basic operation of a flash memory. For comparison, **Figure 6.17a** depicts the operation of a transistor. Transistors exploit the properties of semiconductors so that a small voltage applied to the gate can be used to control the flow of a large current between the source and the drain.

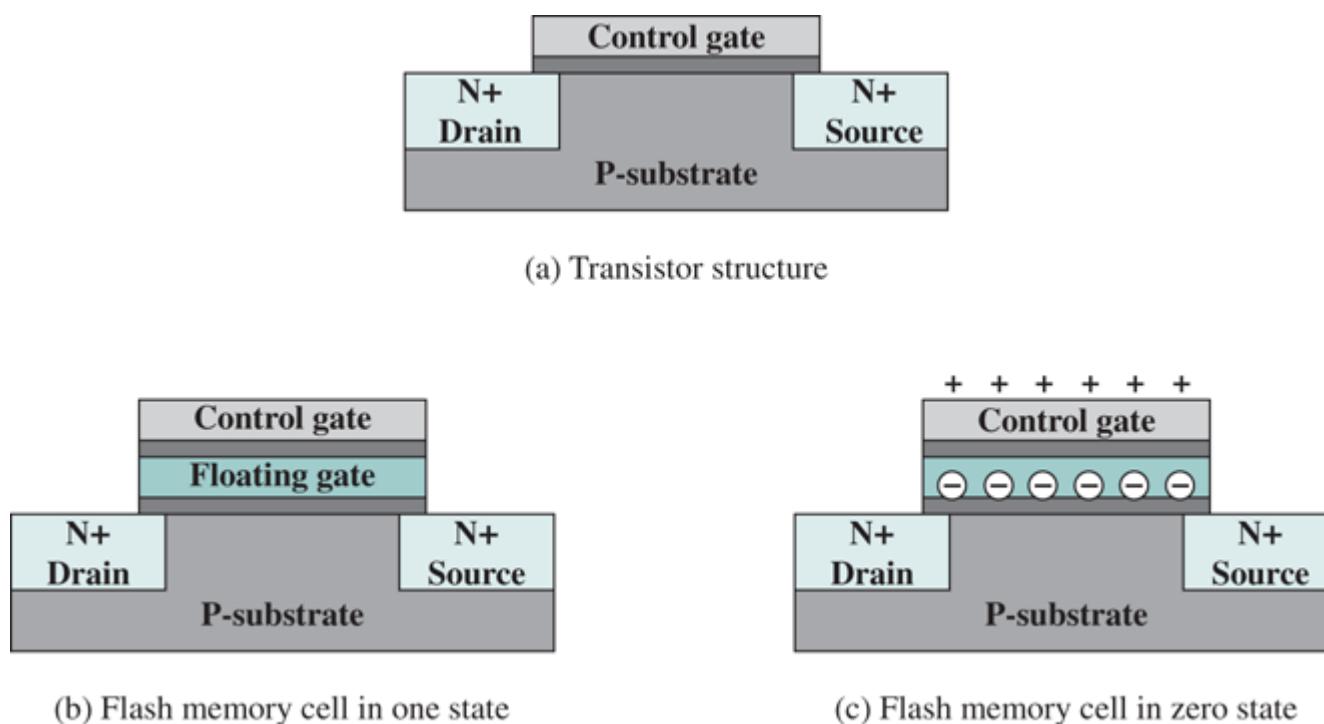

Figure 6.17 Flash Memory Operation

In a flash memory cell, a second gate—called a floating gate, because it is insulated by a thin oxide layer—is added to the transistor. Initially, the floating gate does not interfere with the operation of the transistor (**Figure 6.17b**). In this state, the cell is deemed to represent binary 1. Applying a large voltage across the oxide layer causes electrons to tunnel through it and become trapped on the floating gate, where they remain even if the power is disconnected (**Figure 6.17c**). In this state, the cell is deemed to represent binary 0. The state of the cell can be read by using external circuitry to test whether the transistor is working or not. Applying a large voltage in the opposite direction removes the electrons from the floating gate, returning to a state of binary 1.

An important characteristic of flash memory is that it is persistent memory, which means that it retains data when there is no power applied to the memory. Thus, it is useful for secondary (external) storage, and as an alternative to random access memory in computers.

NOR and NAND Flash Memory

There are two distinctive types of flash memory, designated as NOR and NAND ([Figure 6.18](#)). In **NOR flash memory**, the basic unit of access is a bit, referred to as a *memory cell*. Cells in NOR flash are connected in parallel to the bit lines so that each cell can be read/write/erased individually. If any memory cell of the device is turned on by the corresponding word line, the bit line goes low. This is similar in function to a NOR logic gate.²

² See Chapter 12 for a discussion of NOR and NAND gates.

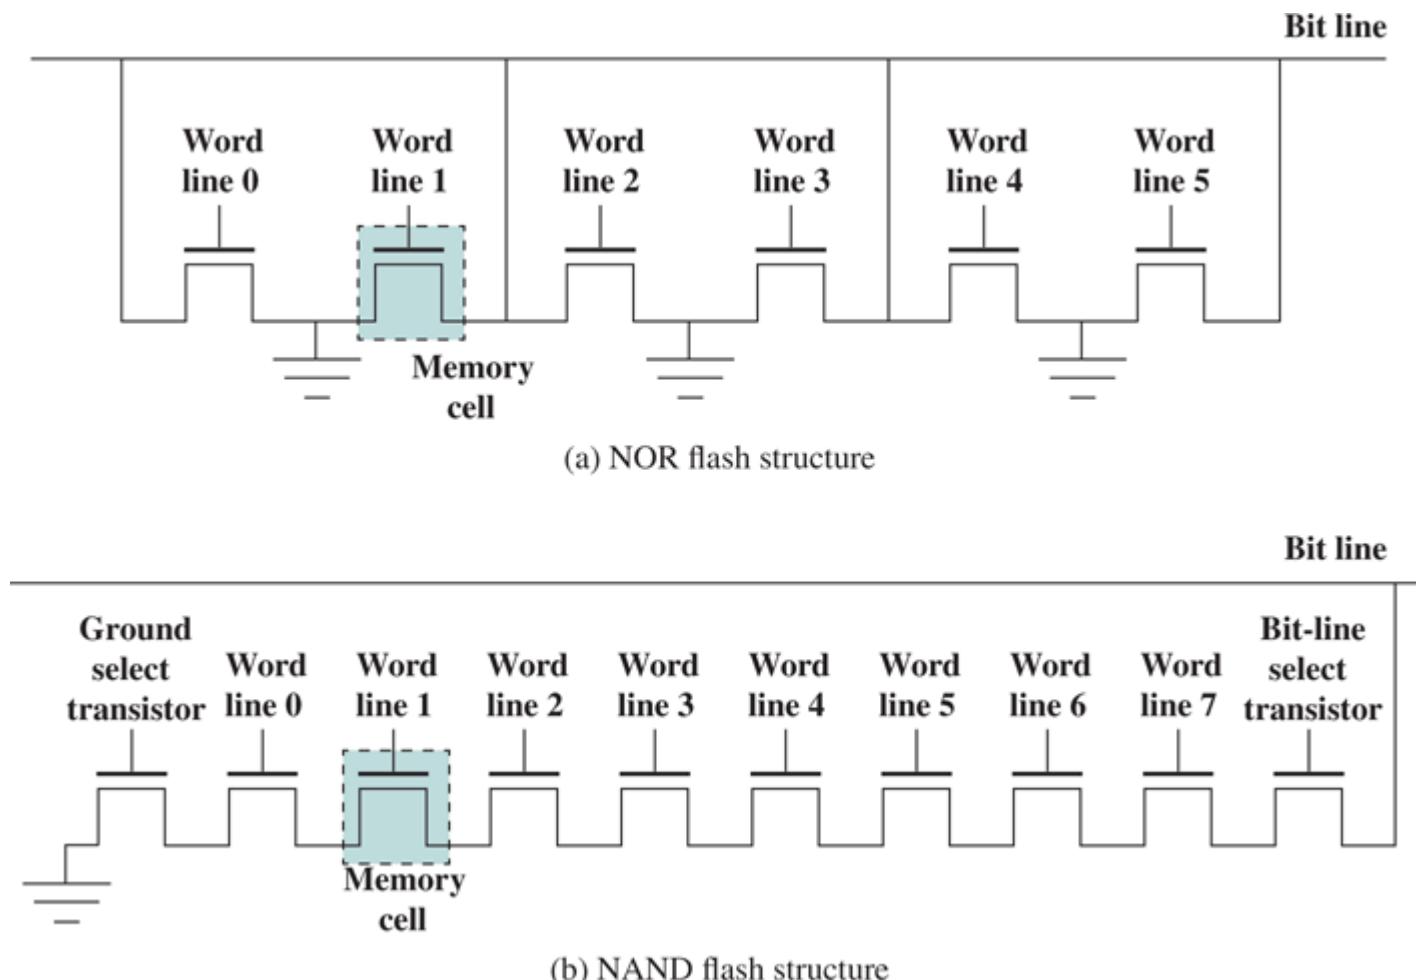

Figure 6.18 Flash Memory Structures

NAND flash memory is organized in transistor arrays with 16 or 32 transistors in series. The bit line goes low only if all the transistors in the corresponding word lines are turned on. This is similar in function to a NAND logic gate.

Although the specific quantitative values of various characteristics of NOR and NAND are changing year by year, the relative differences between the two types has remained stable. These differences are usefully illustrated by the Kiviat graphs³ shown in [Figure 6.19](#).

³ A Kiviat graph provides a pictorial means of comparing systems along multiple variables [MORR74]. The variables are laid out at as lines of equal angular intervals within a circle, each line going from the center of the circle to the circumference. A given system is defined by one point on each line; the closer to the circumference, the better the value. The points are connected to yield a shape that is characteristic of that system. The more area enclosed in the shape, the “better” is the system.

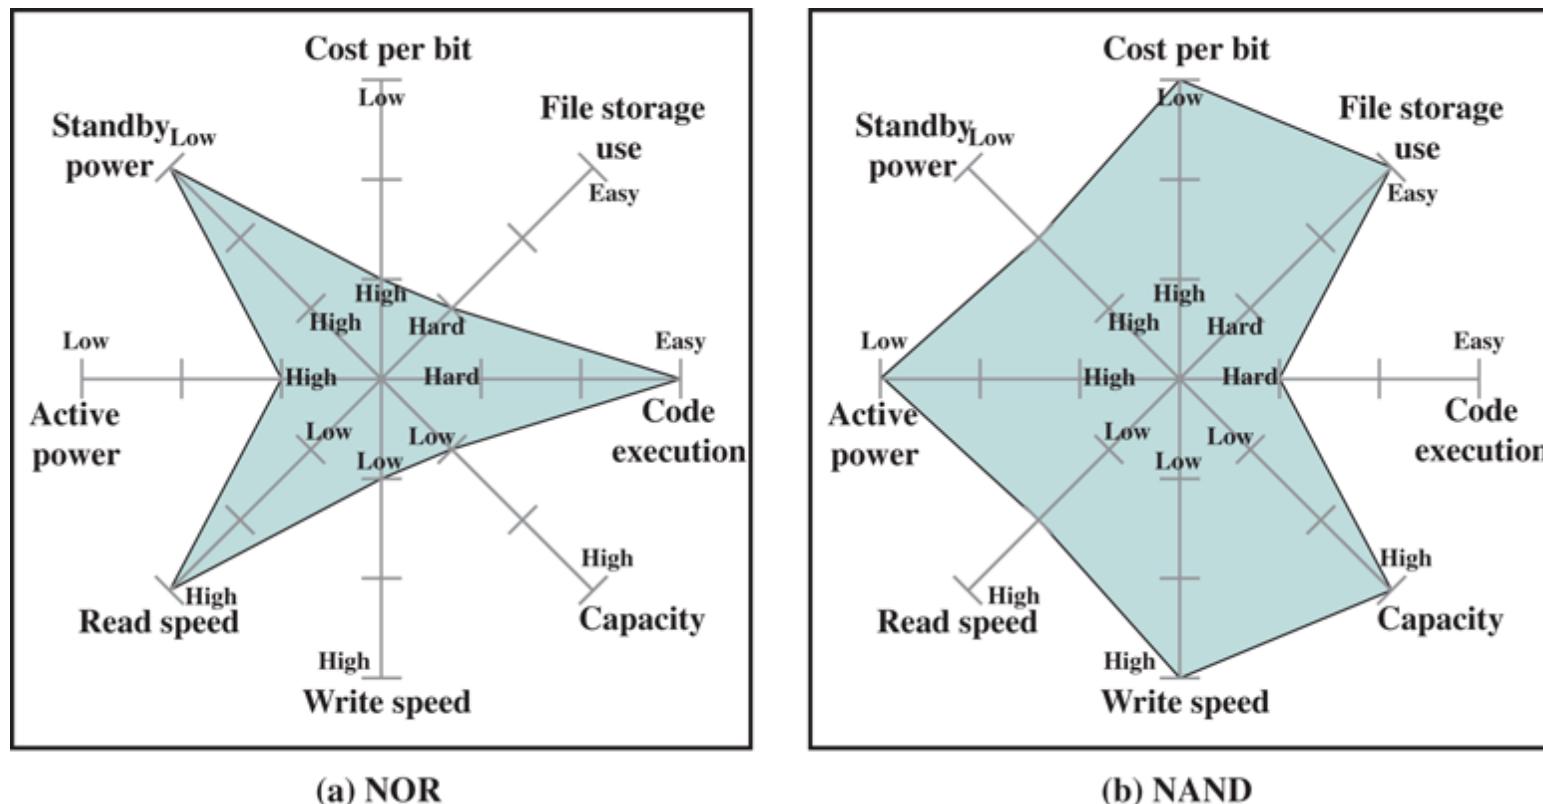

Figure 6.19 Kiviat Graphs for Flash Memory

NOR flash memory provides high-speed random access. It can read and write data to specific locations, and can reference and retrieve a single byte. NAND reads and writes in small blocks. NAND provides higher bit density than NOR and greater write speed. NAND flash does not provide a random-access external address bus, so the data must be read on a blockwise basis (also known as page access), where each block holds hundreds to thousands of bits.

For internal memory in embedded systems, NOR flash memory has traditionally been preferred. NAND memory has made some inroads, but NOR remains the dominant technology for internal memory. It is ideally suited for microcontrollers where the amount of program code is relatively small and a certain amount of application data does not vary. For example, the flash memory in [Figure 1.16](#) is NOR memory.

NAND memory is better suited for external memory, such as USB flash drives, memory cards (in digital cameras, MP3 players, etc.), and in what are known as solid-state disks (SSDs). We discuss SSDs in [Chapter 7](#).

6.6 Newer Nonvolatile Solid-State Memory Technologies

The traditional memory hierarchy has consisted of three levels (Figure 5.20):

- **Static RAM (SRAM):** SRAM provides rapid access time, but is the most expensive and the least dense (bit density). SRAM is suitable for cache memory.
- **Dynamic RAM (DRAM):** Cheaper, denser, and slower than SRAM, DRAM has traditionally been the choice for off-chip main memory.
- **Hard disk:** A magnetic disk provides very high bit density and very low cost per bit, with relatively slow access times. It is the traditional choice for external storage as part of the memory hierarchy.

Into this mix, as we have seen, has been added flash memory. Flash memory has the advantage over traditional memory that it is nonvolatile. NOR flash is best suited to storing programs and static application data in embedded systems, while NAND flash has characteristics intermediate between DRAM and hard disks.

Over time, each of these technologies has seen improvements in scaling: higher bit density, higher speed, lower power consumption, and lower cost. However, for semiconductor memory, it is becoming increasingly difficult to continue the pace of improvement [ITRS14].

Recently, there have been breakthroughs in developing new forms of nonvolatile semiconductor memory that continue scaling beyond flash memory. The most promising technologies are spin-transfer torque RAM (STT-RAM), phase-change RAM (PCRAM), and resistive RAM (ReRAM) ([ITRS14], [GOER12]). All of these are in volume production. However, because NAND Flash and to some extent NOR Flash are still dominating the applications, these emerging memories have been used in specialty applications and have not yet fulfilled their original promise to become dominating mainstream high-density **nonvolatile memory**. This is likely to change in the next few years.

Figure 6.20 shows how these three technologies are likely to fit into the memory hierarchy.

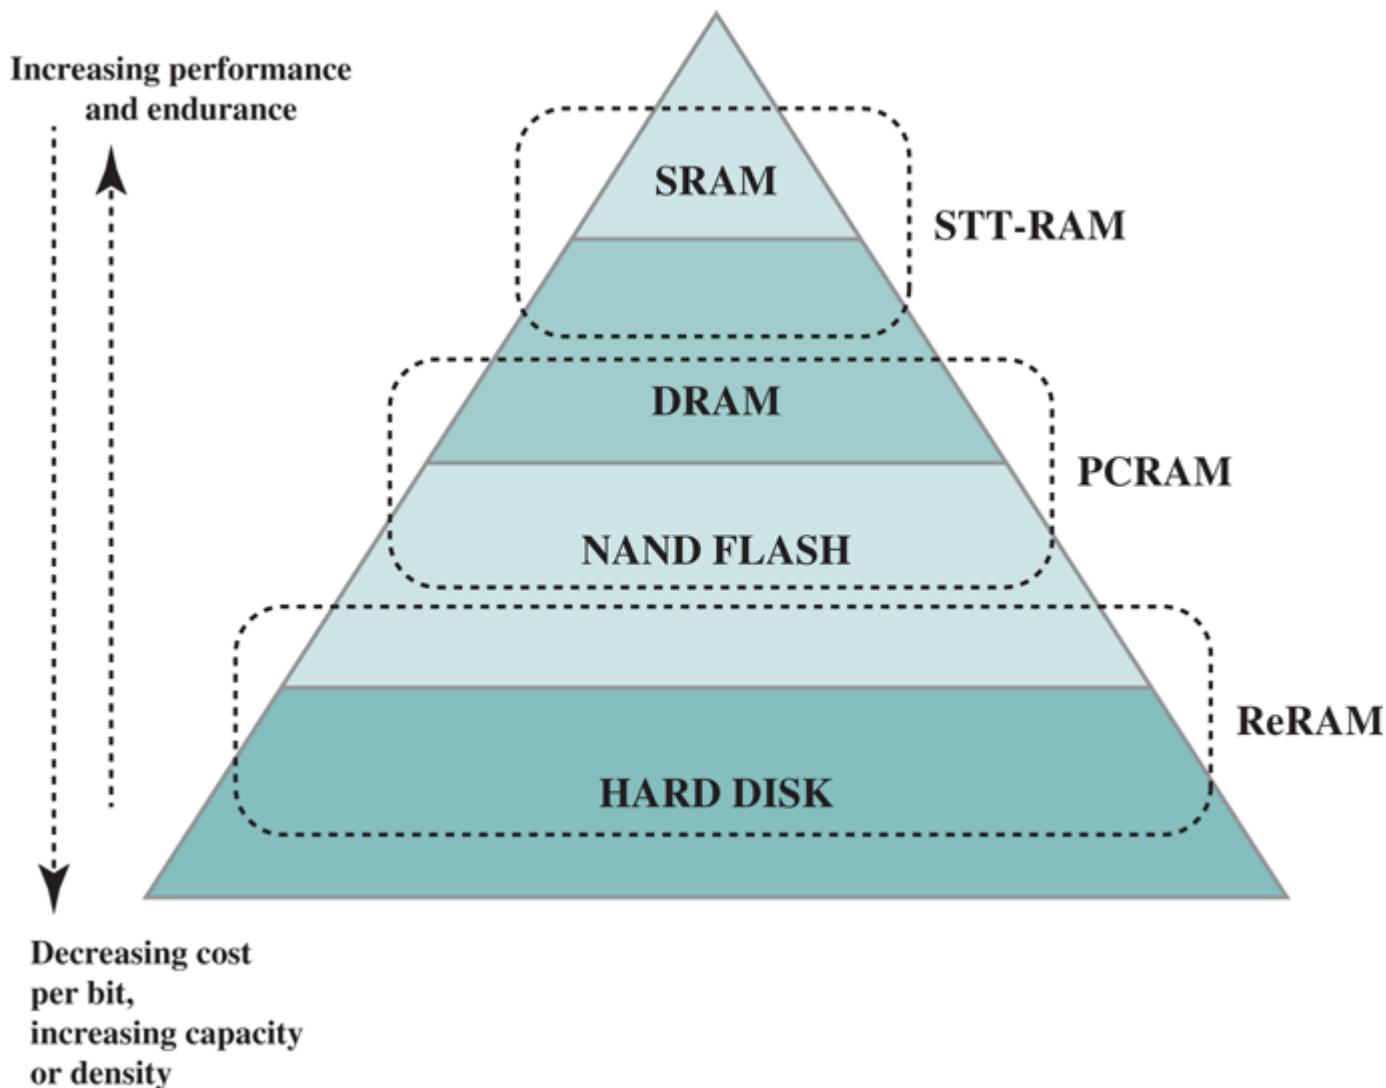

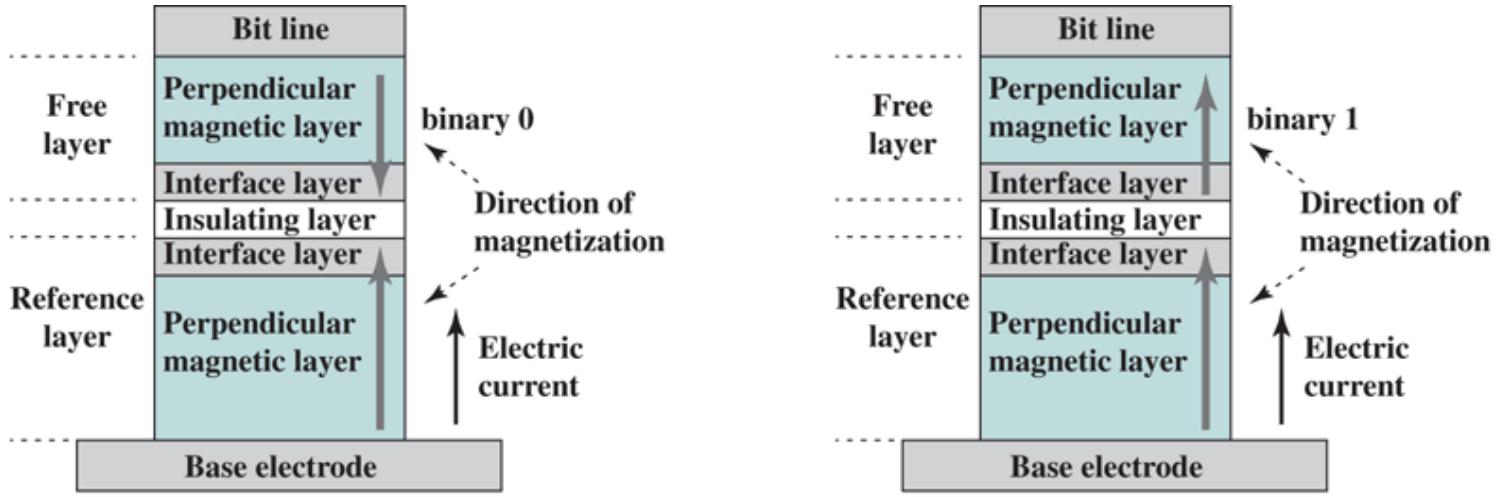

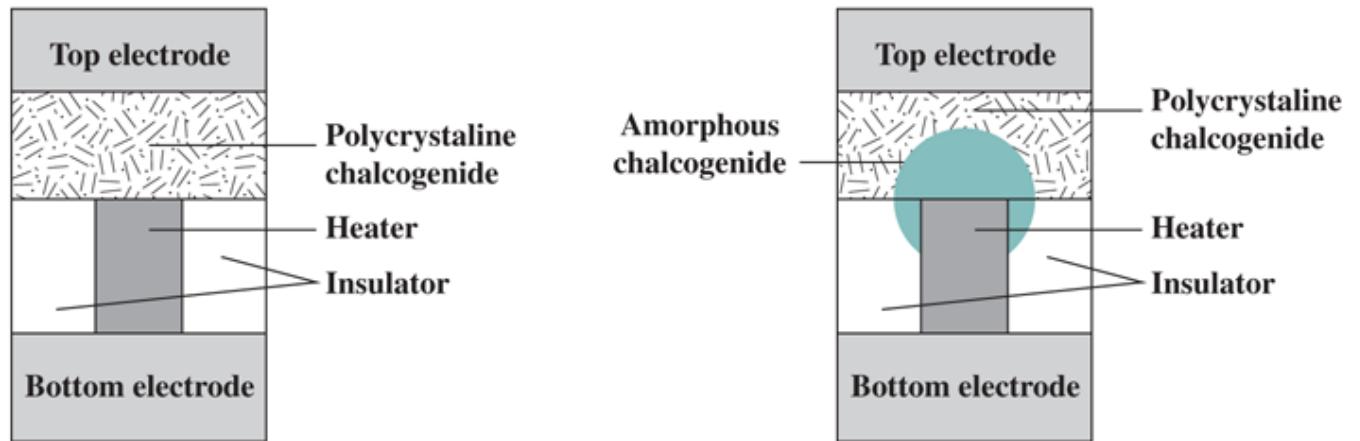

Figure 6.20 Nonvolatile RAM within the Memory Hierarchy

STT-RAM

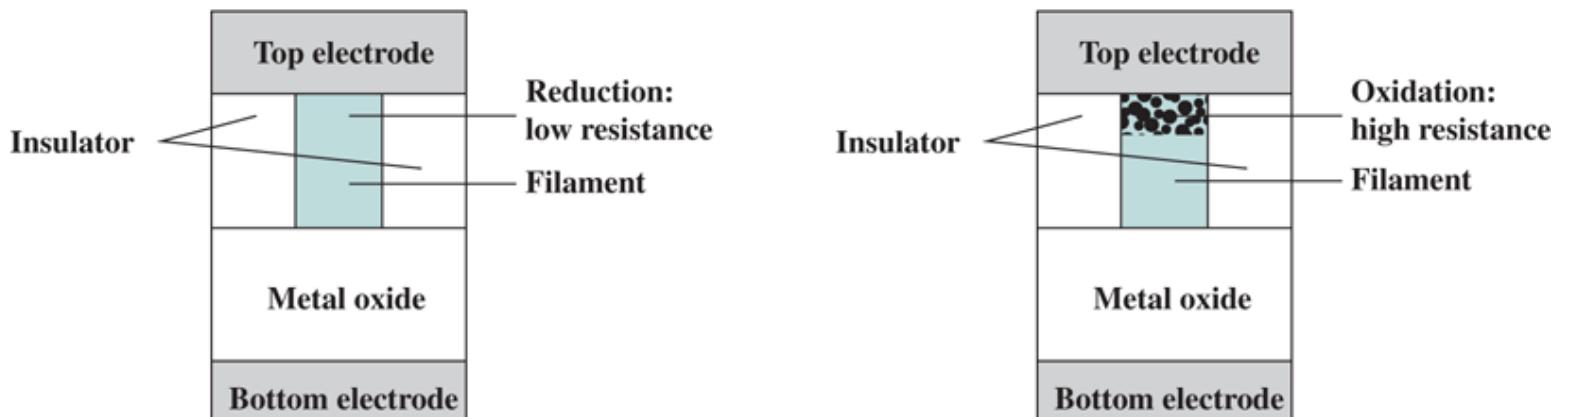

STT-RAM is a new type of **magnetic RAM (MRAM)**, which features non-volatility, fast writing/reading speed ($< 10\text{ns}$), high programming endurance ($> 10^{15}$ cycles) and zero standby power [KULT13]. The storage capability or programmability of MRAM arises from magnetic tunneling junction (MTJ), in which a thin tunneling dielectric is sandwiched between two ferromagnetic layers. One ferromagnetic layer (pinned or reference layer) is designed to have its magnetization pinned, while the magnetization of the other layer (free layer) can be flipped by a write event. An MTJ has a low (high) resistance if the magnetizations of the free layer and the pinned layer are parallel (anti-parallel). In first-generation MRAM design, the magnetization of the free layer is changed by the current-induced magnetic field. In STT-RAM, a new write mechanism, called *polarization-current-induced magnetization switching*, is introduced. For STT-RAM, the magnetization of the free layer is flipped by the electrical current directly. Because the current required to switch an MTJ resistance state is proportional to the MTJ cell area, STT-RAM is believed to have a better scaling property than the first-generation MRAM. [Figure 6.21a](#) illustrates the general configuration.

(a) STT-RAM

(b) PCRAM

(c) ReRAM

Figure 6.21 Nonvolatile RAM Technologies

STT-RAM is a good candidate for either cache or main memory.

PCRAM

Phase-change RAM (pcram) is the most mature of the new technologies, with an extensive technical literature ([RAOU09], [ZHOU09], [LEE10]).

PCRAM technology is based on a chalcogenide alloy material, which is similar to those commonly

used in optical storage media (compact discs and digital versatile discs). The data storage capability is achieved from the resistance differences between an amorphous (high-resistance) and a crystalline (low-resistance) phase of the chalcogenide-based material. In SET operation, the phase change material is crystallized by applying an electrical pulse that heats a significant portion of the cell above its crystallization temperature. In RESET operation, a larger electrical current is applied and then abruptly cut off in order to melt and then quench the material, leaving it in the amorphous state.

Figure 6.21b illustrates the general configuration.

PCRAM is a good candidate to replace or supplement DRAM for main memory.

ReRAM

ReRAM (also known as RRAM) works by creating resistance rather than directly storing charge. An electric current is applied to a material, changing the resistance of that material. The resistance state can then be measured and a 1 or 0 is read as the result. Much of the work done on ReRAM to date has focused on finding appropriate materials and measuring the resistance state of the cells. ReRAM designs are low voltage, endurance is far superior to flash memory, and the cells are much smaller—at least in theory. **Figure 6.21c** shows one ReRam configuration.

ReRAM is a good candidate to replace or supplement both secondary storage and main memory.

6.7 Key Terms, Review Questions, and Problems

Key Terms

bank group
double data rate DRAM (DDR DRAM)
dynamic RAM (DRAM)
electrically erasable programmable ROM (EEPROM)
erasable programmable ROM (EPROM)
error correcting code (ECC)
error correction
flash memory
Hamming code
hard failure
magnetic RAM (MRAM)
NAND flash memory
nonvolatile memory
NOR flash memory
phase-change RAM (PCRAM)
programmable ROM (PROM)
random access memory (RAM)
read-mostly memory
read-only memory (ROM)
resistive RAM (ReRAM)
semiconductor memory
single-error-correcting (SEC) code
single-error-correcting, double-error-detecting (SEC-DED) code
soft error
spin-transfer torque RAM (STT-RAM)
static RAM (SRAM)
synchronous DRAM (SDRAM)

volatile memory

Review Questions

- 6.1 What are the key properties of semiconductor memory?
- 6.2 What are two interpretations of the term *random-access memory*?
- 6.3 What is the difference between DRAM and SRAM in terms of application?
- 6.4 What is the difference between DRAM and SRAM in terms of characteristics such as speed, size, and cost?
- 6.5 Explain why one type of RAM is considered to be analog and the other digital.
- 6.6 What are some applications for ROM?
- 6.7 What are the differences among EPROM, EEPROM, and flash memory?
- 6.8 Explain the function of each pin in [Figure 5.4b](#).
- 6.9 What is a parity bit?
- 6.10 How is the syndrome for the Hamming code interpreted?
- 6.11 How does SDRAM differ from ordinary DRAM?
- 6.12 What is DDR RAM?
- 6.13 What is the difference between NAND and NOR flash memory?
- 6.14 List and briefly define three newer nonvolatile solid-state memory technologies.

Problems

- 6.1 Suggest reasons why RAMs traditionally have been organized as only one bit per chip whereas ROMs are usually organized with multiple bits per chip.
- 6.2 Consider a dynamic RAM that must be given a refresh cycle 64 times per ms. Each refresh operation requires 150 ns; a memory cycle requires 250 ns. What percentage of the memory's total operating time must be given to refreshes?
- 6.3 [Figure 6.22](#) shows a simplified timing diagram for a DRAM read operation over a bus. The access time is considered to last from t_1 to t_2 . Then there is a recharge time, lasting from t_2 to t_3 , during which the DRAM chips will have to recharge before the processor can access them again.

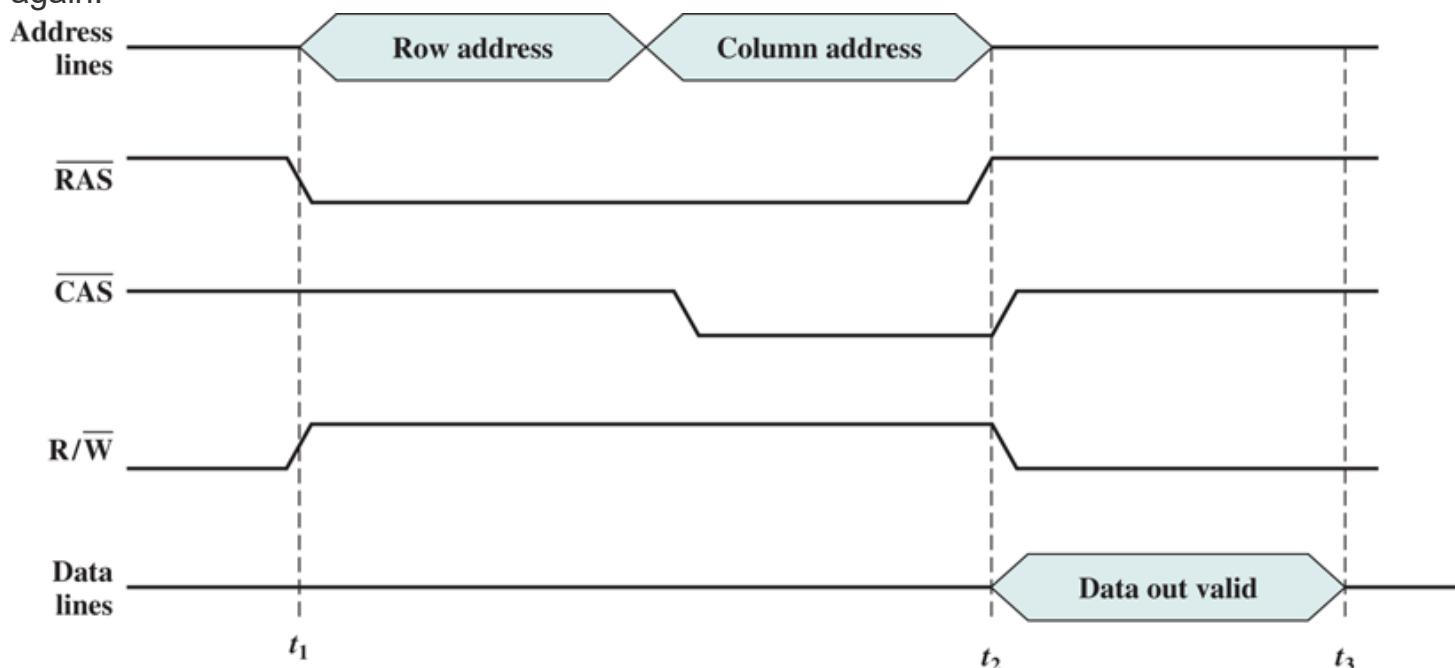

Figure 6.22 Simplified DRAM Read Timing

- a. Assume that the access time is 60 ns and the recharge time is 40 ns. What is the memory cycle time? What is the maximum data rate this DRAM can sustain, assuming a 1-bit output?
- b. Constructing a 32-bit wide memory system using these chips yields what data transfer rate?

6.4 [Figure 6.6](#) indicates how to construct a module of chips that can store 1 MB based on a group of four 256-Kbyte chips. Let's say this module of chips is packaged as a single 1-MB chip, where the word size is 1 byte. Give a high-level chip diagram of how to construct an 8-MB computer memory using eight 1-MB chips. Be sure to show the address lines in your diagram and what the address lines are used for.

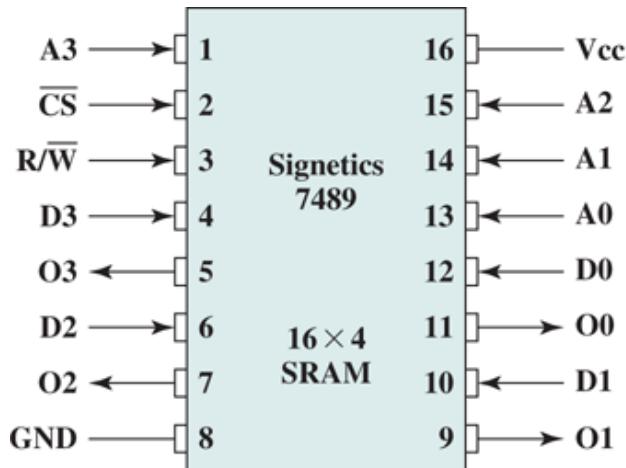

6.5 On a typical Intel 8086-based system, connected via system bus to DRAM memory, for a read operation, RAS is activated by the trailing edge of the Address Enable signal ([Figure A.1](#) in [Appendix A](#)). However, due to propagation and other delays, RAS does not go active until 50 ns after Address Enable returns to a low. Assume the latter occurs in the middle of the second half of state T_1 (somewhat earlier than in [Figure A.1](#)). Data are read by the processor at the end of T_3 . For timely presentation to the processor, however, data must be provided 60 ns earlier by memory. This interval accounts for propagation delays along the data paths (from memory to processor) and processor data hold time requirements. Assume a clocking rate of 10 MHz.

- a. How fast (access time) should the DRAMs be if no wait states are to be inserted?
- b. How many wait states do we have to insert per memory read operation if the access time of the DRAMs is 150 ns?

6.6 The memory of a particular microcomputer is built from $64K \times 1$ DRAMs. According to the data sheet, the cell array of the DRAM is organized into 256 rows. Each row must be refreshed at least once every 4 ms. Suppose we refresh the memory on a strictly periodic basis.

- a. What is the time period between successive refresh requests?
- b. How long a refresh address counter do we need?

6.7 [Figure 6.23](#) shows one of the early SRAMs, the 16×4 Signetics 7489 chip, which stores 16 4-bit words.

(a) Pin layout

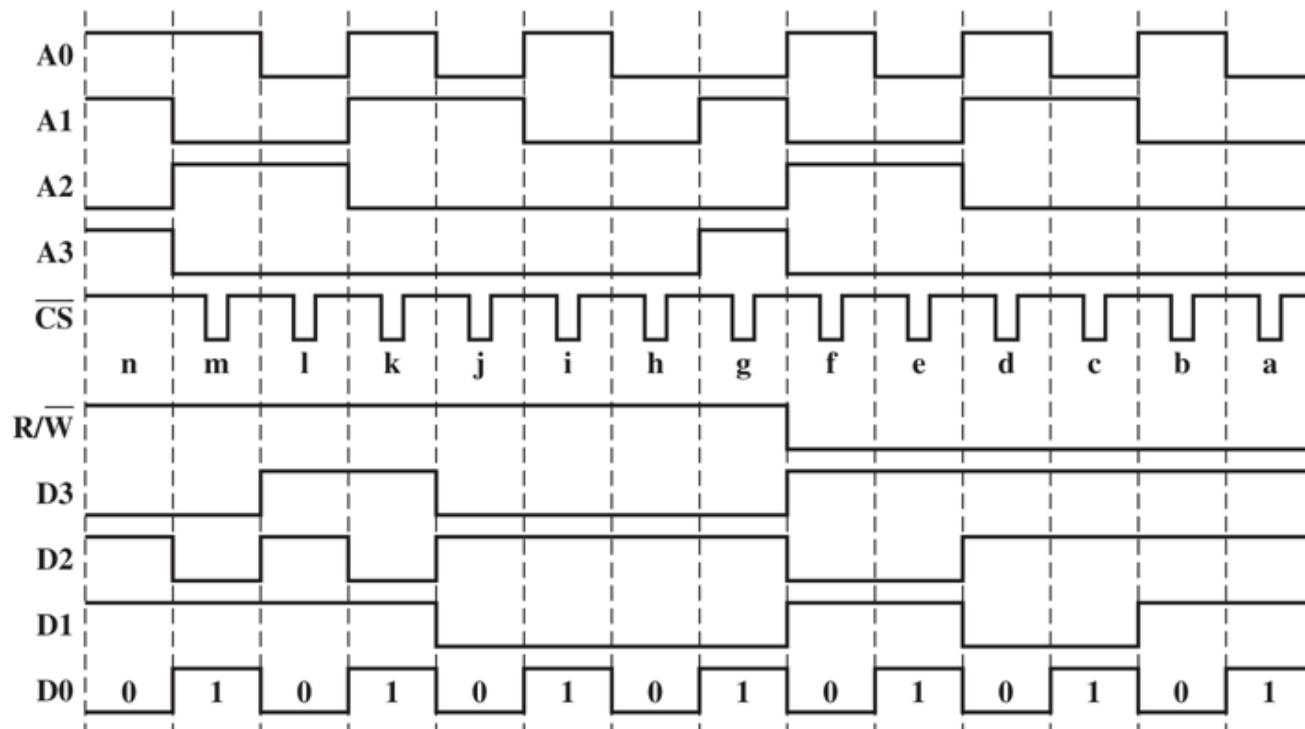

Operating Mode	Inputs			Outputs
	CS	R/W	Dn	On
Write	L	L	L	L
	L	L	H	H
Read	L	H	X	Data
Inhibit writing	H	L	L	H
	H	L	H	L
Store - disable outputs	H	H	X	H

H = high voltage level

L = low voltage level

X = don't care

(b) Truth table

(c) Pulse train

Figure 6.23 The Signetics 7489 SRAM

- List the mode of operation of the chip for each CS input pulse shown in [Figure 6.23c](#).
- List the memory contents of word locations 0 through 6 after pulse n.
- What is the state of the output data leads for the input pulses h through m?

6.8 Design a 16-bit memory of total capacity 8192 bits using SRAM chips of size 64×1 bit. Give the array configuration of the chips on the memory board showing all required input and output signals for assigning this memory to the lowest address space. The design should allow for both byte and 16-bit word accesses.

6.9 A common unit of measure for failure rates of electronic components is the **Failure unit** (FIT), expressed as a rate of failures per billion device hours. Another well known but less used measure is **mean time between failures (MTBF)**, which is the average time of operation of a particular component until it fails. Consider a 1 MB memory of a 16-bit microprocessor with 256K \times 1 DRAMs. Calculate its MTBF assuming 2000 FITS for each DRAM.

6.10 For the Hamming code shown in [Figure 6.10](#), show what happens when a check bit rather than a data bit is in error?

6.11 Suppose an 8-bit data word stored in memory is 11000010. Using the Hamming algorithm, determine what check bits would be stored in memory with the data word. Show how you got your answer.

6.12 For the 8-bit word 00111001, the check bits stored with it would be 0111. Suppose when the word is read from memory, the check bits are calculated to be 1101. What is the data word that was read from memory?

6.13 How many check bits are needed if the Hamming error correction code is used to detect single bit errors in a 1024-bit data word?

6.14 Develop an SEC code for a 16-bit data word. Generate the code for the data word 0101000000111001. Show that the code will correctly identify an error in data bit 5.

7.6 Key Terms, Review Questions, and Problems

Learning Objectives

After studying this chapter, you should be able to:

- Understand the key properties of magnetic disks.
- Understand the performance issues involved in **magnetic disk** access.
- Explain the concept of **RAID** and describe the various levels.
- Compare and contrast hard disk drives and solid disk drives.
- Describe in general terms the operation of **flash memory**.
- Understand the differences among the different optical disk storage media.
- Present an overview of **magnetic tape** storage technology.

*This chapter examines a range of external memory devices and systems. We begin with the most important device, the magnetic disk. Magnetic disks are the foundation of external memory on virtually all computer systems. The next section examines the use of disk arrays to achieve greater performance, looking specifically at the family of systems known as RAID (Redundant Array of Independent Disks). An increasingly important component of many computer systems is the solid state disk, which is discussed next. Then, external **optical memory** is examined. Finally, magnetic tape is described.*

7.1 Magnetic Disk

A disk is a circular **platter** constructed of nonmagnetic material, called the **substrate**, coated with a magnetizable material. Traditionally, the substrate has been an aluminum or aluminum alloy material. More recently, glass substrates have been introduced. The glass substrate has a number of benefits, including the following:

- Improvement in the uniformity of the magnetic film surface to increase disk reliability.
- A significant reduction in overall surface defects to help reduce read-write errors.
- Ability to support lower fly heights (described subsequently).
- Better stiffness to reduce disk dynamics.
- Greater ability to withstand shock and damage.

Magnetic Read and Write Mechanisms

Data are recorded on and later retrieved from the disk via a conducting coil named the **head**; in many systems, there are two heads, a read head and a write head. During a read or write operation, the head is stationary while the platter rotates beneath it.

The write mechanism exploits the fact that electricity flowing through a coil produces a magnetic field. Electric pulses are sent to the write head, and the resulting magnetic patterns are recorded on the surface below, with different patterns for positive and negative currents. The write head itself is made of easily magnetizable material and is in the shape of a rectangular doughnut with a gap along one side and a few turns of conducting wire along the opposite side (**Figure 7.1**). An electric current in the wire induces a magnetic field across the gap, which in turn magnetizes a small area of the recording medium. Reversing the direction of the current reverses the direction of the magnetization on the recording medium.

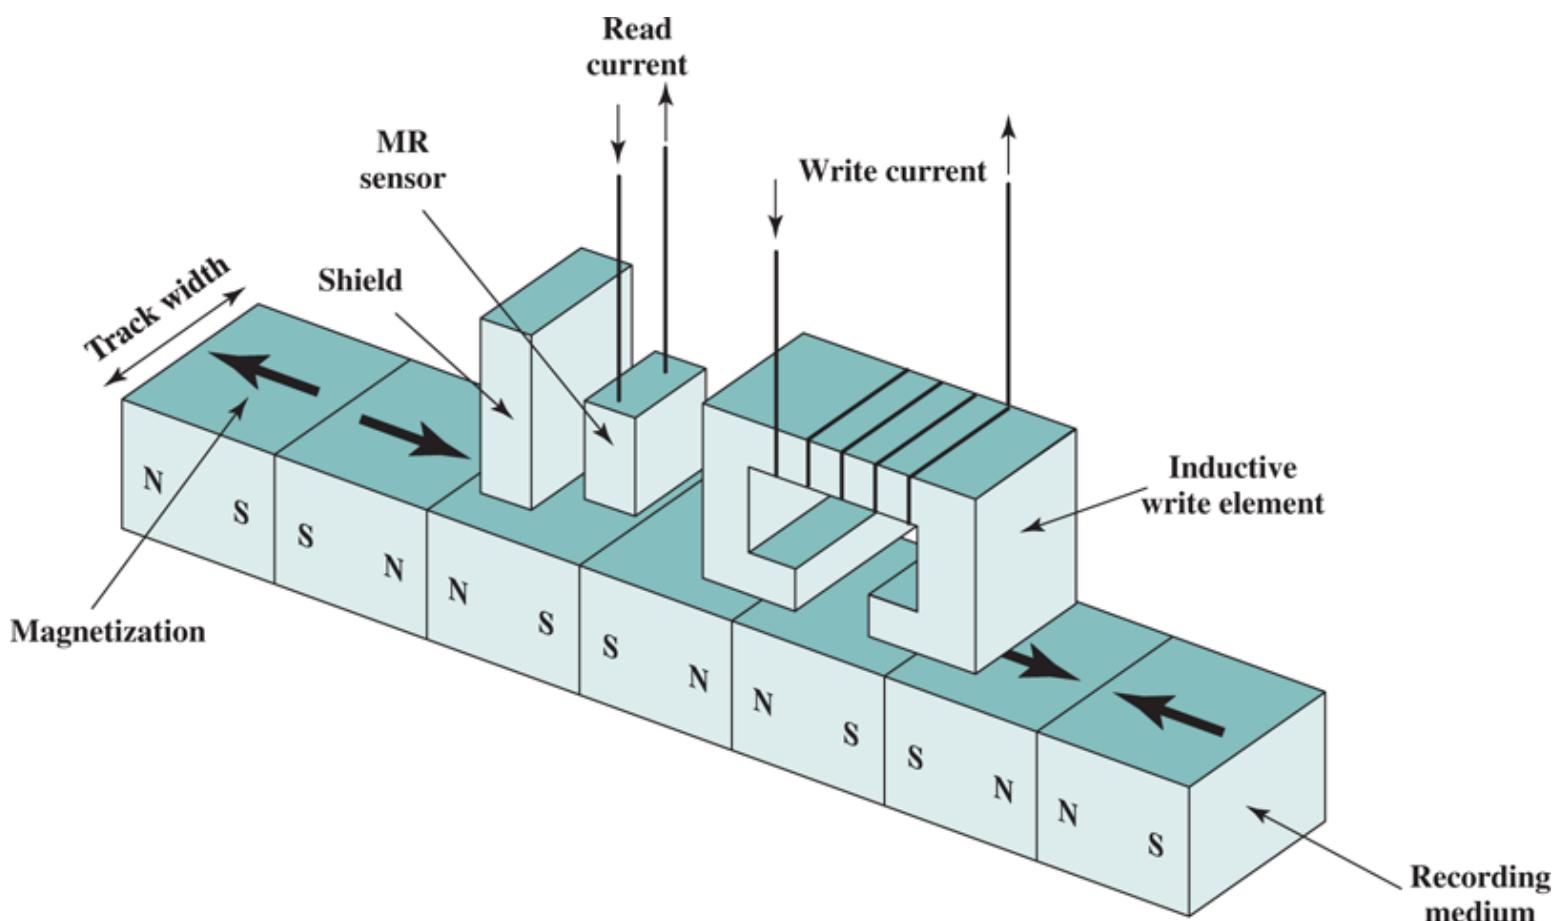

Figure 7.1 Inductive Write/Magnetoresistive Read Head

The traditional read mechanism exploits the fact that a magnetic field moving relative to a coil produces an electrical current in the coil. When the surface of the disk rotates under the head, it generates a current of the same polarity as the one already recorded. The structure of the head for reading is in this case essentially the same as for writing, and therefore the same head can be used for both. Such single heads are used in floppy disk systems and in older rigid disk systems.

Contemporary rigid disk systems use a different read mechanism, requiring a separate read head, positioned for convenience close to the write head. The read head consists of a partially shielded **magnetoresistive (MR)** sensor. The MR material has an electrical resistance that depends on the direction of the magnetization of the medium moving under it. By passing a current through the MR sensor, resistance changes are detected as voltage signals. The MR design allows higher-frequency operation, which equates to greater storage densities and operating speeds.

Data Organization and Formatting

The head is a relatively small device capable of reading from or writing to a portion of the platter rotating beneath it. This gives rise to the organization of data on the platter in a concentric set of rings, called **tracks**. Each track is the same width as the head. There are thousands of tracks per surface.

Figure 7.2 depicts this data layout. Adjacent tracks are separated by **intertrack gaps**. This prevents, or at least minimizes, errors due to misalignment of the head or simply interference of magnetic fields. Data are transferred to and from the disk in **sectors**. There are typically hundreds of sectors per track, and these may be of either fixed or variable length. In most contemporary systems, fixed-length sectors are used. To avoid imposing unreasonable precision requirements on the system, adjacent sectors are separated by intersector gaps.

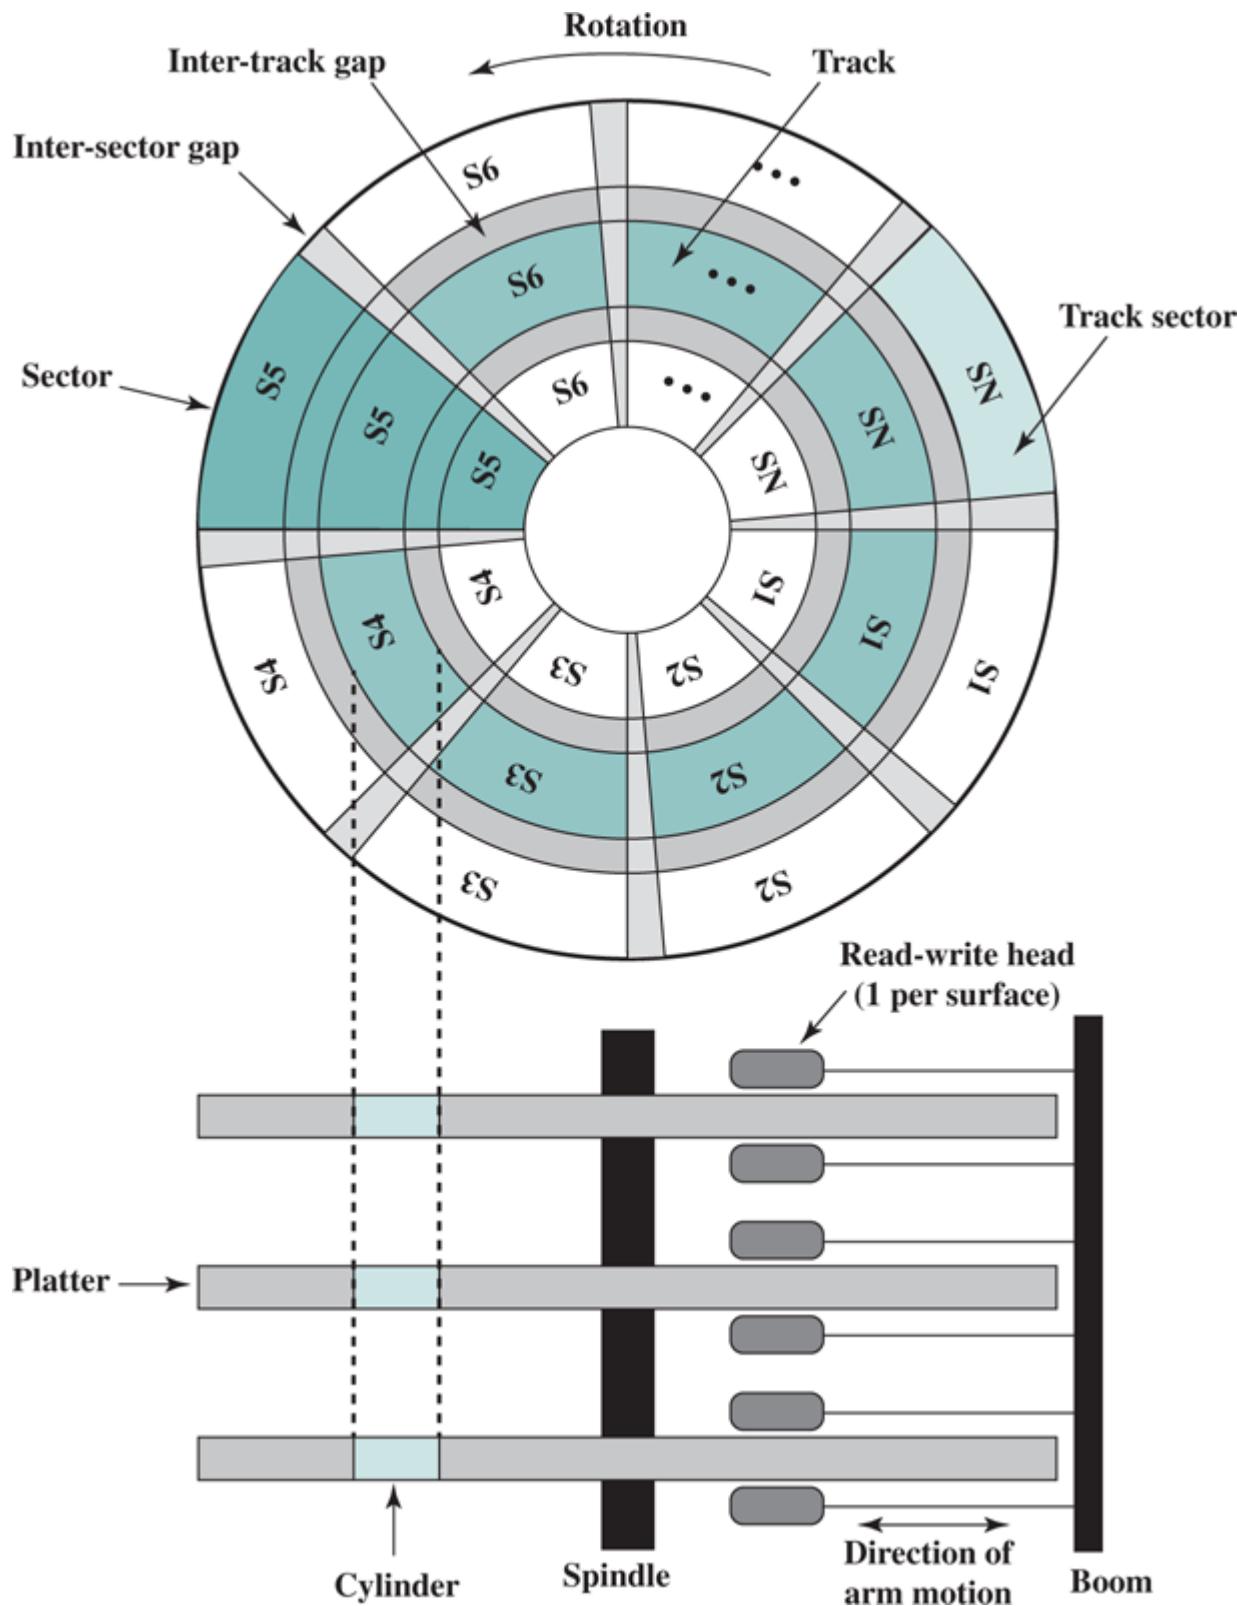

Figure 7.2 Disk Data Layout

A bit near the center of a rotating disk travels past a fixed point (such as a read–write head) slower than a bit on the outside. Therefore, some way must be found to compensate for the variation in speed so that the head can read all the bits at the same rate. This can be done by defining a variable spacing between bits of information recorded in locations on the disk, in a way that the outermost tracks have sectors with bigger spacing. The information can then be scanned at the same rate by rotating the disk at a fixed speed, known as the **constant angular velocity (CAV)**. [Figure 7.3a](#) shows the layout of a disk using CAV. The disk is divided into a number of pie-shaped sectors and into a series of concentric tracks. The advantage of using CAV is that individual blocks of data can be directly addressed by track and sector. To move the head from its current location to a specific

address, it only takes a short movement of the head to a specific track and a short wait for the proper sector to spin under the head. The disadvantage of CAV is that the amount of data that can be stored on the long outer tracks is the same as what can be stored on the short inner tracks.

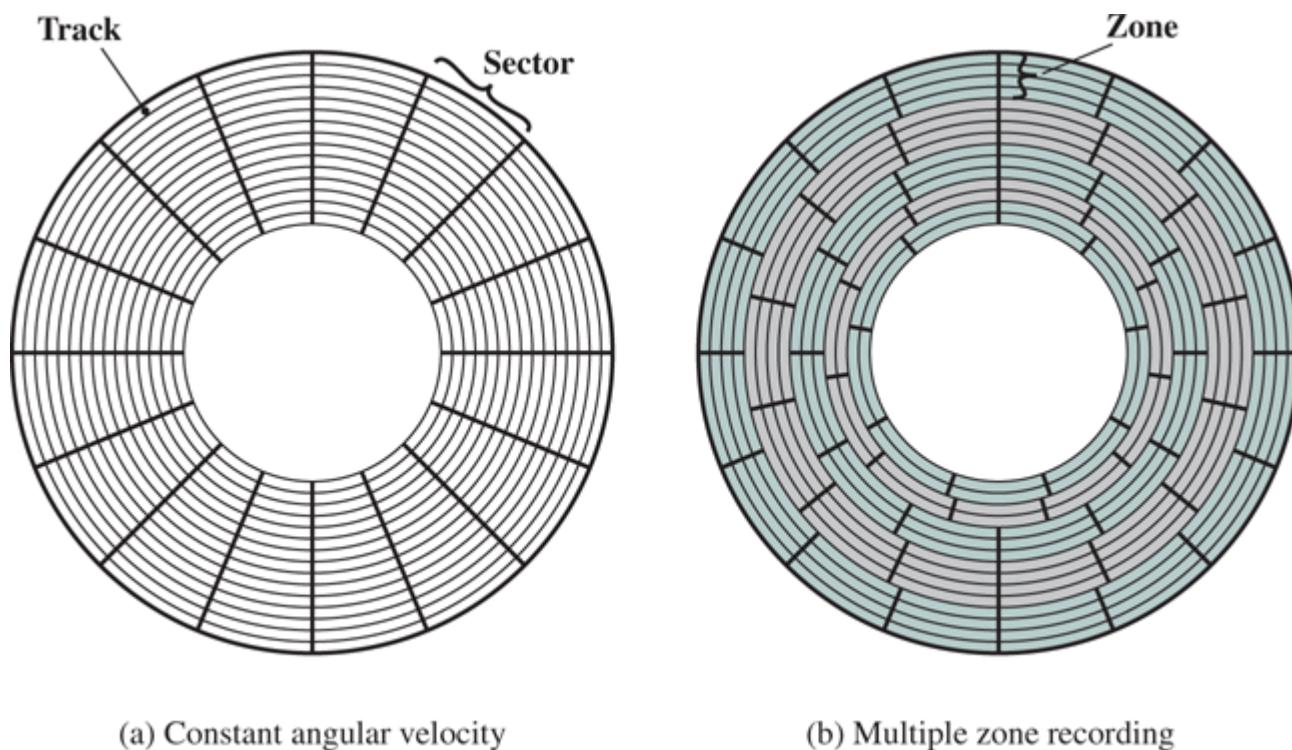

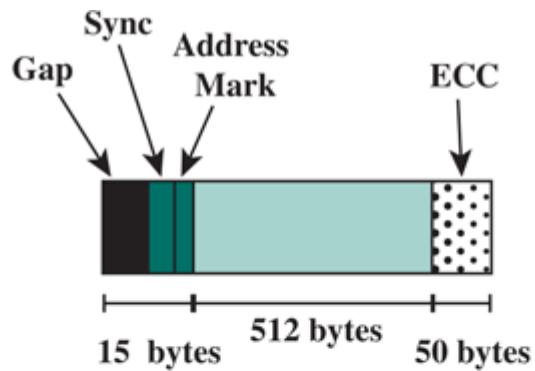

Figure 7.3 Comparison of Disk Layout Methods

Because the **density**, in bits per linear inch, increases in moving from the outermost track to the innermost track, disk storage capacity in a straightforward CAV system is limited by the maximum recording density that can be achieved on the innermost track. To maximize storage capacity, it would be preferable to have the same linear bit density on each track. This would require unacceptably complex circuitry. Modern hard disk systems use a simpler technique, which approximates equal bit density per track, known as **multiple zone recording (MZR)**, in which the surface is divided into a number of concentric zones (16 is typical). Each zone contains a number of contiguous tracks, typically in the thousands. Within a zone, the number of bits per track is constant. Zones farther from the center contain more bits (more sectors) than zones closer to the center. Zones are defined in such a way that the linear bit density is approximately the same on all tracks of the disk. MZR allows for greater overall storage capacity at the expense of somewhat more complex circuitry. As the disk head moves from one zone to another, the length (along the track) of individual bits changes, causing a change in the timing for reads and writes.

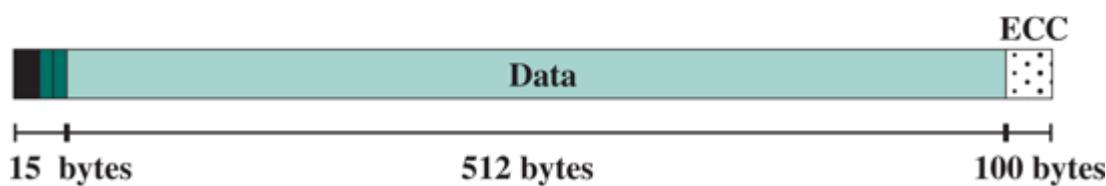

Figure 7.3b is a simplified MZR layout, with 15 tracks organized into 5 zones. The innermost two zones have two tracks each, with each track having nine sectors; the next zone has 3 tracks, each with 12 sectors; and the outermost 2 zones have 4 tracks each, with each track having 16 sectors.

Some means is needed to locate sector positions within a track. Clearly, there must be some starting point on the track and a way of identifying the start and end of each sector. These requirements are handled by means of control data recorded on the disk. Thus, the disk is formatted with some extra data used only by the disk drive and not accessible to the user.

Figure 7.4. shows two common sector formats used in contemporary hard disk drives. The standard format used for many years divided the track into sectors, each containing 512 bytes of data. Each sector also includes control information useful to the disk controller. The structure of the sector layout for this format consists of the following:

(a) Legacy 512-byte sector

(b) Advanced Format 4k-byte sector

Figure 7.4 Legacy and Advanced Sector Formats

- **Gap:** Separates sectors.
- **Sync:** Indicates the beginning of the sector and provides timing alignment.
- **Address mark:** Contains data to identify the sector's number and location. It also provides status about the sector itself.
- **Data:** The 512 bytes of user data.
- **Error correction code (ECC):** Used to correct data that might be damaged in the reading and writing process.

Although this format has served the industry well for many years, it has become increasingly inadequate for two reasons:

1. Applications common in modern computing systems use much greater amounts of data and manage the data in large blocks. Compared to these requirements, the small blocks of traditional sector formatting devote a considerable fraction of each sector to control information. The overhead consists of 65 bytes, yielding a format efficiency of $(512 / 512 + 65) \approx 0.88$.
2. Bit density on disks has increased substantially, so that each sector consumes less physical space. Accordingly, a media defect or other error source can damage a higher percentage of the total payload, requiring more error correction strength.

Accordingly, the industry has responded by standardizing a new Advanced Format for a 4096-byte block, illustrated in Figure 7.4b. The leading overhead remains at 15 bytes and the ECC is expanded to 100 bytes, yielding a format efficiency of $(4096 / 4096 + 115) \approx 0.97$, almost a 10% improvement in efficiency. More significantly, doubling the ECC to 100 bytes enables the correction of longer sequences of error bits.

Physical Characteristics

Table 7.1 lists the major characteristics that differentiate the various types of magnetic disks. First, the

head may either be fixed or movable with respect to the radial direction of the platter. In a **fixed-head disk**, there is one read-write head per track. All of the heads are mounted on a rigid arm that extends across all tracks; such systems are rare today. In a **movable-head disk**, there is only one read-write head. Again, the head is mounted on an arm. Because the head must be able to be positioned above any track, the arm can be extended or retracted for this purpose.

Table 7.1 Physical Characteristics of Disk Systems

Head Motion	Platters
Fixed head (one per track)	Single platter
Movable head (one per surface)	Multiple platter
Disk Portability	Head Mechanism
Nonremovable disk	Contact (floppy)
Removable disk	Fixed gap
Sides	Aerodynamic gap (Winchester)
Single sided	
Double sided	

The disk itself is mounted in a disk drive, which consists of the arm, a spindle that rotates the disk, and the electronics needed for input and output of binary data. A **nonremovable disk** is permanently mounted in the disk drive; the hard disk in a personal computer is a nonremovable disk. A **removable disk** can be removed and replaced with another disk. The advantage of the latter type is that unlimited amounts of data are available with a limited number of disk systems. Furthermore, such a disk may be moved from one computer system to another. Floppy disks and ZIP cartridge disks are examples of removable disks.

For most disks, the magnetizable coating is applied to both sides of the platter, which is then referred to as **double sided**. Some less expensive disk systems use **single-sided** disks.

Some disk drives accommodate **multiple platters** stacked vertically a fraction of an inch apart. Multiple arms are provided ([Figure 7.2](#)). Multiple-platter disks employ a movable head, with one read-write head per platter surface. All of the heads are mechanically fixed so that all are at the same distance from the center of the disk and move together. Thus, at any time, all of the heads are positioned over tracks that are of equal distance from the center of the disk. The set of all the tracks in the same relative position on the platter is referred to as a **cylinder**. This is illustrated in [Figure 7.2](#).

Finally, the head mechanism provides a classification of disks into three types. Traditionally, the read-write head has been positioned a fixed distance above the platter, allowing an air gap. At the other extreme is a head mechanism that actually comes into physical contact with the medium during a read or write operation. This mechanism is used with the **floppy disk**, which is a small, flexible platter and the least expensive type of disk.

To understand the third type of disk, we need to comment on the relationship between data density and the size of the air gap. The head must generate or sense an electromagnetic field of sufficient magnitude to write and read properly. The narrower the head is, the closer it must be to the platter surface to function. A narrower head means narrower tracks and therefore greater data density, which is desirable. However, the closer the head is to the disk, the greater the risk of error from impurities or imperfections. To push the technology further, the Winchester disk was developed. Winchester heads are used in sealed drive assemblies that are almost free of contaminants. They are designed to operate closer to the disk's surface than conventional rigid disk heads, thus allowing greater data density. The head is actually an aerodynamic foil that rests lightly on the platter's surface when the disk is motionless. The air pressure generated by a spinning disk is enough to make the foil rise above the surface. The resulting noncontact system can be engineered to use narrower heads that operate closer to the platter's surface than conventional rigid disk heads.

Disk Performance Parameters

The actual details of disk I/O operation depend on the computer system, the operating system, and the nature of the I/O channel and disk controller hardware. A general timing diagram of disk I/O transfer is shown in [Figure 7.5](#).

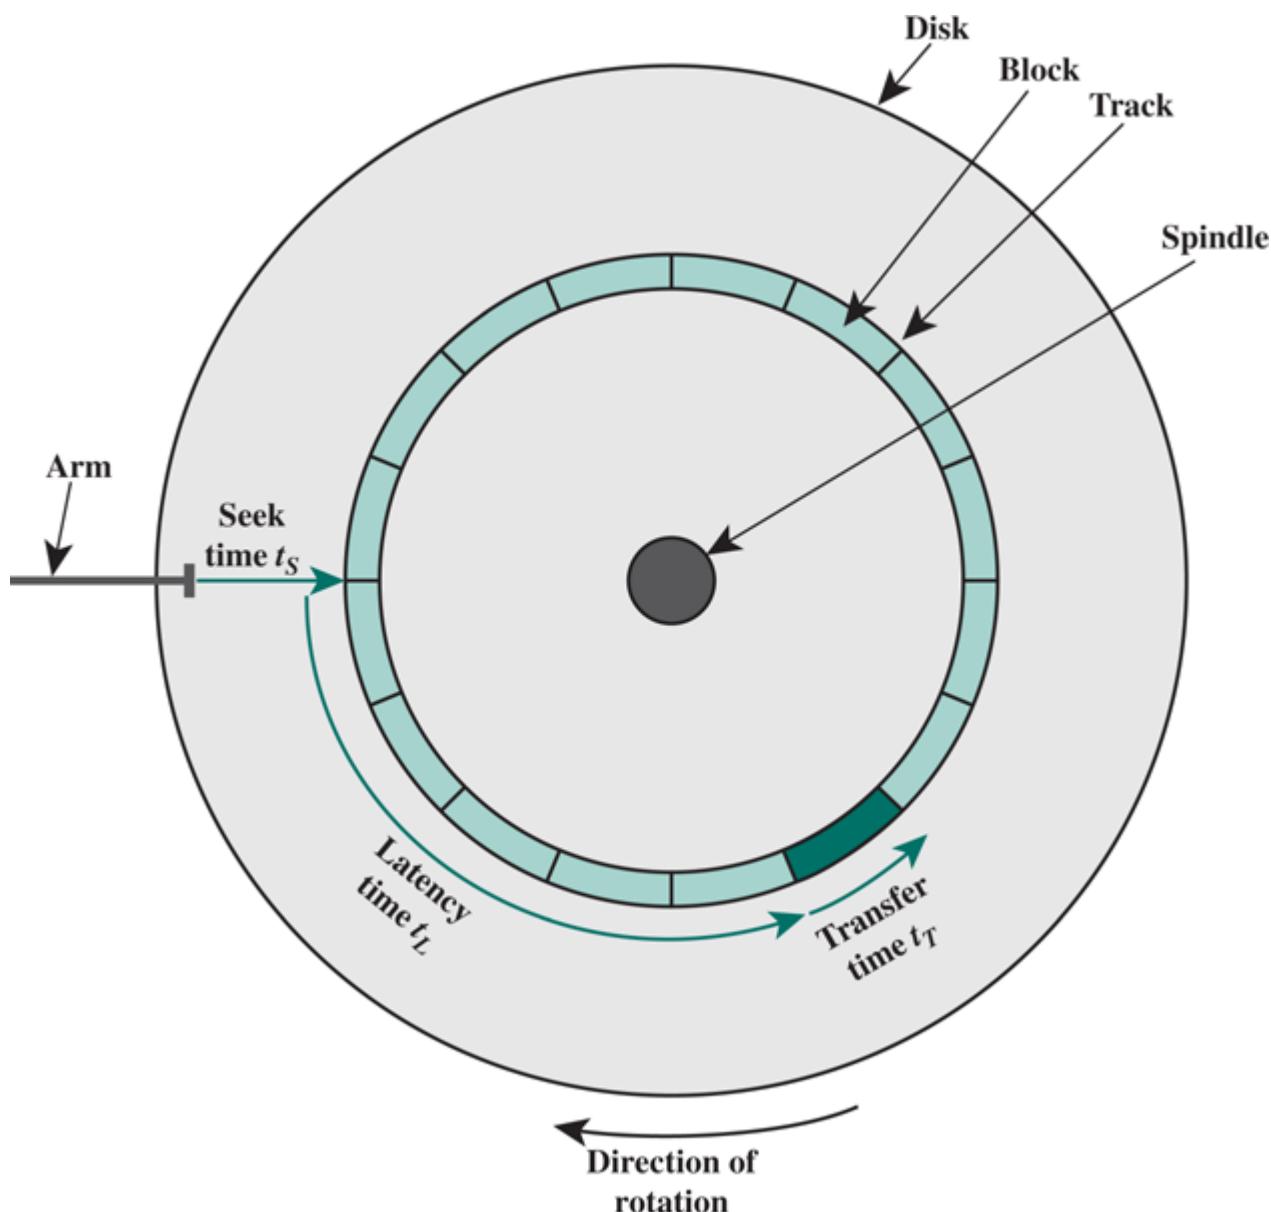

Figure 7.5 Timing of a Disk I/O Transfer

When the disk drive is operating, the disk is rotating at constant speed. To read or write, the head must be positioned at the desired track and at the beginning of the desired sector on that track. Track selection involves moving the head in a movable-head system or electronically selecting one head on a fixed-head system. On a movable-head system, the time it takes to position the head at the track is known as **seek time** t_S . In either case, once the track is selected, the disk controller waits until the appropriate sector rotates to line up with the head. The time it takes for the beginning of the sector to reach the head is known as **rotational latency**, or **latency time** t_L . Once the head is in position, the read or write operation is then performed as the sector moves under the head; this is the data transfer portion of the operation; the time required for the transfer is the **transfer time** t_T . The sum of the seek time, if any, the latency time, and the transfer time equals the **bloc access time** t_B , or simply **access time**:

$$t_B = t_S + t_L + t_T$$

In addition to the access time, there are several queuing delays normally associated with a disk I/O operation. When a process issues an I/O request, it must first wait in a queue for the device to be available. At that time, the device is assigned to the process. If the device shares a single I/O channel or a set of I/O channels with other disk drives, then there may be an additional wait for the channel to be available. At that point, the seek is performed to begin disk access.

In some high-end systems for servers, a technique known as rotational positional sensing (RPS) is used. This works as follows: When the seek command has been issued, the channel is released to handle other I/O operations. When the seek is completed, the device determines when the data will rotate under the head. As that sector approaches the head, the device tries to reestablish the communication path back to the host. If either the control unit or the channel is busy with another I/O, then the reconnection attempt fails and the device must rotate one whole revolution before it can attempt to reconnect, which is called an RPS miss. This is an extra delay element that must be added to the access time.

SEEK TIME

Seek time is the time required to move the disk arm to the required track. It turns out that this is a difficult quantity to pin down. The seek time consists of two key components: the initial startup time, and the time taken to traverse the tracks that have to be crossed once the access arm is up to speed. Unfortunately, the traversal time is not a linear function of the number of tracks, but includes a settling time (time after positioning the head over the target track until track identification is confirmed). A mean value of t_S is typically provided by the manufacturer.

Much improvement comes from smaller and lighter disk components. Some years ago, a typical disk was 14 inches (36 cm) in diameter, whereas the most common size today is 3.5 inches (8.9 cm), reducing the distance that the arm has to travel. A typical average seek time on contemporary hard disks is under 10 ms.

LATENCY TIME

Disks, other than floppy disks, rotate at speeds ranging from 3600 rpm (for handheld devices such as digital cameras) up to, as of this writing, 20,000 rpm; at this latter speed, there is one revolution per 3 ms. Thus, on the average, the latency time t_L will be 1.5 ms.

TRANSFER TIME

The transfer time to or from the disk depends on the rotation speed of the disk in the following fashion:

$$t_T = \frac{b}{rN}$$

where

- b = number of bytes to be transferred
- N = number of bytes on a track
- r = rotation speed, in revolutions per second

Thus the total average block read or write time T_{total} can be expressed as

$$t_B = t_S + \frac{1}{2r} + \frac{b}{rN} \quad (7.1)$$

where t_s is the average seek time. Note that on a zoned drive, the number of bytes per track is variable, complicating the calculation.¹

¹ Compare the two preceding equations to [Equation \(4.1\)](#).

A TIMING COMPARISON

With the foregoing parameters defined, let us look at two different I/O operations that illustrate the danger of relying on average values. Consider a disk with an advertised average seek time of 4 ms, rotation speed of 15,000 rpm, and 512-byte sectors with 500 sectors per track. Suppose that we wish to read a file consisting of 2500 sectors for a total of 1.28 Mbytes. We would like to estimate the total time for the transfer.

First, let us assume that the file is stored as compactly as possible on the disk. That is, the file occupies all of the sectors on 5 adjacent tracks ($5\text{tracks} \times 500\text{sectors / track} = 2500\text{sectors}$). This is known as *sequential organization*. Now, the time to read the first track is as follows:

Average seek	4 ms
Average rotational delay	2 ms
Read 500 sectors	4ms 10ms

Suppose that the remaining tracks can now be read with essentially no seek time. That is, the I/O operation can keep up with the flow from the disk. Then, at most, we need to deal with rotational delay for the four remaining tracks. Thus each successive track is read in $2 + 4 = 6\text{ms}$. To read the entire file,

$$\text{Total time} = 10 + (4 \times 6) = 34\text{ms} = 0.034\text{seconds}$$

Now let us calculate the time required to read the same data using random access rather than

sequential access; that is, accesses to the sectors are distributed randomly over the disk. For each sector, we have

Average seek	4 ms
Rotational delay	2 ms
Read 1 sectors	0.008ms 6.008ms

$$\text{Total time} = 2500 \times 6.008 = 15,020\text{ms} = 15.02\text{seconds}$$

It is clear that the order in which sectors are read from the disk has a tremendous effect on I/O performance. In the case of file access in which multiple sectors are read or written, we have some control over the way in which sectors of data are deployed. However, even in the case of a file access, in a multiprogramming environment, there will be I/O requests competing for the same disk. Thus, it is worthwhile to examine ways in which the performance of disk I/O can be improved over that achieved with purely random access to the disk. This leads to a consideration of disk scheduling algorithms, which is the province of the operating system and beyond the scope of this book text (see [STAL18] for a discussion).

Table 7.2 gives disk parameters for typical contemporary internal high-performance disks. The HGST Ultrastar HE is intended for enterprise applications, such as use in servers and workstations. The HGST Ultrastar C15K600 is designed for use in high-performance computing and mission critical data center installations. The Toshiba L200 is an internal laptop hard disk drive.

Table 7.2 Typical Hard Disk Drive Parameters

Characteristics	HGST Ultrastar HE	HGST Ultrastar C15K600	Toshiba L200
Application	Enterprise	Data Center	Laptop
Capacity	12 TB	600 GB	500 GB
Average seek time	8.0 ms read 8.6 ms write	2.9 ms read 3.1 ms write	11 ms
Spindle speed	7200 rpm	15,030 rpm	5400 rpm
Average latency	4.16	< 2 ms	5.6 ms
Maximum sustained transfer rate	255 MB/s	1.2 GB/s	3 GB/s
Bytes per sector	512/4096	512/4096	4096

Tracks per cylinder (number of platter surfaces)	8	6	4
Cache	256 MB	128 MB	16 MB
Diameter	3.5 in (8.89 cm)s	2.5 in (6.35 cm)	2.5 in (6.35 cm)
Maximum areal density (Gb/cm ²)	134	82	66

We can make some useful observations on this table. The seek time depends in part on the power and quality of the arm actuator. On the other end of the spectrum, a laptop disk needs to be small, inexpensive, and low power, so that the attainable seek time is much greater. Seek time also depends on physical characteristics. The Ultrastar C15K600 has a smaller diameter than the Ultrastar HE. With less average distance to travel, the C15K600 achieves lower seek time. In addition, the C15K600 has a lower bit density on the disk surface, so that less precision is needed in positioning the read/write head, again contributing to lower seek time. Of course the penalty of achieving these lower seek times is a much lower disk capacity. But the Ultrastar C15K600 is likely to be used in applications that call for a high rate of accesses to the disk, so it is reasonable to invest in minimizing the seek time.

Note that for the two HGST disks, the average seek time is less for reads than for writes. For writes, more precision is required to place the write head dead center on the track. Less precision is needed simply to sense the data that is already there.

For the block size, or bytes per physical sector, the two HGST disks can be configured for 512 or 4096 bytes, and the laptop disk is offered only at 4096 bytes. As discussed previously, the larger block size is more efficient in space and more effective in error correction.

Aleksandr Lukin/123RF

RAID Simulator

7.2 RAID

As discussed earlier, the rate in improvement in secondary storage performance has been considerably less than the rate for processors and main memory. This mismatch has made the disk storage system perhaps the main focus of concern in improving overall computer system performance.

As in other areas of computer performance, disk storage designers recognize that if one component can only be pushed so far, additional gains in performance are to be had by using multiple parallel components. In the case of disk storage, this leads to the development of arrays of disks that operate independently and in parallel. With multiple disks, separate I/O requests can be handled in parallel, as long as the data required reside on separate disks. Further, a single I/O request can be executed in parallel if the block of data to be accessed is distributed across multiple disks.

With the use of multiple disks, there is a wide variety of ways in which the data can be organized and in which redundancy can be added to improve reliability. This could make it difficult to develop database schemes that are usable on a number of platforms and operating systems. Fortunately, industry has agreed on a standardized scheme for multiple-disk database design, known as RAID (Redundant Array of Independent Disks). The RAID scheme consists of seven levels,² zero through six. These levels do not imply a hierarchical relationship, but designate different design architectures that share three common characteristics:

² Additional levels have been defined by some researchers and some companies, but the seven levels described in this section are the ones universally agreed on.

1. RAID is a set of physical disk drives viewed by the operating system as a single logical drive.
2. Data are distributed across the physical drives of an array in a scheme known as striping, described subsequently.
3. Redundant disk capacity is used to store parity information, which guarantees data recoverability in case of a disk failure.

The details of the second and third characteristics differ for the different RAID levels. RAID 0 and RAID 1 do not support the third characteristic.

The term *RAID* was originally coined in a paper by a group of researchers at the University of California at Berkeley [PATT88].³ The paper outlined various RAID configurations and applications and introduced the definitions of the RAID levels that are still used. The RAID strategy employs multiple disk drives and distributes data in such a way as to enable simultaneous access to data from multiple drives, thereby improving I/O performance and allowing easier incremental increases in capacity.

³ In that paper, the acronym RAID stood for Redundant Array of Inexpensive Disks. The term *inexpensive* was used to contrast the small relatively inexpensive disks in the RAID array to the alternative, a single large expensive disk (SLED). The SLED is essentially a thing of the past, with similar disk technology being used for both RAID and non-RAID configurations. Accordingly, the industry has adopted the term *independent* to emphasize that the RAID array creates significant performance and reliability gains.

The unique contribution of the RAID proposal is to address effectively the need for redundancy. Although allowing multiple heads and actuators to operate simultaneously achieves higher I/O and transfer rates, the use of multiple devices increases the probability of failure. To compensate for this decreased reliability, RAID makes use of stored parity information that enables the recovery of data lost due to a disk failure.

We now examine each of the RAID levels. **Table 7.3** provides a rough guide to the seven levels. In the table, I/O performance is shown both in terms of data transfer capacity, or ability to move data, and I/O request rate, or ability to satisfy I/O requests, since these RAID levels inherently perform differently relative to these two metrics. Each RAID level's strong point is highlighted by darker shading. **Table 7.6** illustrates the use of the seven RAID schemes to support a data capacity requiring four disks with no redundancy. The figures highlight the layout of user data and redundant data and indicate the relative storage requirements of the various levels. We refer to these figures throughout the following discussion. Of the seven RAID levels described, only four are commonly used: RAID levels 0, 1, 5, and 6.

Table 7.3 RAID Levels

Note: N = number of data disks ; m proportional to $\log N$

Category	Level	Description	Disks Required	Data Availability	Large I/O Data Transfer Capacity	Small I/O Request Rate
Striping	0	Nonredundant	N	Lower than single disk	Very high	Very high for both read and write
Mirroring	1	Mirrored	$2N$	Higher than RAID 2, 3, 4, or 5; lower than RAID 6	Higher than single disk for read; similar to single disk for write	Up to twice that of a single disk for read; similar to single disk for write
Parallel access	2	Redundant via Hamming code	$N + m$	Much higher than single disk; comparable to RAID 3, 4, or 5	Highest of all listed alternatives	Approximately twice that of a single disk
	3	Bit-interleaved parity	$N + 1$	Much higher than single disk; comparable	Highest of all listed alternatives	Approximately twice that of a single disk

				to RAID 2, 4, or 5		
Independent access	4	Block-interleaved parity	$N + 1$	Much higher than single disk; comparable to RAID 2, 3, or 5	Similar to RAID 0 for read; significantly lower than single disk for write	Similar to RAID 0 for read; significantly lower than single disk for write
	5	Block-interleaved distributed parity	$N + 1$	Much higher than single disk; comparable to RAID 2, 3, or 4	Similar to RAID 0 for read; lower than single disk for write	Similar to RAID 0 for read; generally lower than single disk for write
	6	Block-interleaved dual distributed parity	$N + 2$	Highest of all listed alternatives	Similar to RAID 0 for read; lower than RAID 5 for write	Similar to RAID 0 for read; significantly lower than RAID 5 for write

RAID Level 0

RAID level 0 is not a true member of the RAID family because it does not include redundancy to improve performance. However, there are a few applications, such as some on supercomputers in which performance and capacity are primary concerns and low cost is more important than improved reliability.

For RAID 0, the user and system data are distributed across all of the disks in the array. This has a notable advantage over the use of a single large disk: If two-different I/O requests are pending for two different blocks of data, then there is a good chance that the requested blocks are on different disks. Thus, the two requests can be issued in parallel, reducing the I/O queuing time.

But RAID 0, as with all of the RAID levels, goes further than simply distributing the data across a disk array: The data are *striped* across the available disks. This is best understood by considering [Figure 7.7](#). All of the user and system data are viewed as being stored on a logical disk. The logical disk is divided into strips; these strips may be physical blocks, sectors, or some other unit. The strips are mapped round robin to consecutive physical disks in the RAID array. A set of logically consecutive

strips that maps exactly one strip to each array member is referred to as a **stripe**. In an n -disk array, the first n logical strips are physically stored as the first strip on each of the n disks, forming the first stripe; the second n strips are distributed as the second strips on each disk; and so on. The advantage of this layout is that if a single I/O request consists of multiple logically contiguous strips, then up to n strips for that request can be handled in parallel, greatly reducing the I/O transfer time.

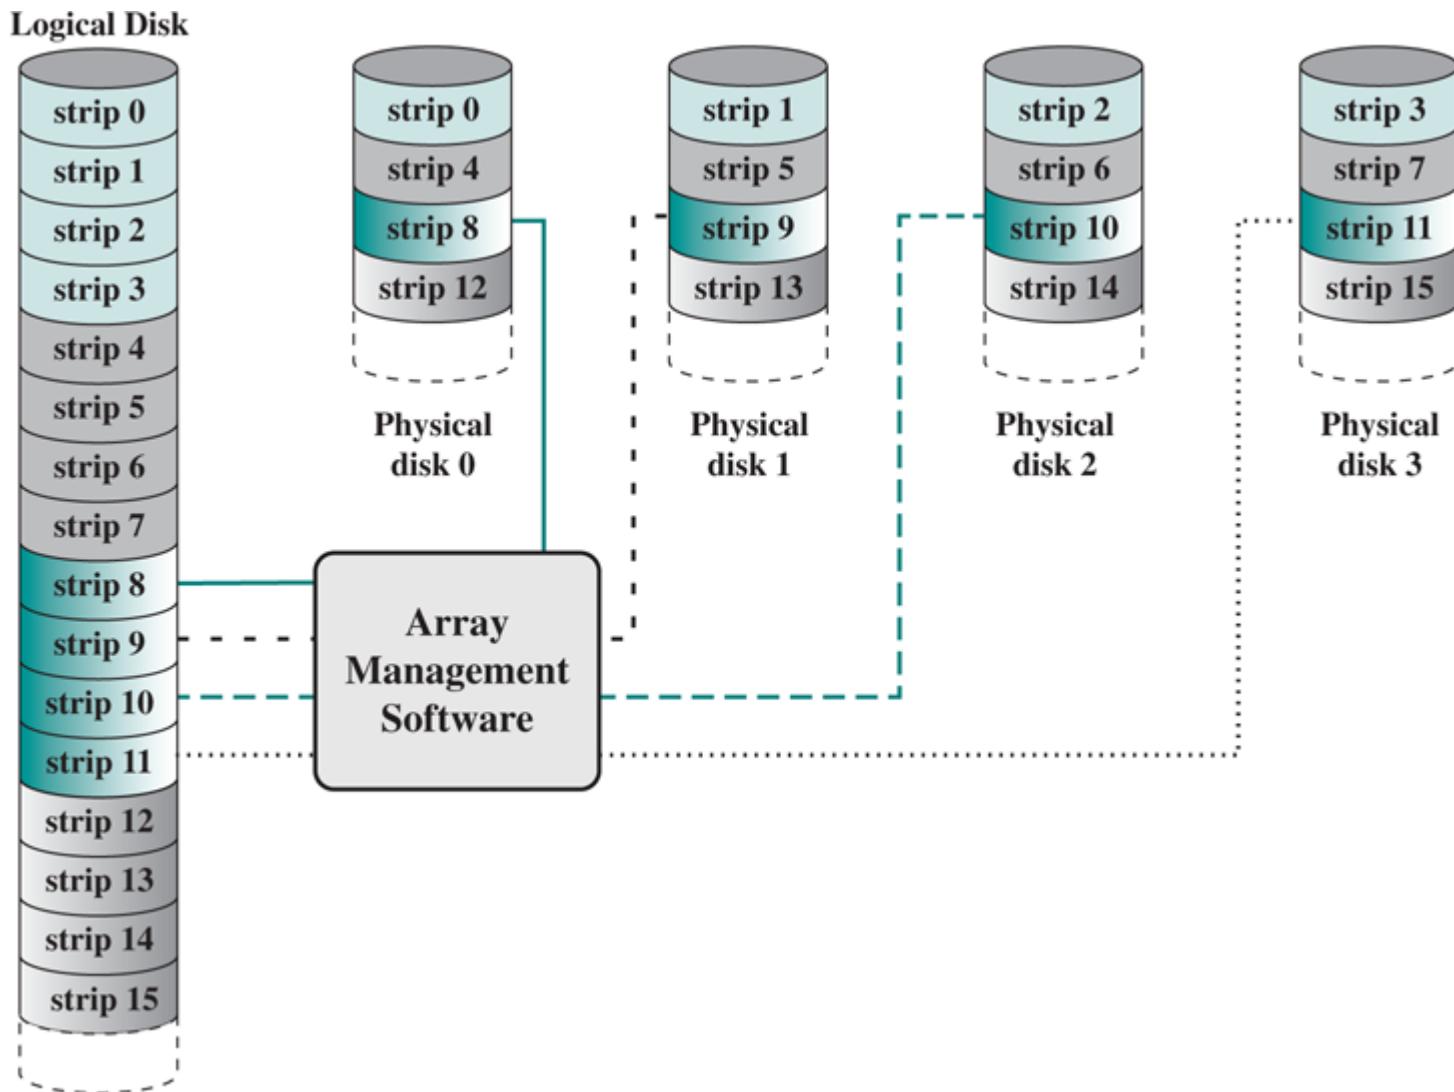

Figure 7.7 Data Mapping for a RAID Level 0 Array

Figure 7.7 indicates the use of array management software to map between logical and physical disk space. This software may execute either in the disk subsystem or in a host computer.

RAID 0 FOR HIGH DATA TRANSFER CAPACITY

The performance of any of the RAID levels depends critically on the request patterns of the host system and on the layout of the data. These issues can be most clearly addressed in RAID 0, where the impact of redundancy does not interfere with the analysis. First, let us consider the use of RAID 0 to achieve a high data transfer rate. For applications to experience a high transfer rate, two requirements must be met. First, a high transfer capacity must exist along the entire path between host memory and the individual disk drives. This includes internal controller buses, host system I/O buses, I/O adapters, and host memory buses.

The second requirement is that the application must make I/O requests that drive the disk array efficiently. This requirement is met if the typical request is for large amounts of logically contiguous data, compared to the size of a strip. In this case, a single I/O request involves the parallel transfer of

data from multiple disks, increasing the effective transfer rate compared to a single-disk transfer.

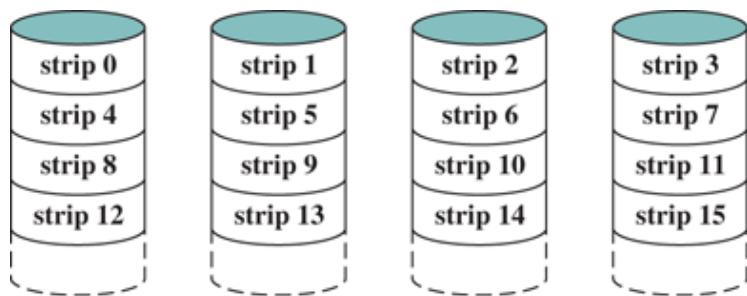

RAID 0 FOR HIGH I/O REQUEST RATE

In a transaction-oriented environment, the user is typically more concerned with response time than with transfer rate. For an individual I/O request for a small amount of data, the I/O time is dominated by the motion of the disk heads (seek time) and the movement of the disk (rotational latency).

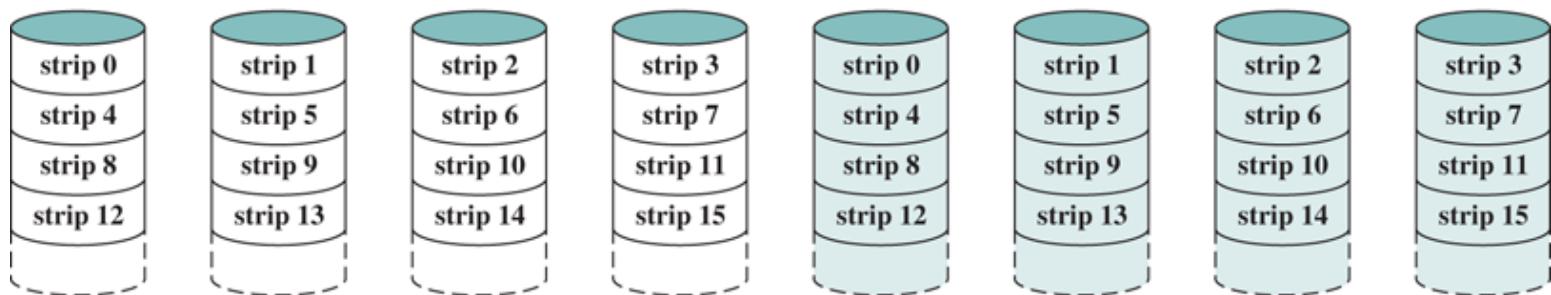

In a transaction environment, there may be hundreds of I/O requests per second. A disk array can provide high I/O execution rates by balancing the I/O load across multiple disks. Effective load balancing is achieved only if there are typically multiple I/O requests outstanding. This, in turn, implies that there are multiple independent applications or a single transaction-oriented application that is capable of multiple asynchronous I/O requests. The performance will also be influenced by the strip size. If the strip size is relatively large, so that a single I/O request only involves a single disk access, then multiple waiting I/O requests can be handled in parallel, reducing the queuing time for each request.

RAID Level 1

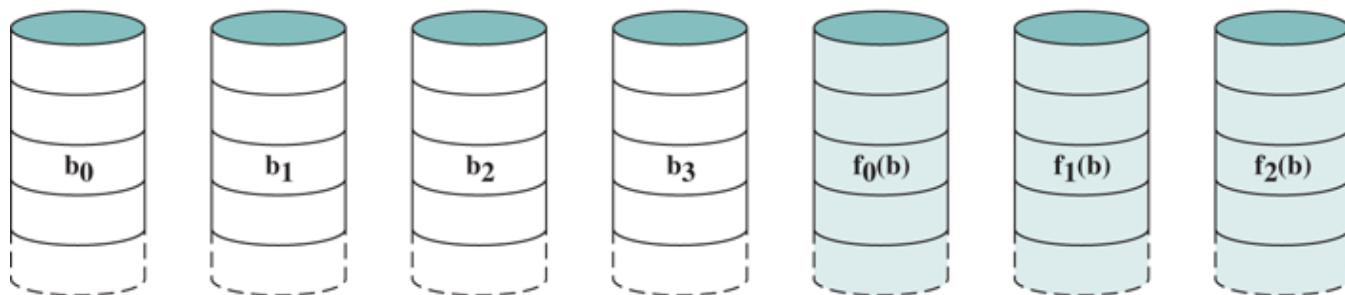

RAID 1 differs from RAID levels 2 through 6 in the way in which redundancy is achieved. In these other RAID schemes, some form of parity calculation is used to introduce redundancy, whereas in RAID 1, redundancy is achieved by the simple expedient of duplicating all the data. As [Figure 7.6b](#) shows, data striping is used, as in RAID 0. But in this case, each logical strip is mapped to two separate physical disks so that every disk in the array has a mirror disk that contains the same data. RAID 1 can also be implemented without data striping, though this is less common.

(a) RAID 0 (Nonredundant)

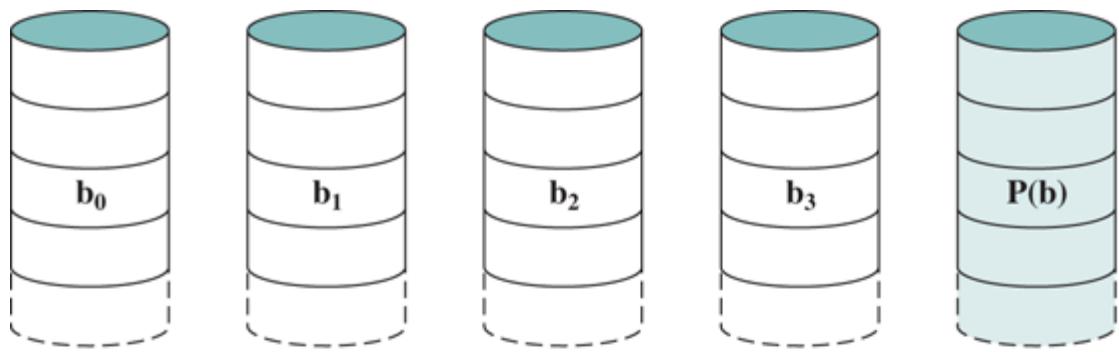

(b) RAID 1 (Mirrored)

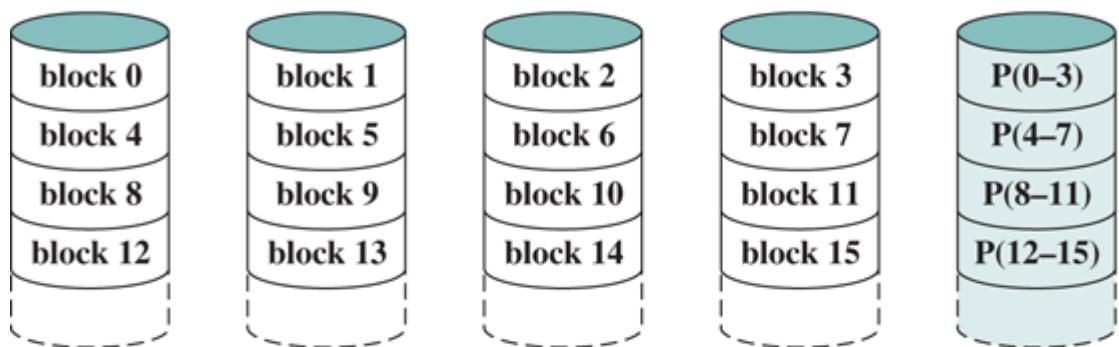

(c) RAID 2 (Redundancy through Hamming code)

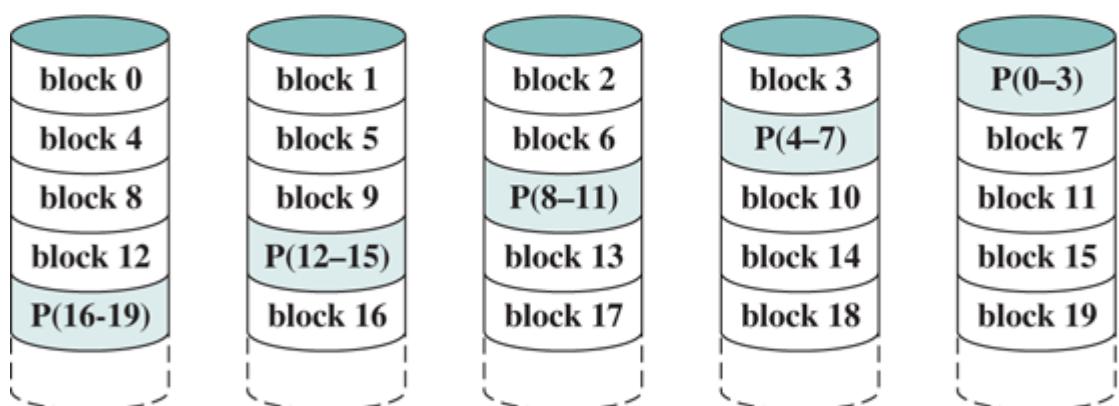

Figure 7.6 RAID Levels

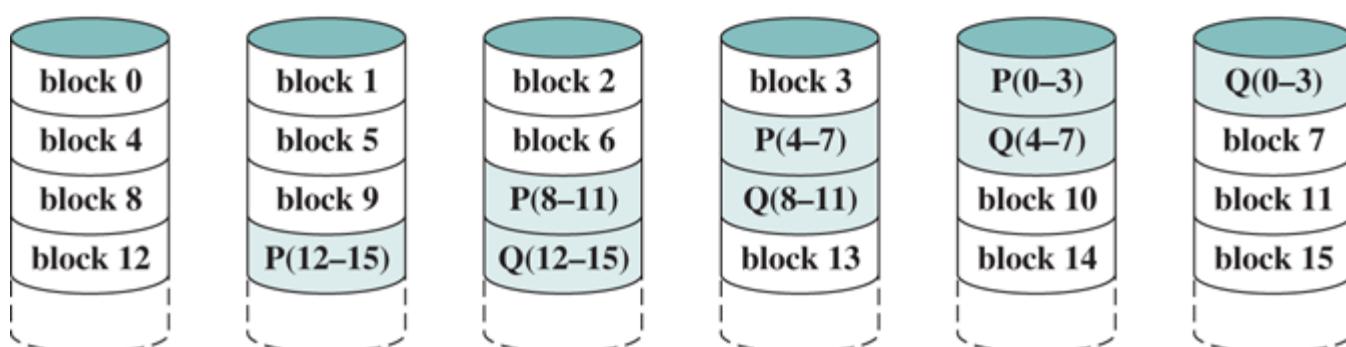

(d) RAID 3 (Bit-interleaved parity)

(e) RAID 4 (Block-level parity)

(f) RAID 5 (Block-level distributed parity)

(g) RAID 6 (Dual redundancy)

There are a number of positive aspects to the RAID 1 organization:

1. A read request can be serviced by either of the two disks that contains the requested data,

- whichever one involves the minimum seek time plus rotational latency.
2. A write request requires that both corresponding strips be updated, but this can be done in parallel. Thus, the write performance is dictated by the slower of the two writes (i.e., the one that involves the larger seek time plus rotational latency). However, there is no “write penalty” with RAID 1. RAID levels 2 through 6 involve the use of parity bits. Therefore, when a single strip is updated, the array management software must first compute and update the parity bits as well as updating the actual strip in question.
 3. Recovery from a failure is simple. When a drive fails, the data may still be accessed from the second drive.

The principal disadvantage of RAID 1 is the cost; it requires twice the disk space of the logical disk that it supports. Because of that, a RAID 1 configuration is likely to be limited to drives that store system software and data, and other highly critical files. In these cases, RAID 1 provides a real-time copy of all data so that in the event of a disk failure, all of the critical data are still immediately available.

In a transaction-oriented environment, RAID 1 can achieve high I/O request rates if the bulk of the requests are reads. In this situation, the performance of RAID 1 can approach double of that of RAID 0. However, if a substantial fraction of the I/O requests are write requests, then there may be no significant performance gain over RAID 0. RAID 1 may also provide improved performance over RAID 0 for data transfer intensive applications with a high percentage of reads. Improvement occurs if the application can split each read request so that both disk members participate.

RAID Level 2

RAID levels 2 and 3 make use of a parallel access technique. In a parallel access array, all member disks participate in the execution of every I/O request. Typically, the spindles of the individual drives are synchronized so that each disk head is in the same position on each disk at any given time.

As in the other RAID schemes, data striping is used. In the case of RAID 2 and 3, the strips are very small, often as small as a single byte or word. With RAID 2, an error-correcting code is calculated across corresponding bits on each data disk, and the bits of the code are stored in the corresponding bit positions on multiple parity disks. Typically, a Hamming code is used, which is able to correct single-bit errors and detect double-bit errors.

Although RAID 2 requires fewer disks than RAID 1, it is still rather costly. The number of redundant disks is proportional to the log of the number of data disks. On a single read, all disks are simultaneously accessed. The requested data and the associated error-correcting code are delivered to the array controller. If there is a single-bit error, the controller can recognize and correct the error instantly, so that the read access time is not slowed. On a single write, all data disks and parity disks must be accessed for the write operation.

RAID 2 would only be an effective choice in an environment in which many disk errors occur. Given the high reliability of individual disks and disk drives, RAID 2 is overkill and is not implemented.

RAID Level 3

RAID 3 is organized in a similar fashion to RAID 2. The difference is that RAID 3 requires only a single redundant disk, no matter how large the disk array. RAID 3 employs parallel access, with data distributed in small strips. Instead of an error-correcting code, a simple parity bit is computed for the set of individual bits in the same position on all of the data disks.

REDUNDANCY

In the event of a drive failure, the parity drive is accessed and data is reconstructed from the remaining devices. Once the failed drive is replaced, the missing data can be restored on the new drive and operation resumed.

Data reconstruction is simple. Consider an array of five drives in which X0 through X3 contain data and X4 is the parity disk. The parity for the i th bit is calculated as follows:

$$X4(i) = X3(i) \oplus X2(i) \oplus X1(i) \oplus X0(i)$$

where \oplus is exclusive-OR function.

Suppose that drive X1 has failed. If we add $X4(i) \oplus X1(i)$ to both sides of the preceding equation, we get

$$X1(i) = X4(i) \oplus X3(i) \oplus X2(i) \oplus X0(i)$$

Thus, the contents of each strip of data on X1 can be regenerated from the contents of the corresponding strips on the remaining disks in the array. This principle is true for RAID levels 3 through 6.

In the event of a disk failure, all of the data are still available in what is referred to as reduced mode. In this mode, for reads, the missing data are regenerated on the fly using the exclusive-OR calculation. When data are written to a reduced RAID 3 array, consistency of the parity must be maintained for later regeneration. Return to full operation requires that the failed disk be replaced and the entire contents of the failed disk be regenerated on the new disk.

PERFORMANCE

Because data are striped in very small strips, RAID 3 can achieve very high data transfer rates. Any I/O request will involve the parallel transfer of data from all of the data disks. For large transfers, the performance improvement is especially noticeable. On the other hand, only one I/O request can be executed at a time. Thus, in a transaction-oriented environment, performance suffers.

RAID Level 4

RAID levels 4 through 6 make use of an independent access technique. In an independent access array, each member disk operates independently, so that separate I/O requests can be satisfied in parallel. Because of this, independent access arrays are more suitable for applications that require high I/O request rates and are relatively less suited for applications that require high data transfer rates.

As in the other RAID schemes, data striping is used. In the case of RAID 4 through 6, the strips are relatively large. With RAID 4, a bit-by-bit parity strip is calculated across corresponding strips on each data disk, and the parity bits are stored in the corresponding strip on the parity disk.

RAID 4 involves a write penalty when an I/O write request of small size is performed. Each time that a write occurs, the array management software must update not only the user data but also the corresponding parity bits. Consider an array of five drives in which X0 through X3 contain data and X4 is the parity disk. Suppose that a write is performed that only involves a strip on disk X1. Initially, for each bit i , we have the following relationship:

$$X4(i) = X3(i) \oplus X2(i) \oplus X1(i) \oplus X0(i) \quad (7.2)$$

After the update, with potentially altered bits indicated by a prime symbol:

$$\begin{aligned} X4'(i) &= X3(i) \oplus X2(i) \oplus X1'(i) \oplus X0(i) \\ &= X3(i) \oplus X2(i) \oplus X1'(i) \oplus X0(i) \oplus X1(i) \oplus X1(i) \\ &= X3(i) \oplus X2(i) \oplus X1(i) \oplus X0(i) \oplus X1(i) \oplus X1'(i) \\ &= X4(i) \oplus X1(i) \oplus X1'(i) \end{aligned}$$

The preceding set of equations is derived as follows. The first line shows that a change in $X1$ will also affect the parity disk $X4$. In the second line, we add the terms $\oplus X1(i) \oplus X1(i)$. Because the exclusive-OR of any quantity with itself is 0, this does not affect the equation. However, it is a convenience that is used to create the third line, by reordering. Finally, **Equation (7.2)** is used to replace the first four terms by $X4(i)$.

To calculate the new parity, the array management software must read the old user strip and the old parity strip. Then it can update these two strips with the new data and the newly calculated parity. Thus, each strip write involves two reads and two writes.

In the case of a larger size I/O write that involves strips on all disk drives, parity is easily computed by calculation using only the new data bits. Thus, the parity drive can be updated in parallel with the data drives and there are no extra reads or writes.

In any case, every write operation must involve the parity disk, which therefore can become a bottleneck.

RAID Level 5

RAID 5 is organized in a similar fashion to RAID 4. The difference is that RAID 5 distributes the parity strips across all disks. A typical allocation is a round-robin scheme, as illustrated in **Figure 7.6f**. For an n -disk array, the parity strip is on a different disk for the first n stripes, and the pattern then repeats.

The distribution of parity strips across all drives avoids the potential I/O bottle-neck found in RAID 4.

RAID Level 6

RAID 6 was introduced in a subsequent paper by the Berkeley researchers [KATZ89]. In the RAID 6 scheme, two different parity calculations are carried out and stored in separate blocks on different disks. Thus, a RAID 6 array whose user data require N disks consists of $N + 2$ disks.

Figure 7.6g illustrates the scheme. P and Q are two different data check algorithms. One of the two is the exclusive-OR calculation used in RAID 4 and 5. But the other is an independent data check algorithm. This makes it possible to regenerate data even if two disks containing user data fail.

The advantage of RAID 6 is that it provides extremely high data availability. Three disks would have to fail within the MTTR (mean time to repair) interval to cause data to be lost. On the other hand, RAID 6 incurs a substantial write penalty, because each write affects two parity blocks. Performance benchmarks [EISC07] show a RAID 6 controller can suffer more than a 30% drop in overall write performance compared with a RAID 5 implementation. RAID 5 and RAID 6 read performance is comparable.

Table 7.4 is a comparative summary of the seven levels.

Table 7.4 RAID Comparison

Level	Advantages	Disadvantages	Applications
0	I/O performance is greatly improved by spreading the I/O load across many channels and drives No parity calculation overhead is involved Very simple design Easy to implement	The failure of just one drive will result in all data in an array being lost	Video production and editing Image Editing Pre-press applications Any application requiring high bandwidth
1	100% redundancy of data means no rebuild is necessary in case of a disk failure, just a copy to the replacement disk Under certain circumstances, RAID 1 can sustain multiple simultaneous drive failures Simplest RAID storage subsystem design	Highest disk overhead of all RAID types (100%)—inefficient	Accounting Payroll Financial Any application requiring very high availability
2	Extremely high data transfer rates possible The higher the data transfer rate required, the better the ratio of data disks to ECC disks Relatively simple controller design compared to RAID levels 3, 4, & 5	Very high ratio of ECC disks to data disks with smaller word sizes—inefficient Entry level cost very high—requires very high transfer rate requirement to justify	No commercial implementations exist/not commercially viable
3	Very high read data transfer rate Very high write data transfer rate Disk failure has an insignificant impact	Transaction rate equal to that of a single disk drive at best (if spindles are synchronized)	Video production and live streaming Image editing

	<p>on throughput</p> <p>Low ratio of ECC (parity) disks to data disks means high efficiency</p>	<p>Controller design is fairly complex</p>	<p>Video editing</p> <p>Prepress applications</p> <p>Any application requiring high throughput</p>
4	<p>Very high Read data transaction rate</p> <p>Low ratio of ECC (parity) disks to data disks means high efficiency</p>	<p>Quite complex controller design</p> <p>Worst write transaction rate and Write aggregate transfer rate</p> <p>Difficult and inefficient data rebuild in the event of disk failure</p>	<p>No commercial implementations exist/not commercially viable</p>
5	<p>Highest Read data transaction rate</p> <p>Low ratio of ECC (parity) disks to data disks means high efficiency</p> <p>Good aggregate transfer rate</p>	<p>Most complex controller design</p> <p>Difficult to rebuild in the event of a disk failure (as compared to RAID level 1)</p>	<p>File and application servers</p> <p>Database servers</p> <p>Web, e-mail, and news servers</p> <p>Intranet servers</p> <p>Most versatile RAID level</p>
6	<p>Provides for an extremely high data fault tolerance and can sustain multiple simultaneous drive failures</p>	<p>More complex controller design</p> <p>Controller overhead to compute parity addresses is extremely high</p>	<p>Perfect solution for mission critical applications</p>

7.3 Solid State Drives

One of the most significant developments in computer architecture in recent years is the increasing use of **solid state drives (SSDs)** to complement or even replace **hard disk drives (HDDs)**, both as internal and external secondary memory. The term *solid state* refers to electronic circuitry built with semiconductors. An SSD is a memory device made with solid state components that can be used as a replacement to a hard disk drive. The SSDs now on the market and coming on line use NAND flash memory, which is described in [Chapter 5](#).

SSD Compared to HDD

As the cost of flash-based SSDs has dropped and the performance and bit density increased, SSDs have become increasingly competitive with HDDs. [Table 7.5](#) shows typical measures of comparison at the time of this writing.

Table 7.5 Comparison of Solid State Drives and Disk Drives

	NAND Flash Drives	Seagate Laptop Internal HDD
File copy/write speed	200–550 Mbps	50–120 Mbps
Power draw/battery life	Less power draw, averages 2–3 watts, resulting in 30 + minute battery boost	More power draw, averages 6–7 watts and therefore uses more battery
Storage capacity	Typically not larger than 1 TB for notebook size drives; 4 max for desktops	Typically around 500 GB and 2 TB max for notebook size drives; 10 TB max for desktops
Cost	Approx. \$0.20 per GB for a 1-TB drive	Approx. \$0.03 per GB for a 4-TB drive

SSDs have the following advantages over HDDs:

- **High-performance input/output operations per second (IOPS):** Significantly increases performance I/O subsystems.
- **Durability:** Less susceptible to physical shock and vibration.
- **Longer lifespan:** SSDs are not susceptible to mechanical wear.
- **Lower power consumption:** SSDs use considerably less power than comparable-size HDDs.
- **Quieter and cooler running capabilities:** Less space required, lower energy costs, and a greener enterprise.
- **Lower access times and latency rates:** Over 10 times faster than the spinning disks in an HDD. Currently, HDDs enjoy a cost per bit advantage and a capacity advantage, but these differences are shrinking.

SSD Organization

Figure 7.8 illustrates a general view of the common architectural system component associated with any SSD system. On the host system, the operating system invokes file system software to access data on the disk. The file system, in turn, invokes I/O driver software. The I/O driver software provides host access to the particular SSD product. The interface component in **Figure 7.8** refers to the physical and electrical interface between the host processor and the SSD peripheral device. If the device is an internal hard drive, a common interface is PCIe. For external devices, one common interface is USB.

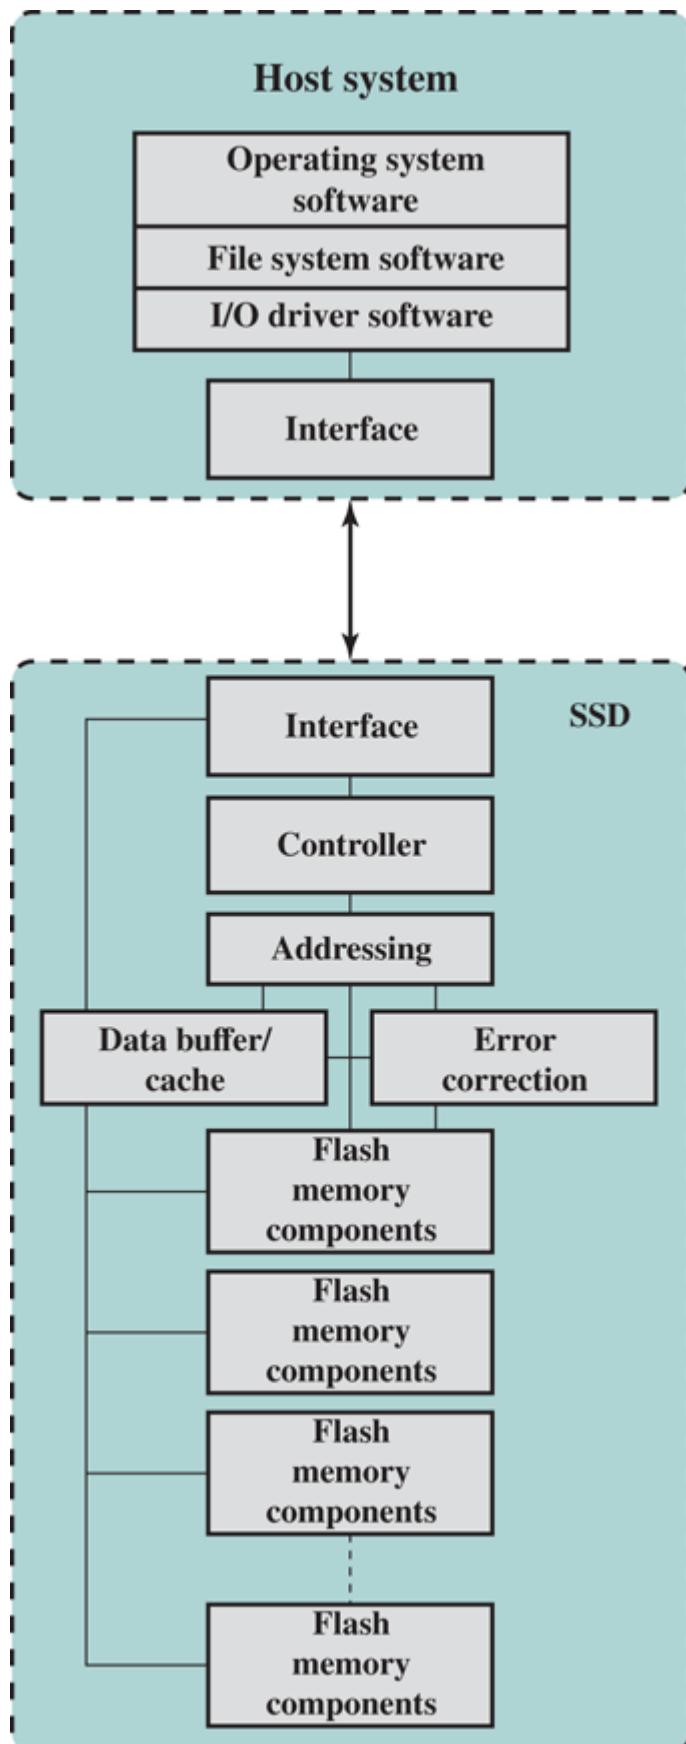

Figure 7.8 Solid State Drive Architecture

In addition to the interface to the host system, the SSD contains the following components:

- **Controller:** Provides SSD device level interfacing and firmware execution.
- **Addressing:** Logic that performs the selection function across the flash memory components.
- **Data buffer/cache:** High speed RAM memory components used for speed matching and to

increased data throughput.

- **Error correction:** Logic for error detection and correction.
- **Flash memory components:** Individual NAND flash chips.

Practical Issues

There are two practical issues peculiar to SSDs that are not faced by HDDs. First, SSD performance has a tendency to slow down as the device is used. To understand the reason for this, you need to know that files are stored on disk as a set of pages, typically 4 KB in length. These pages are not necessarily, and indeed not typically, stored as a contiguous set of pages on the disk. The reason for this arrangement is explained in our discussion of virtual memory in [Chapter 9](#). However, flash memory is accessed in blocks, with a typical block size of 512 KB, so that there are typically 128 pages per block. Now consider what must be done to write a page onto a flash memory.

1. The entire block must be read from the flash memory and placed in a RAM buffer. Then the appropriate page in the RAM buffer is updated.
2. Before the block can be written back to flash memory, the entire block of flash memory must be erased—it is not possible to erase just one page of the flash memory.
3. The entire block from the buffer is now written back to the flash memory.

Now, when a flash drive is relatively empty and a new file is created, the pages of that file are written on to the drive contiguously, so that one or only a few blocks are affected. However, over time, because of the way virtual memory works, files become fragmented, with pages scattered over multiple blocks. As the drive becomes more occupied, there is more fragmentation, so the writing of a new file can affect multiple blocks. Thus, the writing of multiple pages from one block becomes slower, the more fully occupied the disk is. Manufacturers have developed a variety of techniques to compensate for this property of flash memory, such as setting aside a substantial portion of the SSD as extra space for write operations (called overprovisioning), then to erase inactive pages during idle time used to defragment the disk. Another technique is the TRIM command, which allows an operating system to inform an SSD which blocks of data are no longer considered in use and can be wiped internally.⁴

⁴ While TRIM is frequently spelled in capital letters, it is not an acronym; it is merely a command name.

A second practical issue with flash memory drives is that a flash memory becomes unusable after a certain number of writes. As flash cells are stressed, they lose their ability to record and retain values. A typical limit is 100,000 writes [GSOE08]. Techniques for prolonging the life of an SSD drive include front-ending the flash with a cache to delay and group write operations, using wear-leveling algorithms that evenly distribute writes across block of cells, and sophisticated bad-block management techniques. In addition, vendors are deploying SSDs in RAID configurations to further reduce the probability of data loss. Most flash devices are also capable of estimating their own remaining lifetimes, so systems can anticipate failure and take preemptive action.

7.4 Optical Memory

In 1983, one of the most successful consumer products of all time was introduced: the compact disk (**CD**) digital audio system. The CD is a nonerasable disk that can store more than 60 minutes of audio information on one side. The huge commercial success of the CD enabled the development of low-cost optical-disk storage technology that has revolutionized computer data storage. A variety of optical-disk systems have been introduced (**Table 7.6**). We briefly review each of these.

Table 7.6 Optical Disk Products

CD
Compact Disk. A nonerasable disk that stores digitized audio information. The standard system uses 12-cm disks and can record more than 60 minutes of uninterrupted playing time.
CD-ROM
Compact Disk Read-Only Memory. A nonerasable disk used for storing computer data. The standard system uses 12-cm disks and can hold more than 650 Mbytes.
CD-R
CD Recordable. Similar to a CD-ROM. The user can write to the disk only once.
CD-RW
CD Rewritable. Similar to a CD-ROM. The user can erase and rewrite to the disk multiple times.
DVD
Digital Versatile Disk. A technology for producing digitized, compressed representation of video information, as well as large volumes of other digital data. Both 8 and 12 cm diameters are used, with a double-sided capacity of up to 17 Gbytes. The basic DVD is read-only (DVD-ROM).
DVD-R
DVD Recordable. Similar to a DVD-ROM. The user can write to the disk only once. Only one-sided disks can be used.
DVD-RW
DVD Rewritable. Similar to a DVD-ROM. The user can erase and rewrite to the disk multiple times. Only one-sided disks can be used.
Blu-ray DVD

High-definition video disk. Provides considerably greater data storage density than DVD, using a 405-nm (blue-violet) laser. A single layer on a single side can store 25 Gbytes.

Compact Disk

CD-ROM

Both the audio CD and the **CD-ROM** (compact disk read-only memory) share a similar technology. The main difference is that CD-ROM players are more rugged and have error correction devices to ensure that data are properly transferred from disk to computer. Both types of disk are made the same way. The disk is formed from a resin, such as polycarbonate. Digitally recorded information (either music or computer data) is imprinted as a series of microscopic pits on the surface of the polycarbonate. This is done, first of all, with a finely focused, high-intensity laser to create a master disk. The master is used, in turn, to make a die to stamp out copies onto polycarbonate. The pitted surface is then coated with a highly reflective surface, usually aluminum or gold. This shiny surface is protected against dust and scratches by a top coat of clear acrylic. Finally, a label can be silkscreened onto the acrylic.

Information is retrieved from a CD or CD-ROM by a low-powered laser housed in an optical-disk player, or drive unit. The laser shines through the clear polycarbonate while a motor spins the disk past it (**Figure 7.9**). The intensity of the reflected light of the laser changes as it encounters a **pit**. Specifically, if the laser beam falls on a pit, which has a somewhat rough surface, the light scatters and a low intensity is reflected back to the source. The areas between pits are called **lands**. A land is a smooth surface, which reflects back at higher intensity. The change between pits and lands is detected by a photosensor and converted into a digital signal. The sensor tests the surface at regular intervals. The beginning or end of a pit represents a 1; when no change in elevation occurs between intervals, a 0 is recorded.

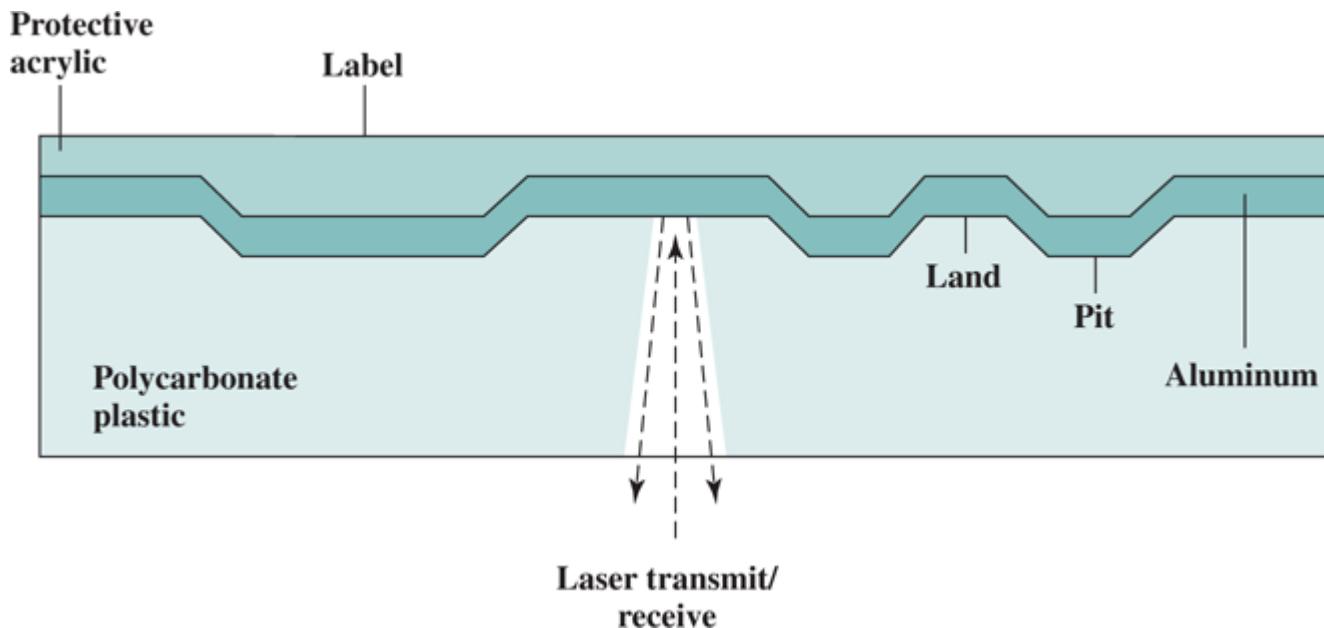

Figure 7.9 CD Operation

Recall that on a magnetic disk, information is recorded in concentric tracks. With the simplest constant angular velocity (CAV) system, the number of bits per track is constant. An increase in density is achieved with **multiple zone recording**, in which the surface is divided into a number of zones, with

zones farther from the center containing more bits than zones closer to the center. Although this technique increases capacity, it is still not optimal.

To achieve greater capacity, CDs and CD-ROMs do not organize information on concentric tracks. Instead, the disk contains a single spiral track, beginning near the center and spiraling out to the outer edge of the disk. Sectors near the outside of the disk are the same length as those near the inside. Thus, information is packed evenly across the disk in segments of the same size and these are scanned at the same rate by rotating the disk at a variable speed. The pits are then read by the laser at a **constant linear velocity (CLV)**. The disk rotates more slowly for accesses near the outer edge than for those near the center. Thus, the capacity of a track and the rotational delay both increase for positions nearer the outer edge of the disk. The data capacity for a CD-ROM is about 680 MB.

Data on the CD-ROM are organized as a sequence of blocks. A typical block format is shown in **Figure 7.10**. It consists of the following fields:

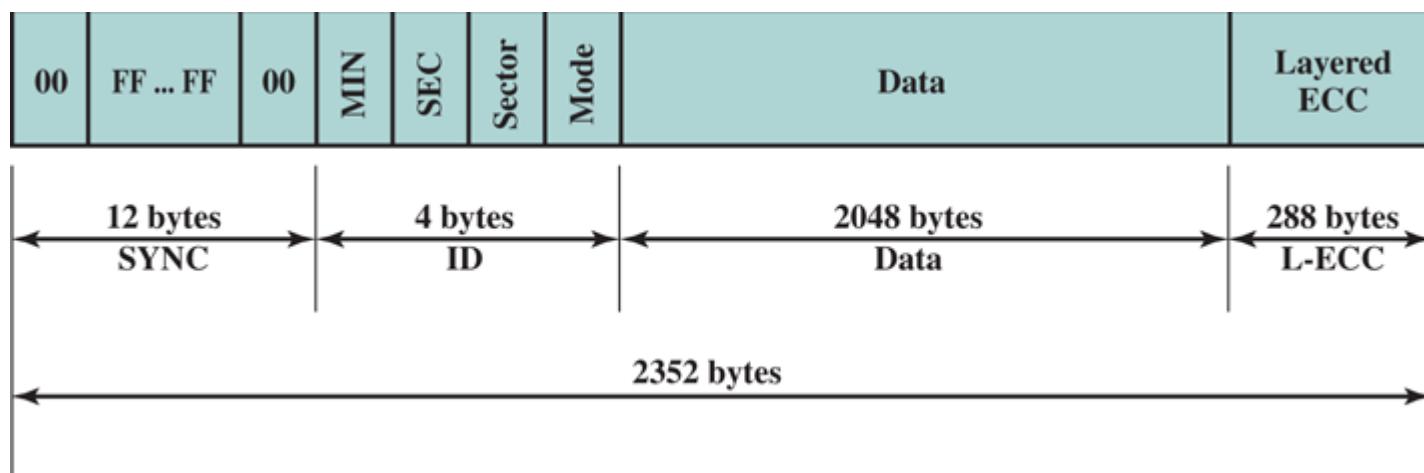

Figure 7.10 CD-ROM Block Format

- **Sync:** The sync field identifies the beginning of a block. It consists of a byte of all 0s, 10 bytes of all 1s, and a byte of all 0s.
- **Header:** The header contains the block address and the mode byte. Mode 0 specifies a blank data field; mode 1 specifies the use of an error-correcting code and 2048 bytes of data; mode 2 specifies 2336 bytes of user data with no error-correcting code.
- **Data:** User data.
- **Auxiliary:** Additional user data in mode 2. In mode 1, this is a 288-byte error-correcting code. With the use of CLV, random access becomes more difficult. Locating a specific address involves moving the head to the general area, adjusting the rotation speed and reading the address, and then making minor adjustments to find and access the specific sector.

CD-ROM is appropriate for the distribution of large amounts of data to a large number of users. Because of the expense of the initial writing process, it is not appropriate for individualized applications. Compared with traditional magnetic disks, the CD-ROM has two advantages:

- The optical disk together with the information stored on it can be mass replicated inexpensively—unlike a magnetic disk. The database on a magnetic disk has to be reproduced by copying one disk at a time using two disk drives.
- The optical disk is removable, allowing the disk itself to be used for archival storage. Most magnetic disks are nonremovable. The information on nonremovable magnetic disks must first be copied to another storage medium before the disk drive/disk can be used to store new information.

The disadvantages of CD-ROM are as follows:

- It is read-only and cannot be updated.
- It has an access time much longer than that of a magnetic disk drive, as much as half a second.

CD RECORDABLE

To accommodate applications in which only one or a small number of copies of a set of data is needed, the write-once read-many CD, known as the **CD recordable (CD-R)**, has been developed. For CD-R, a disk is prepared in such a way that it can be subsequently written once with a laser beam of modest intensity. Thus, with a somewhat more expensive disk controller than for CD-ROM, the customer can write once as well as read the disk.

The CD-R medium is similar but not identical to that of a CD or CD-ROM. For CDs and CD-ROMs, information is recorded by the pitting of the surface of the medium, which changes reflectivity. For a CD-R, the medium includes a dye layer. The dye is used to change reflectivity and is activated by a high-intensity laser. The resulting disk can be read on a CD-R drive or a CD-ROM drive.

The CD-R optical disk is attractive for archival storage of documents and files. It provides a permanent record of large volumes of user data.

CD REWRITABLE

The **CD-RW** optical disk can be repeatedly written and overwritten, as with a magnetic disk. Although a number of approaches have been tried, the only pure optical approach that has proved attractive is called **phase change**. The phase change disk uses a material that has two significantly different reflectivities in two different phase states. There is an amorphous state, in which the molecules exhibit a random orientation that reflects light poorly; and a crystalline state, which has a smooth surface that reflects light well. A beam of laser light can change the material from one phase to the other. The primary disadvantage of phase change optical disks is that the material eventually and permanently loses its desirable properties. Current materials can be used for between 500,000 and 1,000,000 erase cycles.

The CD-RW has the obvious advantage over CD-ROM and CD-R that it can be rewritten and thus used as a true secondary storage. As such, it competes with magnetic disks. A key advantage of the optical disk is that the engineering tolerances for optical disks are much less severe than for high-capacity magnetic disks. Thus, they exhibit higher reliability and longer life.

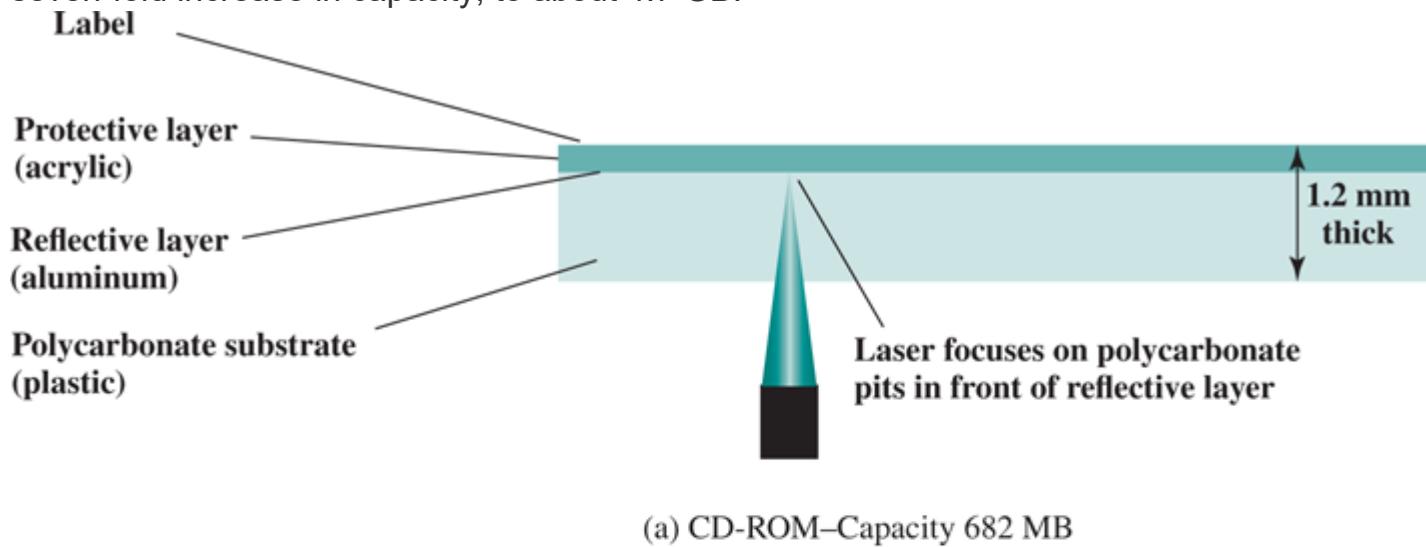

Digital Versatile Disk

With the capacious **digital versatile disk (DVD)**, the electronics industry has at last found an acceptable replacement for the analog VHS video tape. The DVD has replaced the videotape used in video cassette recorders (VCRs) and, more important for this discussion, replaced the CD-ROM in personal computers and servers. The DVD takes video into the digital age. It delivers movies with impressive picture quality, and it can be randomly accessed like audio CDs, which DVD machines can also play. Vast volumes of data can be crammed onto the disk, currently seven times as much as a CD-ROM. With DVD's huge storage capacity and vivid quality, PC games have become more realistic and educational software incorporates more video. Following in the wake of these developments has been a new crest of traffic over the Internet and corporate intranets, as this material is incorporated into Web sites.

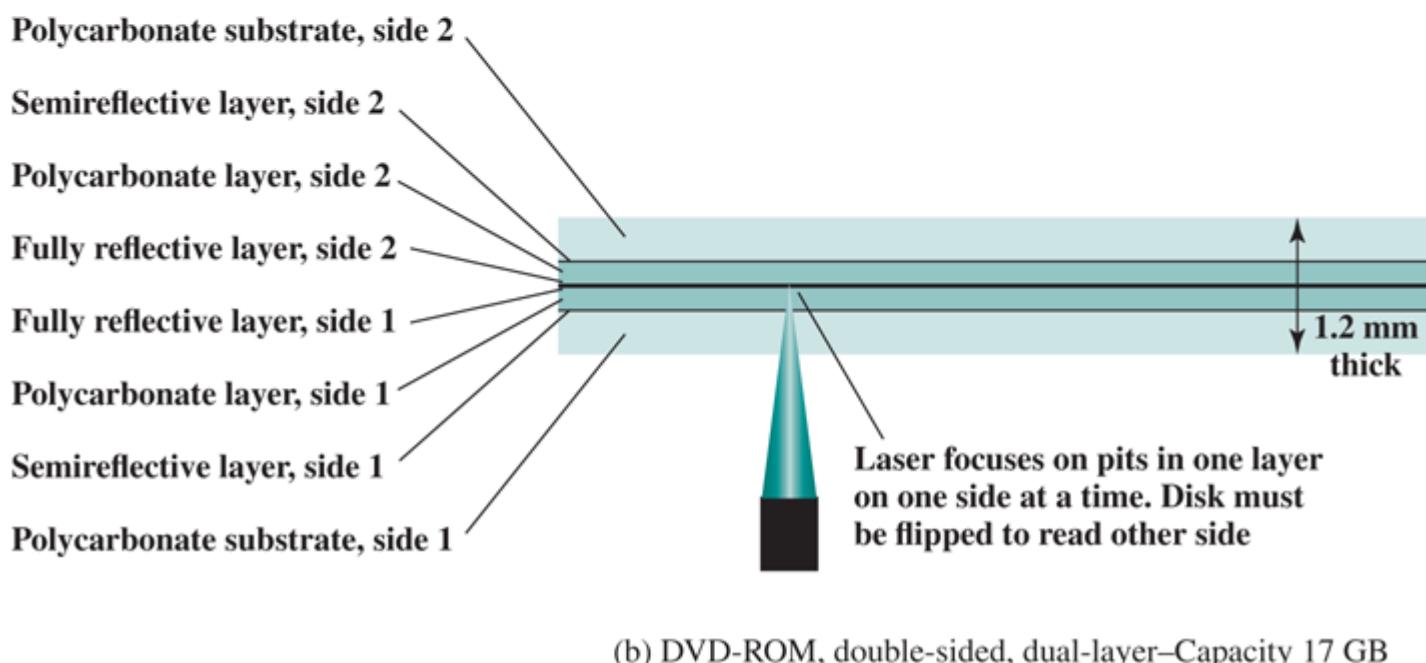

The DVD's greater capacity is due to three differences from CDs (**Figure 7.11**):

1. Bits are packed more closely on a DVD. The spacing between loops of a spiral on a CD is $1.6\mu\text{m}$ and the minimum distance between pits along the spiral is $0.834\mu\text{m}$.

The DVD uses a laser with shorter wavelength and achieves a loop spacing of $0.74 \mu\text{m}$ and a minimum distance between pits of $0.4\mu\text{m}$. The result of these two improvements is about a seven-fold increase in capacity, to about 4.7 GB.

(a) CD-ROM—Capacity 682 MB

(b) DVD-ROM, double-sided, dual-layer—Capacity 17 GB

Figure 7.11 CD-ROM and DVD-ROM

2. The DVD employs a second layer of pits and lands on top of the first layer. A dual-layer DVD has a semireflective layer on top of the reflective layer, and by adjusting focus, the lasers in DVD drives can read each layer separately. This technique almost doubles the capacity of the disk, to about 8.5 GB. The lower reflectivity of the second layer limits its storage capacity, so that a full doubling is not achieved.
3. The **DVD-ROM** can be two sided, whereas data are recorded on only one side of a CD. This brings total capacity up to 17 GB.

As with the CD, DVDs come in writeable as well as read-only versions ([Table 7.6](#)).

High-Definition Optical Disks

High-definition optical disks are designed to store high-definition videos and to provide significantly greater storage capacity compared to DVDs. The higher bit density is achieved by using a laser with a shorter wavelength, in the blue-violet range. The data pits, which constitute the digital 1s and 0s, are smaller on the high-definition optical disks compared to DVDs because of the shorter laser wavelength.

Two competing disk formats and technologies initially competed for market acceptance: HD DVD and **Blu-ray** DVD. The Blu-ray scheme ultimately achieved market dominance. The HD DVD scheme can store 15 GB on a single layer on a single side. Blu-ray positions the data layer on the disk closer to the laser (shown on the right-hand side of each diagram in **Figure 7.12**). This enables a tighter focus and less distortion, and thus smaller pits and tracks. Blu-ray can store 25 GB on a single layer. Three versions are available: read only (BD-ROM), recordable once (BD-R), and rerecordable (BD-RE).

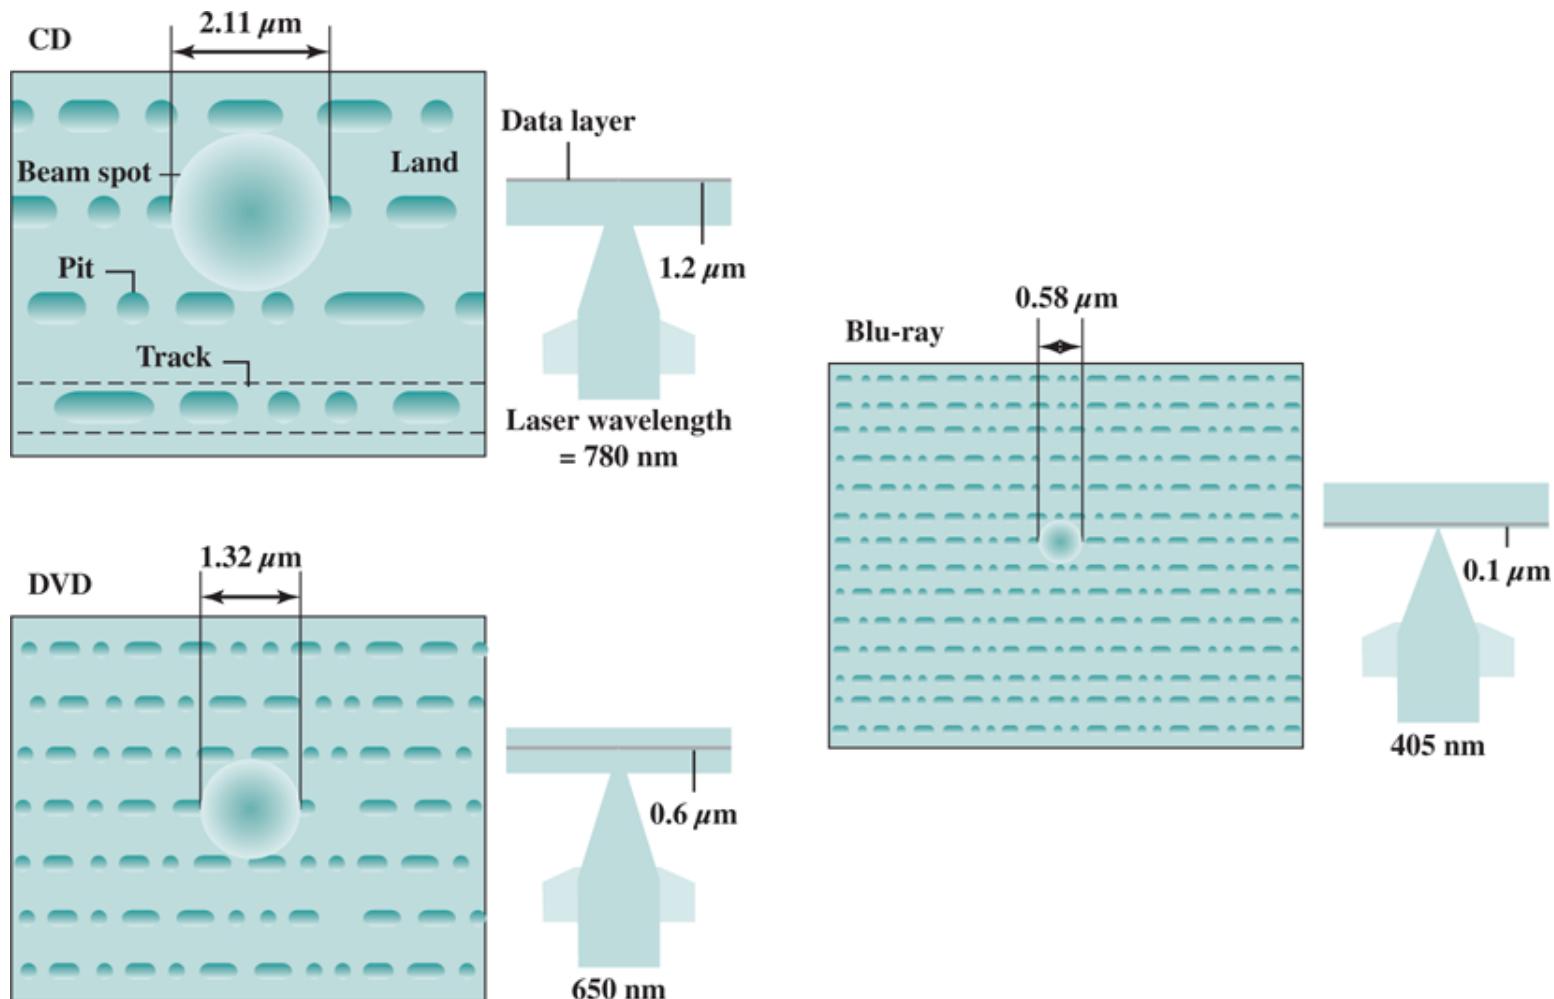

Figure 7.12 Optical Memory Characteristics

7.5 Magnetic Tape

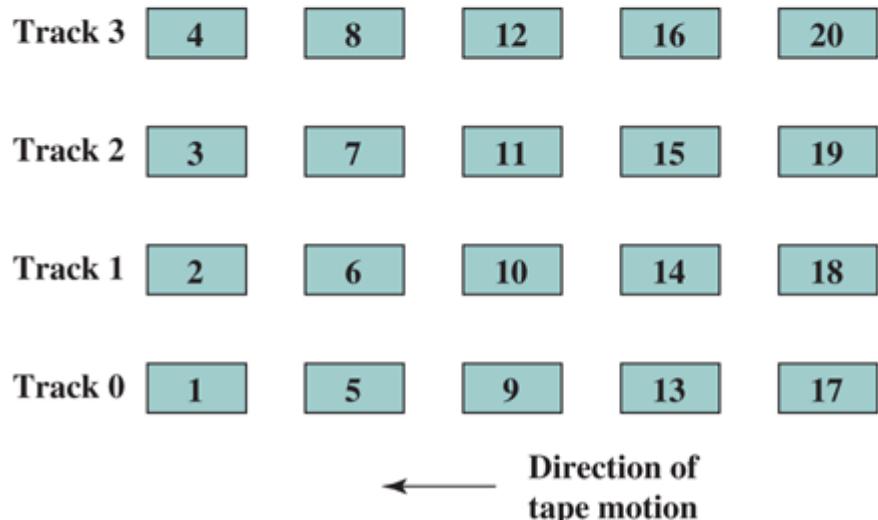

Tape systems use the same reading and recording techniques as disk systems. The medium is flexible polyester (similar to that used in some clothing) tape coated with magnetizable material. The coating may consist of particles of pure metal in special binders or vapor-plated metal films. The tape and the tape drive are analogous to a home tape recorder system. Tape widths vary from 0.38 cm (0.15 inch) to 1.27 cm (0.5 inch). Tapes used to be packaged as open reels that have to be threaded through a second spindle for use. Today, virtually all tapes are housed in cartridges.

Data on the tape are structured as a number of parallel tracks running lengthwise. Earlier tape systems typically used nine tracks. This made it possible to store data one byte at a time, with an additional parity bit as the ninth track. This was followed by tape systems using 18 or 36 tracks, corresponding to a digital word or double word. The recording of data in this form is referred to as **parallel recording**. Most modern systems instead use **serial recording**, in which data are laid out as a sequence of bits along each track, as is done with magnetic disks. As with the disk, data are read and written in contiguous blocks, called *physical records*, on a tape. Blocks on the tape are separated by gaps referred to as *interrecord gaps*. As with the disk, the tape is formatted to assist in locating physical records.

The typical recording technique used in serial tapes is referred to as **serpentine recording**. In this technique, when data are being recorded, the first set of bits is recorded along the whole length of the tape. When the end of the tape is reached, the heads are repositioned to record a new track, and the tape is again recorded on its whole length, this time in the opposite direction. That process continues, back and forth, until the tape is full ([Figure 7.13a](#)). To increase speed, the read-write head is capable of reading and writing a number of adjacent tracks simultaneously (typically two to eight tracks). Data are still recorded serially along individual tracks, but blocks in sequence are stored on adjacent tracks, as suggested by [Figure 7.13b](#).

(a) Serpentine reading and writing

(b) Block layout for system that reads–writes four tracks simultaneously

Figure 7.13 Typical Magnetic Tape Features

A tape drive is a *sequential-access* device. If the tape head is positioned at record 1, then to read record N , it is necessary to read physical records 1 through $N - 1$, one at a time. If the head is currently positioned beyond the desired record, it is necessary to rewind the tape a certain distance and begin reading forward. Unlike the disk, the tape is in motion only during a read or write operation.

In contrast to the tape, the disk drive is referred to as a *direct-access* device. A disk drive need not read all the sectors on a disk sequentially to get to the desired one. It must only wait for the intervening sectors within one track and can make successive accesses to any track.

Magnetic tape was the first kind of secondary memory. It is still widely used as the lowest-cost, slowest-speed member of the memory hierarchy.

The dominant tape technology today is a cartridge system known as linear tape-open (LTO). LTO was developed in the late 1990s as an open-source alternative to the various proprietary systems on the market. **Table 7.7** shows parameters for the various LTO generations.

Table 7.7 LTO Tape Drives

	LTO-1	LTO-2	LTO-3	LTO-4	LTO-5	LTO-6	LTO-7	LTO-8
Release date	2000	2003	2005	2007	2010	2012	TBA	TBA

Review Questions

- 7.1 What are the advantages of using a glass substrate for a magnetic disk?
- 7.2 How are data written onto a magnetic disk?
- 7.3 How are data read from a magnetic disk?
- 7.4 Explain the difference between a simple CAV system and a multiple zone recording system.
- 7.5 Define the terms *track*, *cylinder*, and *sector*.
- 7.6 What is the typical disk sector size?
- 7.7 Define the terms *seek time*, *rotational delay*, *access time*, and *transfer time*.
- 7.8 What common characteristics are shared by all RAID levels?
- 7.9 Briefly define the seven RAID levels.
- 7.10 Explain the term *striped data*.
- 7.11 How is redundancy achieved in a RAID system?
- 7.12 In the context of RAID, what is the distinction between parallel access and independent access?
- 7.13 What is the difference between CAV and CLV?
- 7.14 What differences between a CD and a DVD account for the larger capacity of the latter?
- 7.15 Explain serpentine recording.

Problems

- 7.1 Justify **Equation 7.1**. That is, explain how each of the three terms on the right-hand side of the equation contributes to the value on the left-hand side.

- 7.2 Consider a disk with N tracks numbered from 0 to $(N - 1)$ and assume that requested sectors are distributed randomly and evenly over the disk. We want to calculate the average number of tracks traversed by a seek.

- a. First, calculate the probability of a seek of length j when the head is currently positioned over track t . *Hint:* This is a matter of determining the total number of combinations, recognizing that all track positions for the destination of the seek are equally likely.
- b. Next, calculate the probability of a seek of length K . *Hint:* This involves the summing over all possible combinations of movements of K tracks.
- c. Calculate the average number of tracks traversed by a seek, using the formula for expected value

$$E[x] = \sum_{i=0}^n i \times \Pr[x=i]$$

Hint: Use the equalities: $\sum_{i=1}^n i = \frac{n(n+1)}{2}$; $\sum_{i=1}^n i^2 = \frac{n(n+1)(2n+1)}{6}$.

- d. Show that for large values of N , the average number of tracks traversed by a seek approaches $N/3$.

7.3 Define the following for a disk system:

t_s = seek time, average time to position head over track
 r = rotation speed of the disk, in revolutions per second
 n = number of bits per sector
 N = capacity of a track, in bits
 t_{sector} = time to access a sector

Develop a formula for t_{sector} as a function of the other parameters.

7.4 Consider a magnetic disk drive with 8 surfaces, 512 tracks per surface, and 64 sectors per track. Sector size is 1 kB. The average seek time is 8 ms, the track-to-track access time is 1.5 ms, and the drive rotates at 3600 rpm. Successive tracks in a cylinder can be read without head movement.

- a. What is the disk capacity?
- b. What is the average access time? Assume this file is stored in successive sectors and tracks of successive cylinders, starting at sector 0, track 0, of cylinder i .
- c. Estimate the time required to transfer a 5-MB file.
- d. What is the burst transfer rate?

7.5 Consider a single-platter disk with the following parameters: rotation speed: 7200 rpm; number of tracks on one side of platter: 30,000; number of sectors per track: 600; seek time: one ms for every hundred tracks traversed. Let the disk receive a request to access a random sector on a random track and assume the disk head starts at track 0.

- a. What is the average seek time?
- b. What is the average rotational latency?
- c. What is the transfer time for a sector?
- d. What is the total average time to satisfy a request?

7.6 A distinction is made between physical records and logical records. A **logical record** is a collection of related data elements treated as a conceptual unit, independent of how or where the information is stored. A **physical record** is a contiguous area of storage space that is defined by the characteristics of the storage device and operating system. Assume a disk system in which each physical record contains thirty 120-byte logical records. Calculate how much disk space (in sectors, tracks, and surfaces) will be required to store 300,000 logical records if the disk is fixed-sector with 512 bytes/sector, with 96 sectors/track, 110 tracks per surface, and 8 usable surfaces. Ignore any file header record(s) and track indexes, and assume that records cannot span two sectors.

7.7 Consider a disk that rotates at 3600 rpm. The seek time to move the head between adjacent tracks is 2 ms. There are 32 sectors per track, which are stored in linear order from sector 0 through sector 31. The head sees the sectors in ascending order. Assume the read/write head is positioned at the start of sector 1 on track 8. There is a main memory buffer large enough to hold an entire track. Data is transferred between disk locations by reading from the source track into the main memory buffer and then writing the data from the buffer to the target track.

- a. How long will it take to transfer sector 1 on track 8 to sector 1 on track 9?

- b. How long will it take to transfer all the sectors of track 8 to the corresponding sectors of track 9?

7.8 It should be clear that disk striping can improve data transfer rate when the strip size is small compared to the I/O request size. It should also be clear that RAID 0 provides improved performance relative to a single large disk, because multiple I/O requests can be handled in parallel. However, in this latter case, is disk striping necessary? That is, does disk striping improve I/O request rate performance compared to a comparable disk array without striping?

7.9 Consider a 4-drive, 200 GB-per-drive RAID array. What is the available data storage capacity for each of the RAID levels 0, 1, 3, 4, 5, and 6?

7.10 For a compact disk, audio is converted to digital with 16-bit samples, and is treated as a stream of 8-bit bytes for storage. One simple scheme for storing this data, called direct recording, would be to represent a 1 by a land and a 0 by a pit. Instead, each byte is expanded into a 14-bit binary number. It turns out that exactly $256(2^8)$ of the total of $16,134(2^{14})$ 14-bit numbers have at least two 0s between every pair of 1s, and these are the numbers selected for the expansion from 8 to 14 bits. The optical system detects the presence of 1s by detecting a transition from pit to land or land to pit. It detects 0s by measuring the distances between intensity changes. This scheme requires that there are no 1s in succession; hence the use of the 8-to-14 code.

The advantage of this scheme is as follows. For a given laser beam diameter, there is a minimum-pit size, regardless of how the bits are represented. With this scheme, this minimum-pit size stores 3 bits, because at least two 0s follow every 1. With direct recording, the same pit would be able to store only one bit. Considering both the number of bits stored per pit and the 8-to-14 bit expansion, which scheme stores the most bits and by what factor?

7.11 Design a backup strategy for a computer system. One option is to use plug-in external disks, which cost \$150 for each 500 GB drive. Another option is to buy a tape drive for \$2500, and 400 GB tapes for \$50 apiece. (These were realistic prices in 2008.) A typical backup strategy is to have two sets of backup media onsite, with backups alternately written on them so in case the system fails while making a backup, the previous version is still intact. There's also a third set kept offsite, with the offsite set periodically swapped with an on-site set.

- a. Assume you have 1 TB (1000 GB) of data to back up. How much would a disk backup system cost?
- b. How much would a tape backup system cost for 1 TB?
- c. How large would each backup have to be in order for a tape strategy to be less expensive?
- d. What kind of backup strategy favors tapes?

Learning Objectives

After studying this chapter, you should be able to:

- Explain the use of I/O modules as part of computer organization.
- Understand the difference between **programmed I/O** and **interrupt-driven I/O** and discuss their relative merits.
- Present an overview of the operation of direct memory access.
- Present an overview of direct cache access.
- Explain the function and use of I/O channels.

Aleksandr Lukin/123RF

I/O System Design Tool

In addition to the processor and a set of memory modules, the third key element of a computer system is a set of I/O modules. Each module interfaces to the system bus or central switch and controls one or more peripheral devices. An I/O module is not simply a set of mechanical connectors that wire a device into the system bus. Rather, the I/O module contains logic for performing a communication function between the peripheral and the bus.

The reader may wonder why one does not connect peripherals directly to the system bus. The reasons are as follows:

- There are a wide variety of peripherals with various methods of operation. It would be impractical to incorporate the necessary logic within the processor to control a range of devices.
- The data transfer rate of peripherals is often much slower than that of the memory or processor. Thus, it is impractical to use the high-speed system bus to communicate directly with a peripheral.
- On the other hand, the data transfer rate of some peripherals is faster than that of the memory or processor. Again, the mismatch would lead to inefficiencies if not managed properly.
- Peripherals often use different data formats and word lengths than the computer to which they are attached.
- Thus, an I/O module is required. This module has two major functions (**Figure 8.1**):

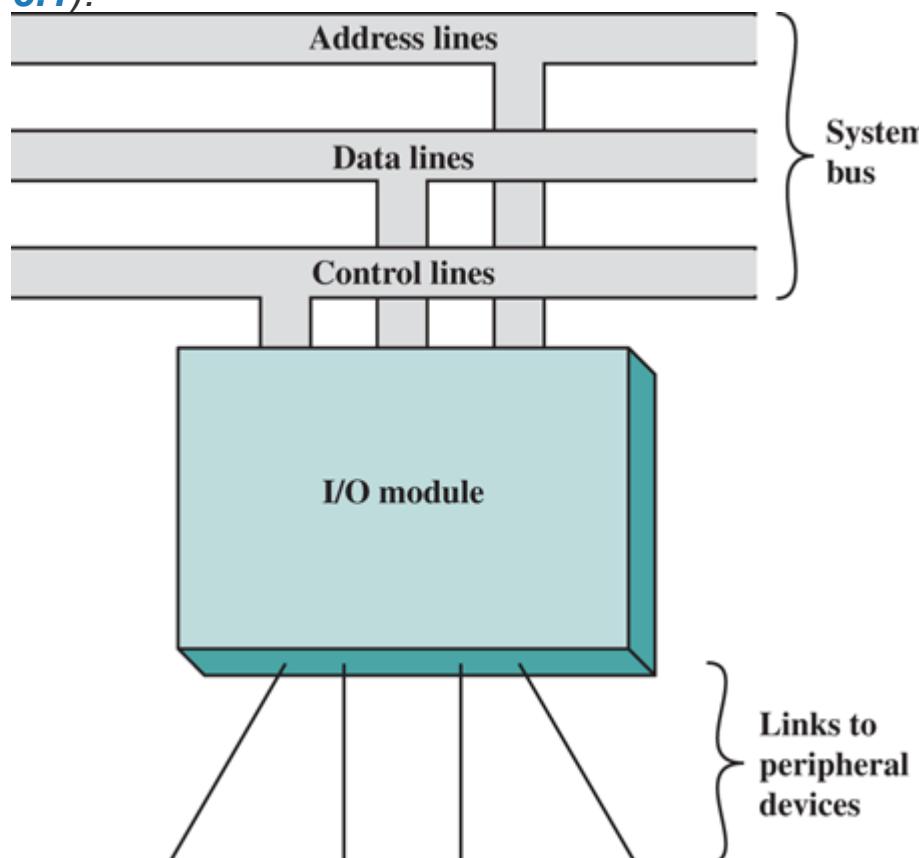

Figure 8.1 Generic Model of an I/O Module

- Interface to the processor and memory via the system bus or central switch.
- Interface to one or more peripheral devices by tailored data links.

We begin this chapter with a brief discussion of external devices, followed by an overview of the structure and function of an I/O module. Then we look at the various ways in which the I/O function can be performed in cooperation with the processor and memory: the internal I/O interface. Next, we examine in some detail direct memory access and the more recent innovation of direct cache access. Finally, we examine the external I/O interface, between the I/O module and the outside world.

8.1 External Devices

I/O operations are accomplished through a wide assortment of external devices that provide a means of exchanging data between the external environment and the computer. An external device attaches to the computer by a link to an I/O module ([Figure 8.1](#)). The link is used to exchange control, status, and data between the I/O module and the external device. An external device connected to an I/O module is often referred to as a *peripheral device* or, simply, a *peripheral*.

We can broadly classify external devices into three categories:

- **Human readable:** Suitable for communicating with the computer user;
- **Machine readable:** Suitable for communicating with equipment;
- **Communication:** Suitable for communicating with remote devices.

Examples of human-readable devices are video display terminals (VDTs) and printers. Examples of machine-readable devices are magnetic disk and tape systems, and sensors and actuators, such as are used in a robotics application. Note that we are viewing disk and tape systems as I/O devices in this chapter, whereas in [Chapter 7](#) we viewed them as memory devices. From a functional point of view, these devices are part of the memory hierarchy, and their use is appropriately discussed in [Chapter 7](#). From a structural point of view, these devices are controlled by I/O modules and are hence to be considered in this chapter.

Communication devices allow a computer to exchange data with a remote device, which may be a human-readable device, such as a terminal, a machine-readable device, or even another computer.

In very general terms, the nature of an external device is indicated in [Figure 8.2](#). The interface to the I/O module is in the form of control, data, and status signals. *Control signals* determine the function that the device will perform, such as send data to the I/O module (INPUT or READ), accept data from the I/O module (OUTPUT or WRITE), report status, or perform some control function particular to the device (e.g., position a disk head). *Data* are in the form of a set of bits to be sent to or received from the I/O module. *Status signals* indicate the state of the device. Examples are READY/NOT-READY to show whether the device is ready for data transfer.

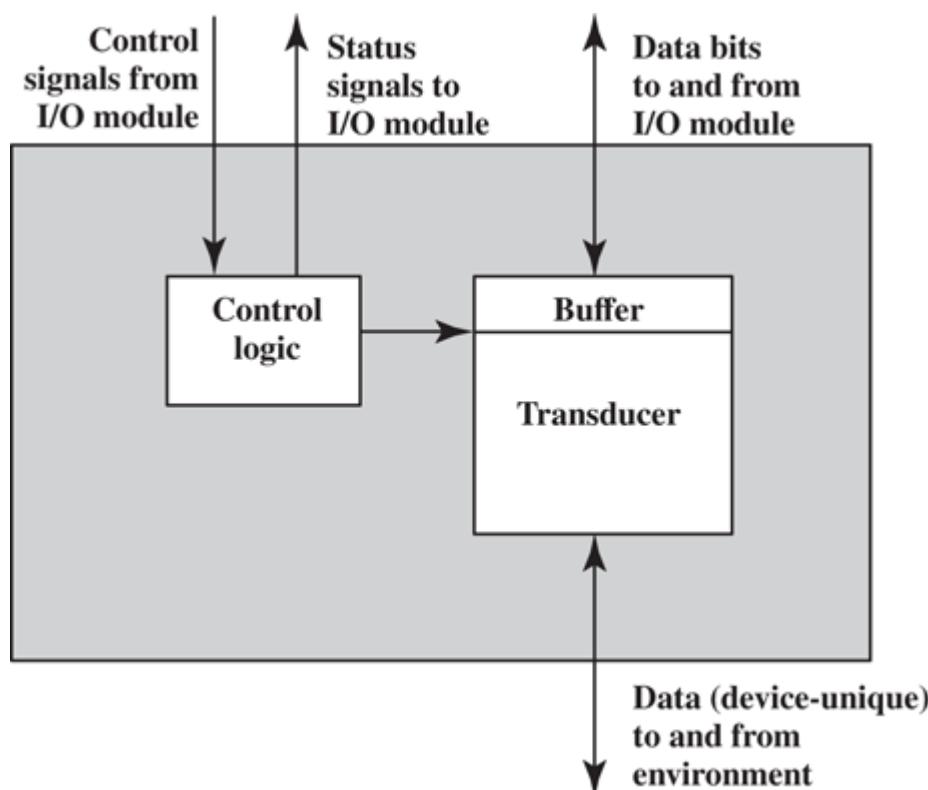

Figure 8.2 Block Diagram of an External Device

Control logic associated with the device controls the device's operation in response to direction from the I/O module. The *transducer* converts data from electrical to other forms of energy during output and from other forms to electrical during input. Typically, a buffer is associated with the transducer to temporarily hold data being transferred between the I/O module and the external environment. A buffer size of 8 to 16 bits is common for serial devices, whereas block-oriented devices such as disk drive controllers may have much larger buffers.

The interface between the I/O module and the external device will be examined in [Section 8.7](#). The interface between the external device and the environment is beyond the scope of this book, but several brief examples are given here.

Keyboard/Monitor

The most common means of computer/user interaction is a keyboard/monitor arrangement. The user provides input through the keyboard, the input is then transmitted to the computer and may also be displayed on the monitor. In addition, the monitor displays data provided by the computer.

The basic unit of exchange is the character. Associated with each character is a code, typically 7 or 8 bits in length. The most commonly used text code is the International Reference Alphabet (IRA).¹ Each character in this code is represented by a unique 7-bit binary code; thus, 128 different characters can be represented. Characters are of two types: printable and control. Printable characters are the alphabetic, numeric, and special characters that can be printed on paper or displayed on a screen. Some of the control characters have to do with controlling the printing or displaying of characters; an example is carriage return. Other control characters are concerned with communications procedures. See [Appendix D](#) for details.

¹ IRA is defined in ITU-T Recommendation T.50 and was formerly known as International Alphabet Number 5 (IA5). The U.S. national version of IRA is referred to as the American Standard Code for Information Interchange (ASCII).

For keyboard input, when the user depresses a key, this generates an electronic signal that is interpreted by the transducer in the keyboard and translated into the bit pattern of the corresponding IRA code. This bit pattern is then transmitted to the I/O module in the computer. At the computer, the text can be stored in the same IRA code. On output, IRA code characters are transmitted to an external device from the I/O module. The transducer at the device interprets this code and sends the required electronic signals to the output device either to display the indicated character or perform the requested control function.

Disk Drive

A disk drive contains electronics for exchanging data, control, and status signals with an I/O module plus the electronics for controlling the disk read/write mechanism. In a fixed-head disk, the transducer is capable of converting between the magnetic patterns on the moving disk surface and bits in the device's buffer ([Figure 8.2](#)). A moving-head disk must also be able to cause the disk arm to move radially in and out across the disk's surface.

8.2 I/O Modules

Module Function

The major functions or requirements for an I/O module fall into the following categories:

- Control and timing
- Processor communication
- Device communication
- Data buffering
- Error detection

During any period of time, the processor may communicate with one or more external devices in unpredictable patterns, depending on the program's need for I/O. The internal resources, such as main memory and the system bus, must be shared among a number of activities, including data I/O. Thus, the I/O function includes a **control and timing** requirement, to coordinate the flow of traffic between internal resources and external devices. For example, the control of the transfer of data from an external device to the processor might involve the following sequence of steps:

1. The processor interrogates the I/O module to check the status of the attached device.
2. The I/O module returns the device status.
3. If the device is operational and ready to transmit, the processor requests the transfer of data, by means of a command to the I/O module.
4. The I/O module obtains a unit of data (e.g., 8 or 16 bits) from the external device.
5. The data are transferred from the I/O module to the processor.

If the system employs a bus, then each of the interactions between the processor and the I/O module involves one or more bus arbitrations.

The preceding simplified scenario also illustrates that the I/O module must communicate with the processor and with the external device. **Processor communication** involves the following:

- **Command decoding:** The I/O module accepts commands from the processor, typically sent as signals on the control bus. For example, an I/O module for a disk drive might accept the following commands: READ SECTOR, WRITE SECTOR, SEEK track number, and SCAN record ID. The latter two commands each include a parameter that is sent on the data bus.
- **Data:** Data are exchanged between the processor and the I/O module over the data bus.
- **Status reporting:** Because peripherals are so slow, it is important to know the status of the I/O module. For example, if an I/O module is asked to send data to the processor (read), it may not be ready to do so because it is still working on the previous I/O command. This fact can be reported with a status signal. Common status signals are BUSY and READY. There may also be signals to report various error conditions.
- **Address recognition:** Just as each word of memory has an address, so does each I/O device. Thus, an I/O module must recognize one unique address for each peripheral it controls.

On the other side, the I/O module must be able to perform **device communication**. This communication involves commands, status information, and data ([Figure 8.2](#)).

An essential task of an I/O module is **data buffering**. The need for this function is apparent from [Figure 2.1](#). Whereas the transfer rate into and out of main memory or the processor is quite high, the rate is orders of magnitude lower for many peripheral devices and covers a wide range. Data coming from main memory are sent to an I/O module in a rapid burst. The data are buffered in the I/O module and then sent to the peripheral device at its data rate. In the opposite direction, data are buffered so

as not to tie up the memory in a slow transfer operation. Thus, the I/O module must be able to operate at both device and memory speeds. Similarly, if the I/O device operates at a rate higher than the memory access rate, then the I/O module performs the needed buffering operation.

Finally, an I/O module is often responsible for **error detection** and for subsequently reporting errors to the processor. One class of errors includes mechanical and electrical malfunctions reported by the device (e.g., paper jam, bad disk track). Another class consists of unintentional changes to the bit pattern as it is transmitted from device to I/O module. Some form of error-detecting code is often used to detect transmission errors. A simple example is the use of a parity bit on each character of data. For example, the IRA character code occupies 7 bits of a byte. The eighth bit is set so that the total number of 1s in the byte is even (even parity) or odd (odd parity). When a byte is received, the I/O module checks the parity to determine whether an error has occurred.

I/O Module Structure

I/O modules vary considerably in complexity and the number of external devices that they control. We will attempt only a very general description here. (One specific device, the Intel 8255A, is described in [Section 8.4](#).) [Figure 8.3](#) provides a general block diagram of an I/O module. The module connects to the rest of the computer through a set of signal lines (e.g., system bus lines). Data transferred to and from the module are buffered in one or more data registers. There may also be one or more status registers that provide current status information. A status register may also function as a control register, to accept detailed control information from the processor. The logic within the module interacts with the processor via a set of control lines. The processor uses the control lines to issue commands to the I/O module. Some of the control lines may be used by the I/O module (e.g., for arbitration and status signals). The module must also be able to recognize and generate addresses associated with the devices it controls. Each I/O module has a unique address or, if it controls more than one external device, a unique set of addresses. Finally, the I/O module contains logic specific to the interface with each device that it controls.

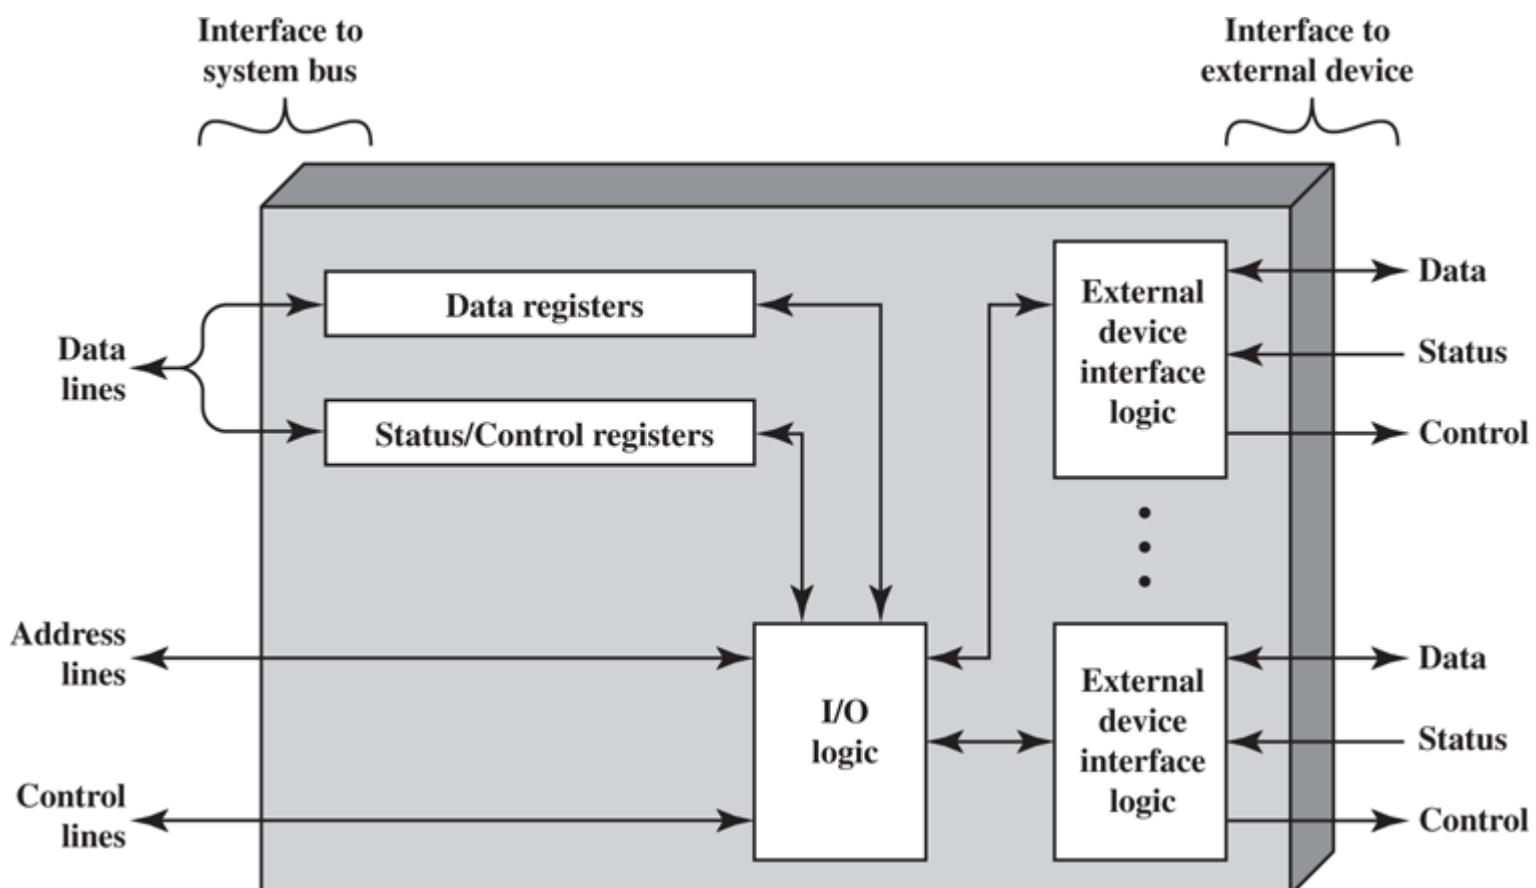

Figure 8.3 Block Diagram of an I/O Module

An I/O module functions to allow the processor to view a wide range of devices in a simple-minded way. There is a spectrum of capabilities that may be provided. The I/O module may hide the details of timing, formats, and the electromechanics of an external device so that the processor can function in terms of simple read and write commands, and possibly open and close file commands. In its simplest form, the I/O module may still leave much of the work of controlling a device (e.g., rewinding a tape) visible to the processor.

An I/O module that takes on most of the detailed processing burden, presenting a high-level interface to the processor, is usually referred to as an **I/O channel** or *I/O processor*. An I/O module that is quite primitive and requires detailed control is usually referred to as an *I/O controller* or *device controller*. I/O controllers are commonly seen on microcomputers, whereas I/O channels are used on mainframes.

In what follows, we will use the generic term *I/O module* when no confusion results and will use more specific terms where necessary.

8.3 Programmed I/O

Three techniques are possible for I/O operations. With *programmed I/O*, data are exchanged between the processor and the I/O module. The processor executes a program that gives it direct control of the I/O operation, including sensing device status, sending a read or write command, and transferring the data. When the processor issues a command to the I/O module, it must wait until the I/O operation is complete. If the processor is faster than the I/O module, this is a waste of processor time. With **interrupt-driven I/O**, the processor issues an *I/O command*, continues to execute other instructions, and is interrupted by the I/O module when the latter has completed its work. With both programmed and *interrupt I/O*, the processor is responsible for extracting data from main memory for output and storing data in main memory for input. The alternative is known as **direct memory access (DMA)**. In this mode, the I/O module and main memory exchange data directly, without processor involvement.

Table 8.1 indicates the relationship among these three techniques. In this section, we explore programmed I/O. Interrupt I/O and DMA are explored in the following two sections, respectively.

Table 8.1 I/O Techniques

	No Interrupts	Use of Interrupts
I/O-to-memory transfer through processor	Programmed I/O	Interrupt-driven I/O
Direct I/O-to-memory transfer		Direct memory access (DMA)

Overview of Programmed I/O

When the processor is executing a program and encounters an instruction relating to I/O, it executes that instruction by issuing a command to the appropriate I/O module. With programmed I/O, the I/O module will perform the requested action and then set the appropriate bits in the I/O status register (**Figure 8.3**). The I/O module takes no further action to alert the processor. In particular, it does not interrupt the processor. Thus, it is the responsibility of the processor to periodically check the status of the I/O module until it finds that the operation is complete.

To explain the programmed I/O technique, we view it first from the point of view of the I/O commands issued by the processor to the I/O module, and then from the point of view of the I/O instructions executed by the processor.

I/O Commands

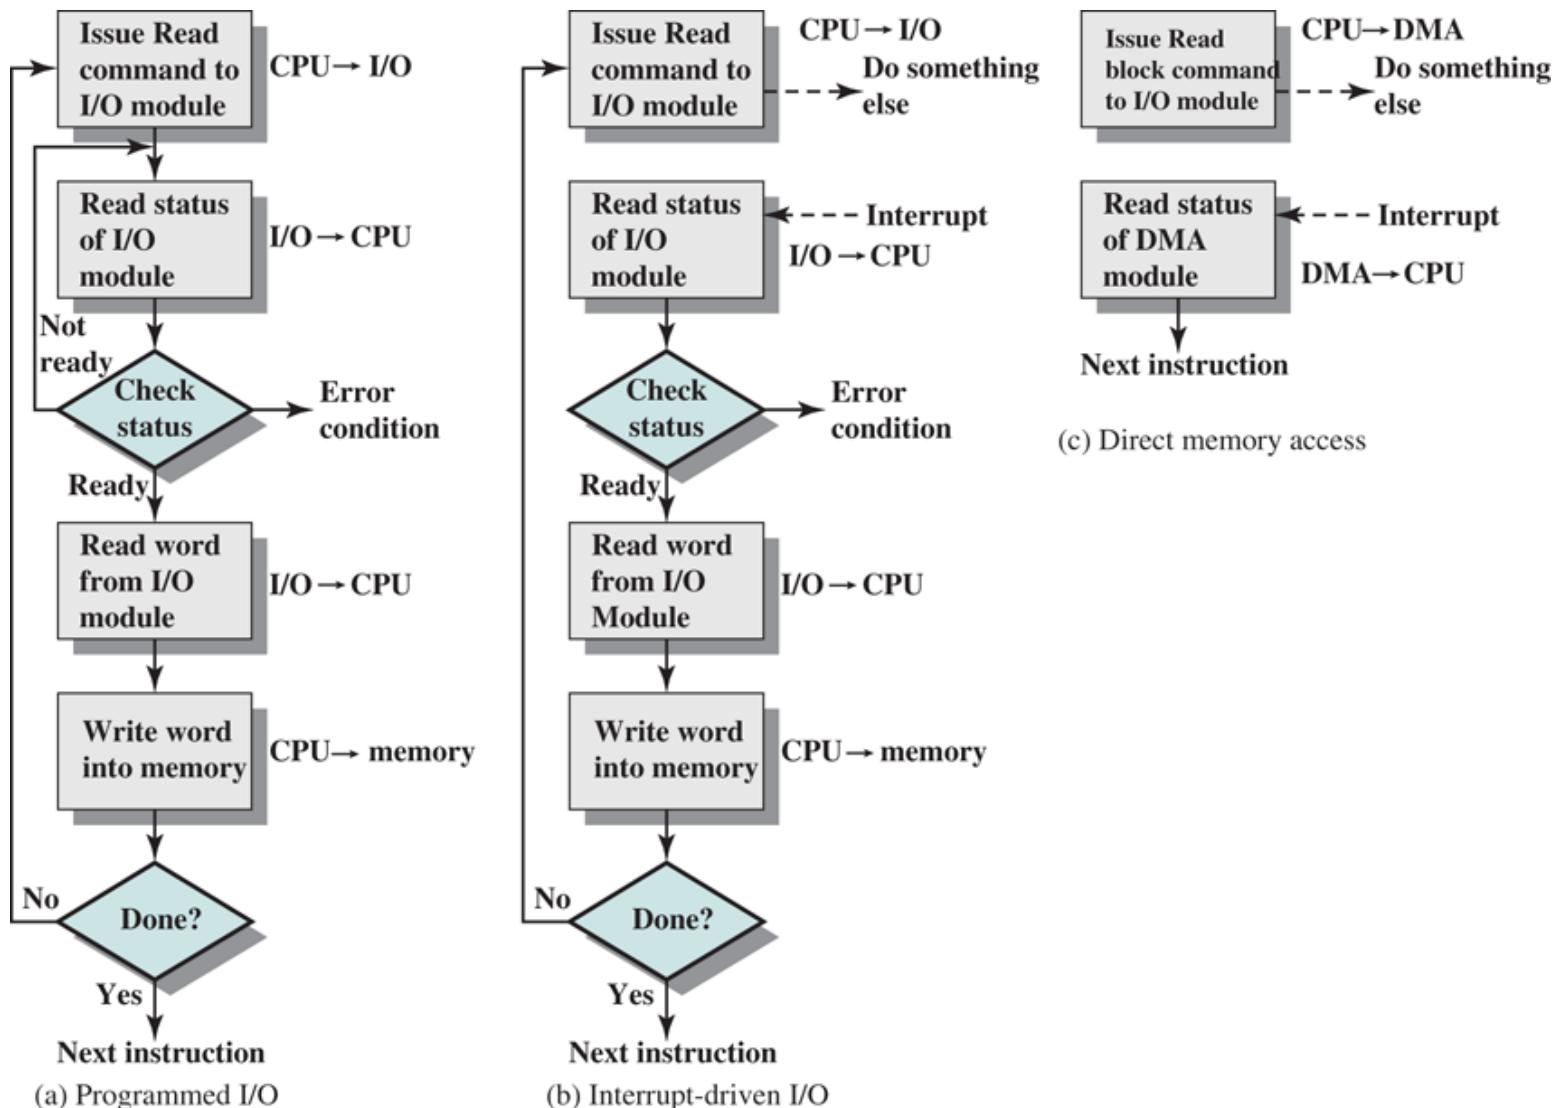

To execute an I/O-related instruction, the processor issues an address, specifying the particular I/O module and external device, and an I/O command. There are four types of I/O commands that an I/O module may receive when it is addressed by a processor:

- **Control:** Used to activate a peripheral and tell it what to do. For example, a magnetic-tape unit may be instructed to rewind or to move forward one record. These commands are tailored to the particular type of peripheral device.
- **Test:** Used to test various status conditions associated with an **I/O module** and its peripherals. The processor will want to know that the peripheral of interest is powered on and available for use.

It will also want to know if the most recent I/O operation is completed and if any errors occurred.

- **Read:** Causes the I/O module to obtain an item of data from the peripheral and place it in an internal buffer (depicted as a data register in [Figure 8.3](#)). The processor can then obtain the data item by requesting that the I/O module place it on the data bus.
- **Write:** Causes the I/O module to take an item of data (byte or word) from the data bus and subsequently transmit that data item to the peripheral.

[Figure 8.4a](#) gives an example of the use of programmed I/O to read in a block of data from a peripheral device (e.g., a record from tape) into memory. Data are read in one word (e.g., 16 bits) at a time. For each word that is read in, the processor must remain in a status-checking cycle until it determines that the word is available in the I/O module's data register. This flowchart highlights the main disadvantage of this technique: it is a time-consuming process that keeps the processor busy needlessly.

[Figure 8.4](#) Three Techniques for Input of a Block of Data

I/O Instructions

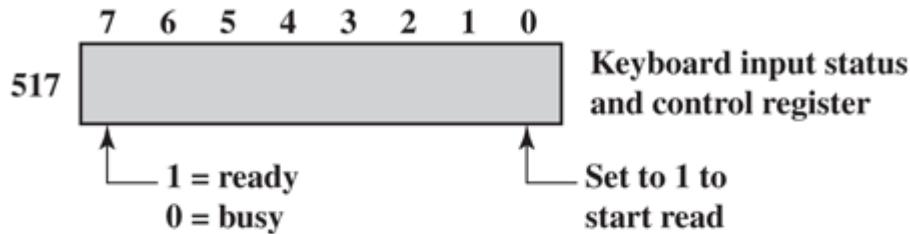

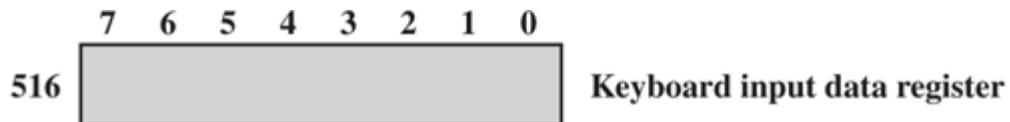

With programmed I/O, there is a close correspondence between the I/O-related instructions that the processor fetches from memory and the I/O commands that the processor issues to an I/O module to execute the instructions. That is, the instructions are easily mapped into I/O commands, and there is often a simple one-to-one relationship. The form of the instruction depends on the way in which external devices are addressed.

Typically, there will be many I/O devices connected through I/O modules to the system. Each device is given a unique identifier or address. When the processor issues an I/O command, the command contains the address of the desired device. Thus, each I/O module must interpret the address lines to determine if the command is for itself.

When the processor, main memory, and I/O share a common bus, two modes of addressing are possible: memory mapped and isolated. With **memory-mapped I/O**, there is a single address space for memory locations and I/O devices. The processor treats the status and data registers of I/O modules as memory locations and uses the same machine instructions to access both memory and I/O devices. So, for example, with 10 address lines, a combined total of $2^{10} = 1024$ memory locations and I/O addresses can be supported, in any combination.

With memory-mapped I/O, a single read line and a single write line are needed on the bus. Alternatively, the bus may be equipped with memory read and write plus input and output command lines. The command line specifies whether the address refers to a memory location or an I/O device. The full range of addresses may be available for both. Again, with 10 address lines, the system may now support both 1024 memory locations and 1024 I/O addresses. Because the address space for I/O is isolated from that for memory, this is referred to as **isolated I/O**.

Figure 8.5 contrasts these two programmed I/O techniques. **Figure 8.5a** shows how the interface for a simple input device such as a terminal keyboard might appear to a programmer using memory-mapped I/O. Assume a 10-bit address, with a 512-bit memory (locations 0–511) and up to 512 I/O addresses (locations 512–1023). Two addresses are dedicated to keyboard input from a particular terminal. Address 516 refers to the data register and address 517 refers to the status register, which also functions as a control register for receiving processor commands. The program shown will read 1 byte of data from the keyboard into an accumulator register in the processor. Note that the processor loops until the data byte is available.

ADDRESS	INSTRUCTION	OPERAND	COMMENT
200	Load AC	"1"	Load accumulator
	Store AC	517	Initiate keyboard read
202	Load AC	517	Get status byte
	Branch if Sign = 0	202	Loop until ready
	Load AC	516	Load data byte

(a) Memory-mapped I/O

ADDRESS	INSTRUCTION	OPERAND	COMMENT
200	Load I/O	5	Initiate keyboard read
201	Test I/O	5	Check for completion
	Branch Not Ready	201	Loop until complete
	In	5	Load data byte

(b) Isolated I/O

Figure 8.5 Memory-Mapped and Isolated I/O

With isolated I/O ([Figure 8.5b](#)), the I/O ports are accessible only by special I/O commands, which activate the I/O command lines on the bus.

For most types of processors, there is a relatively large set of different instructions for referencing memory. If isolated I/O is used, there are only a few I/O instructions. Thus, an advantage of memory-mapped I/O is that this large repertoire of instructions can be used, allowing more efficient programming. A disadvantage is that valuable memory address space is used up. Both memory-mapped and isolated I/O are in common use.

8.4 Interrupt-Driven I/O

The problem with programmed I/O is that the processor has to wait a long time for the I/O module of concern to be ready for either reception or transmission of data. The processor, while waiting, must repeatedly interrogate the status of the I/O module. As a result, the performance of the entire system is severely degraded.

An alternative is for the processor to issue an I/O command to a module and then go on to do some other useful work. The I/O module will then interrupt the processor to request service when it is ready to exchange data with the processor. The processor then executes the data transfer, as before, and then resumes its former processing.

Let us consider how this works, first from the point of view of the I/O module. For input, the I/O module receives a READ command from the processor. The I/O module then proceeds to read data in from an associated peripheral. Once the data are in the module's data register, the module signals an interrupt to the processor over a control line. The module then waits until its data are requested by the processor. When the request is made, the module places its data on the data bus and is then ready for another I/O operation.

From the processor's point of view, the action for input is as follows. The processor issues a READ command. It then goes off and does something else (e.g., the processor may be working on several different programs at the same time). At the end of each instruction cycle, the processor checks for interrupts ([Figure 3.9](#)). When the interrupt from the I/O module occurs, the processor saves the context (e.g., program counter and processor registers) of the current program and processes the interrupt. In this case, the processor reads the word of data from the I/O module and stores it in memory. It then restores the context of the program it was working on (or some other program) and resumes execution.

[Figure 8.4b](#) shows the use of interrupt I/O for reading in a block of data. Compare this with [Figure 8.4a](#). Interrupt I/O is more efficient than programmed I/O because it eliminates needless waiting. However, interrupt I/O still consumes a lot of processor time, because every word of data that goes from memory to I/O module or from I/O module to memory must pass through the processor.

Interrupt Processing

Let us consider the role of the processor in interrupt-driven I/O in more detail. The occurrence of an interrupt triggers a number of events, both in the processor hardware and in software. [Figure 8.6](#) shows a typical sequence. When an I/O device completes an I/O operation, the following sequence of hardware events occurs:

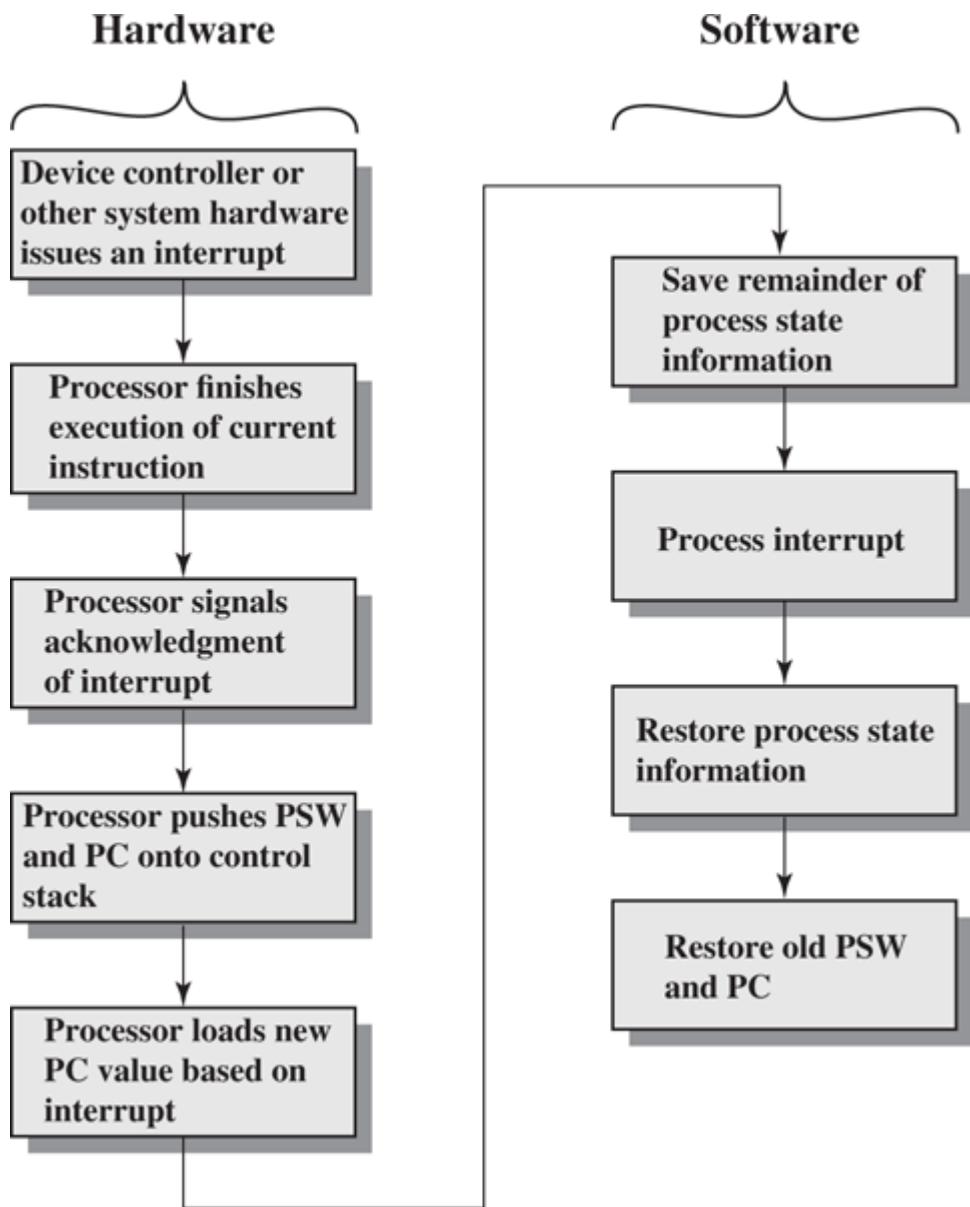

Figure 8.6 Simple Interrupt Processing

1. The device issues an interrupt signal to the processor.
2. The processor finishes execution of the current instruction before responding to the interrupt, as indicated in [Figure 3.9](#).
3. The processor tests for an interrupt, determines that there is one, and sends an acknowledgment signal to the device that issued the interrupt. The acknowledgment allows the device to remove its interrupt signal.
4. The processor now needs to prepare to transfer control to the interrupt routine. To begin, it needs to save information needed to resume the current program at the point of interrupt. The minimum information required is (a) the status of the processor, which is contained in a register called the **program status word (PSW)**; and (b) the location of the next instruction to be executed, which is contained in the program counter. These can be pushed onto the system control stack.²
5. The processor now loads the program counter with the entry location of the interrupt-handling program that will respond to this interrupt. Depending on the computer architecture and operating system design, there may be a single program; one program for each type of

² See [Appendix E](#) for a discussion of stack operation.

interrupt; or one program for each device and each type of interrupt. If there is more than one interrupt-handling routine, the processor must determine which one to invoke. This information may have been included in the original interrupt signal, or the processor may have to issue a request to the device that issued the interrupt to get a response that contains the needed information.

Once the program counter has been loaded, the processor proceeds to the next instruction cycle, which begins with an instruction fetch. Because the instruction fetch is determined by the contents of the program counter, the result is that control is transferred to the interrupt-handler program. The execution of this program results in the following operations:

6. At this point, the program counter and PSW relating to the interrupted program have been saved on the system stack. However, there is other information that is considered part of the “state” of the executing program. In particular, the contents of the processor registers need to be saved, because these registers may be used by the interrupt handler. So, all of these values, plus any other state information, need to be saved. Typically, the interrupt handler will begin by saving the contents of all registers on the stack. **Figure 8.7a** shows a simple example. In this case, a user program is interrupted after the instruction at location N . The contents of all of the registers plus the address of the next instruction ($N + 1$) are pushed onto the stack. The stack pointer is updated to point to the new top of stack, and the program counter is updated to point to the beginning of the interrupt service routine.

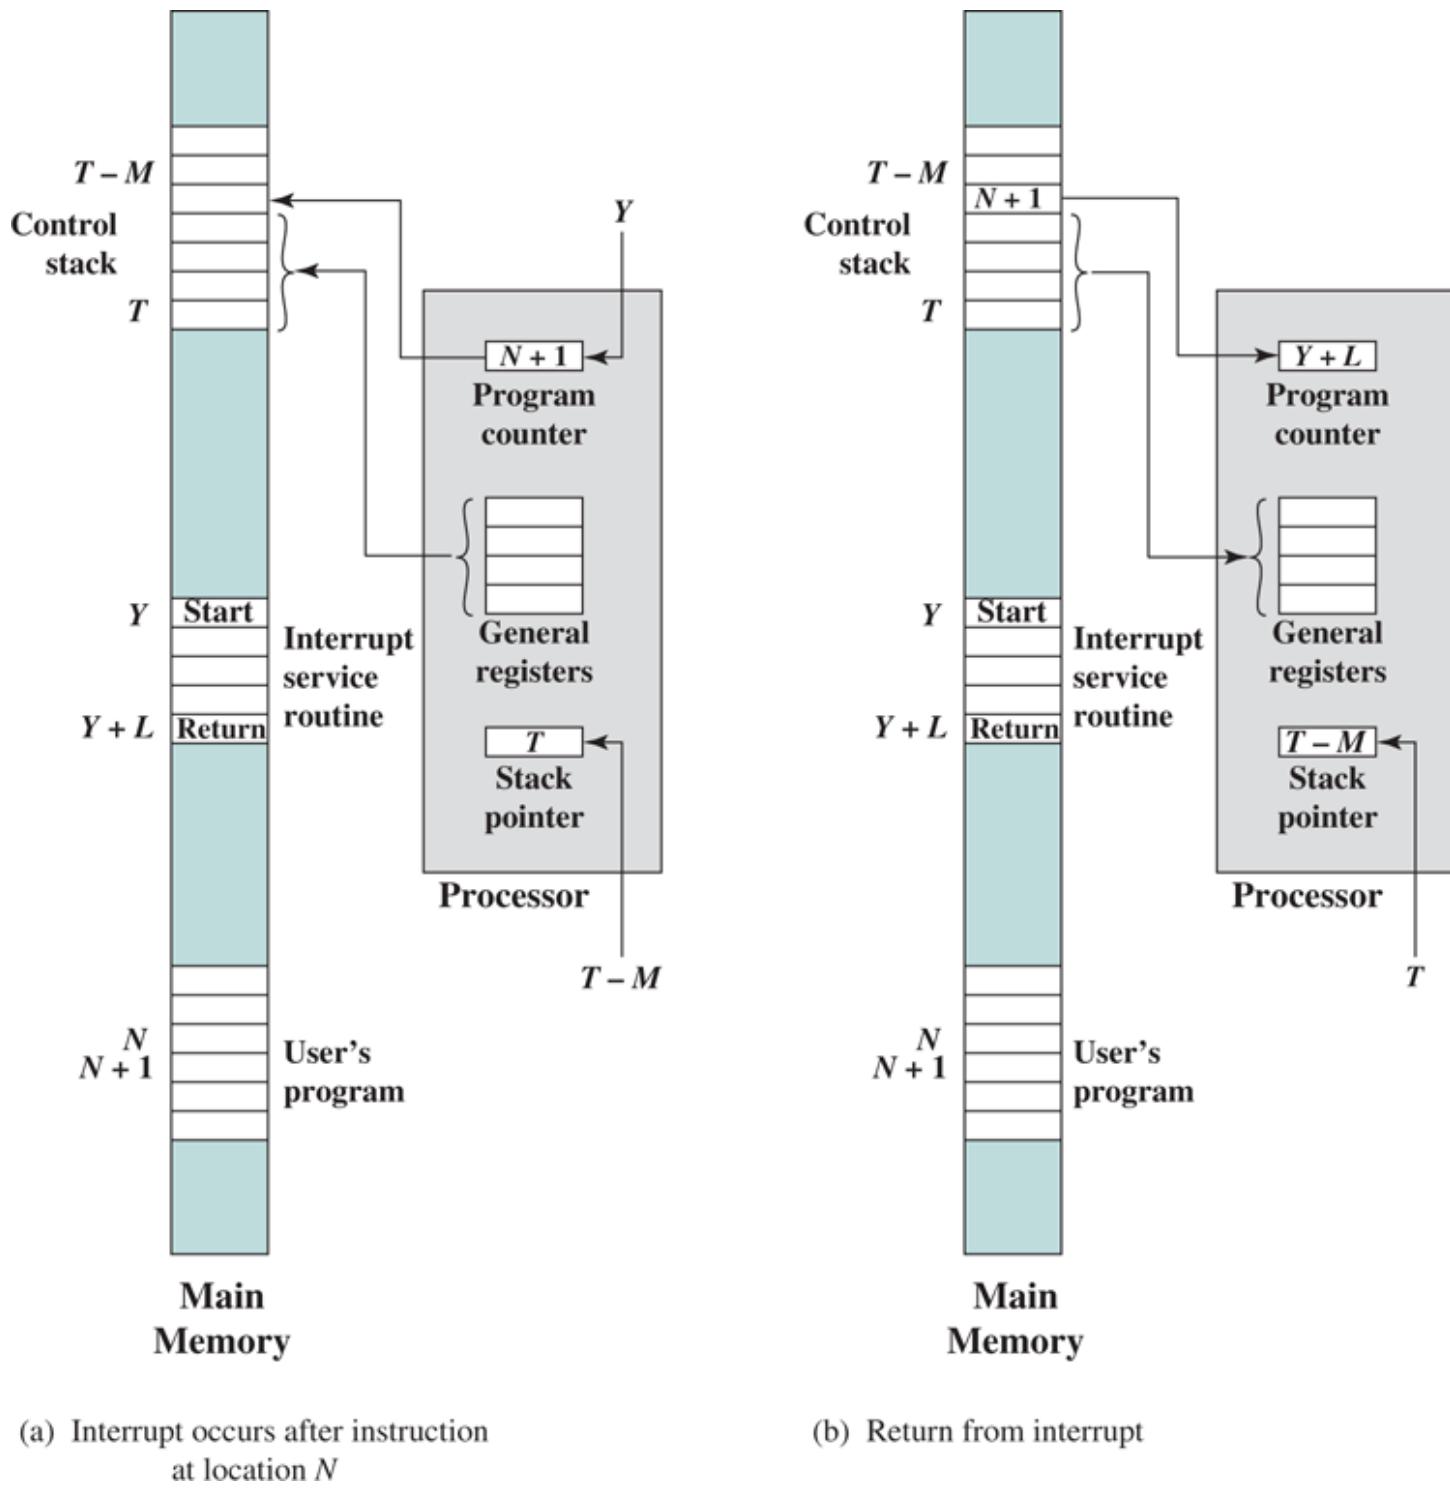

Figure 8.7 Changes in Memory and Registers for an Interrupt

7. The interrupt handler next processes the interrupt. This includes an examination of status information relating to the I/O operation or other event that caused an interrupt. It may also involve sending additional commands or acknowledgments to the I/O device.
8. When interrupt processing is complete, the saved register values are retrieved from the stack and restored to the registers (e.g., see [Figure 8.7b](#)).
9. The final act is to restore the PSW and program counter values from the stack. As a result, the next instruction to be executed will be from the previously interrupted program.

Note that it is important to save all the state information about the interrupted program for later resumption. This is because the interrupt is not a routine called from the program. Rather, the interrupt can occur at any time and therefore at any point in the execution of a user program. Its occurrence is

unpredictable. Indeed, as we will see in the next chapter, the two programs may not have anything in common and may belong to two different users.

Design Issues

Two design issues arise in implementing interrupt I/O. First, because there will almost invariably be multiple I/O modules, how does the processor determine which device issued the interrupt? And second, if multiple interrupts have occurred, how does the processor decide which one to process?

Let us consider device identification first. Four general categories of techniques are in common use:

- Multiple interrupt lines
- Software poll
- Daisy chain (hardware poll, vectored)
- Bus arbitration (vectored)

The most straightforward approach to the problem is to provide **multiple interrupt lines** between the processor and the I/O modules. However, it is impractical to dedicate more than a few bus lines or processor pins to interrupt lines. Consequently, even if multiple lines are used, it is likely that each line will have multiple I/O modules attached to it. Thus, one of the other three techniques must be used on each line.

One alternative is the **software poll**. When the processor detects an interrupt, it branches to an interrupt-service routine that polls each I/O module to determine which module caused the interrupt. The poll could be in the form of a separate command line (e.g., TESTI/O). In this case, the processor raises TESTI/O and places the address of a particular I/O module on the address lines. The I/O module responds positively if it set the interrupt. Alternatively, each I/O module could contain an addressable status register. The processor then reads the status register of each I/O module to identify the interrupting module. Once the correct module is identified, the processor branches to a device-service routine specific to that device.

The disadvantage of the software poll is that it is time consuming. A more efficient technique is to use a **daisy chain**, which provides, in effect, a hardware poll. An example of a daisy-chain configuration is shown in [Figure 3.26](#). For interrupts, all I/O modules share a common interrupt request line. The interrupt acknowledge line is daisy chained through the modules. When the processor senses an interrupt, it sends out an interrupt acknowledge. This signal propagates through a series of I/O modules until it gets to a requesting module. The requesting module typically responds by placing a word on the data lines. This word is referred to as a *vector* and is either the address of the I/O module or some other unique identifier. In either case, the processor uses the vector as a pointer to the appropriate device-service routine. This avoids the need to execute a general interrupt-service routine first. This technique is called a *vectored interrupt*.

There is another technique that makes use of vectored interrupts, and that is **bus arbitration**. With bus arbitration, an I/O module must first gain control of the bus before it can raise the interrupt request line. Thus, only one module can raise the line at a time. When the processor detects the interrupt, it responds on the interrupt acknowledge line. The requesting module then places its vector on the data lines.

The aforementioned techniques serve to identify the requesting I/O module. They also provide a way of assigning priorities when more than one device is requesting interrupt service. With multiple lines, the processor just picks the interrupt line with the highest priority. With software polling, the order in which modules are polled determines their priority. Similarly, the order of modules on a daisy chain determines their priority. Finally, bus arbitration can employ a priority scheme, as discussed in

Section 3.4.

We now turn to two examples of interrupt structures.

Intel 82C59A Interrupt Controller

The Intel 80386 provides a single Interrupt Request (INTR) and a single Interrupt Acknowledge (INTA) line. To allow the 80386 to handle a variety of devices and priority structures, it is usually configured with an external interrupt arbiter, the 82C59A. External devices are connected to the 82C59A, which in turn connects to the 80386.

Figure 8.8 shows the use of the 82C59A to connect multiple I/O modules for the 80386. A single 82C59A can handle up to eight modules. If control for more than eight modules is required, a cascade arrangement can be used to handle up to 64 modules.

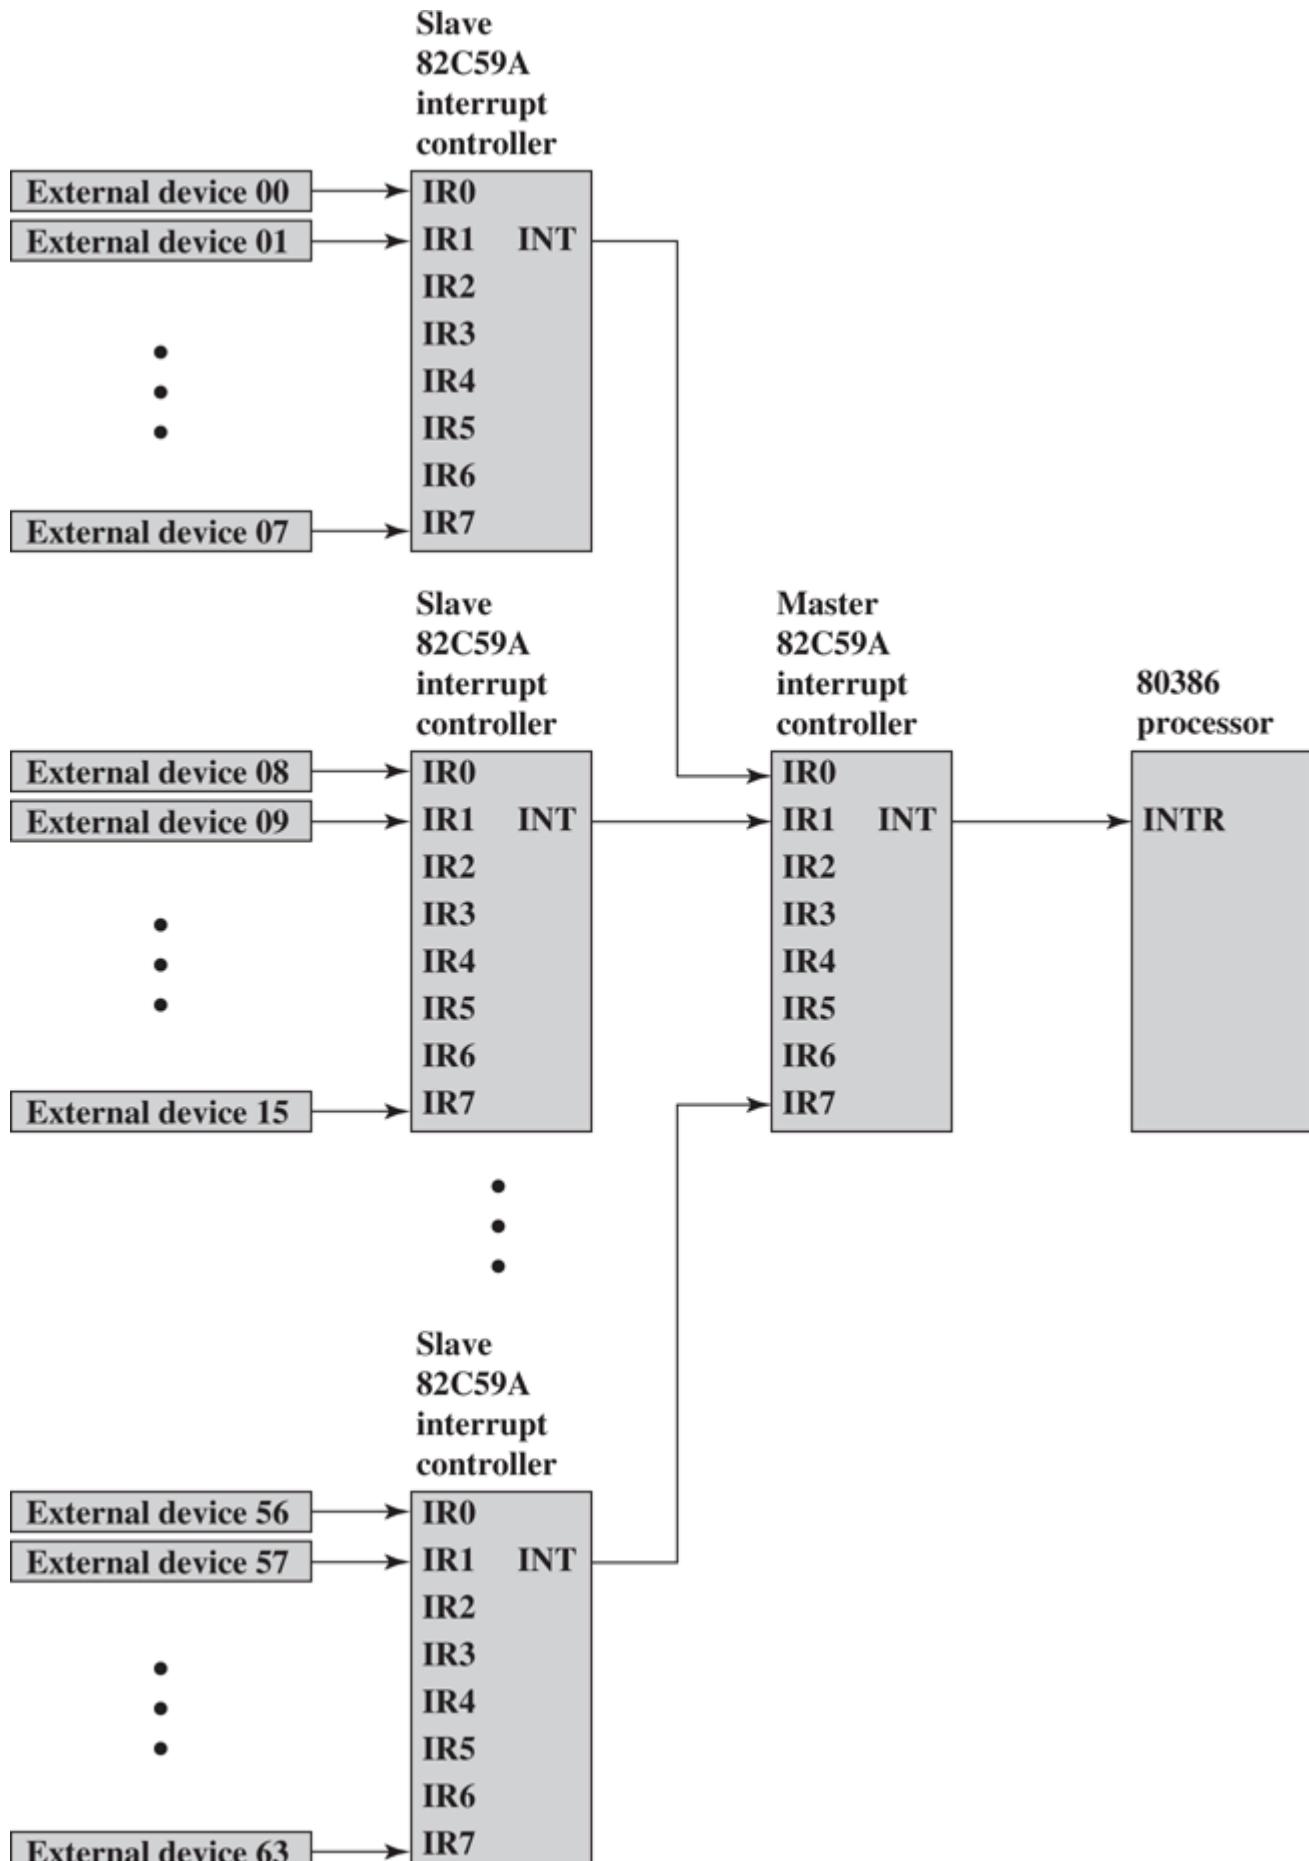

Figure 8.8 Use of the 82C59A Interrupt Controller

The 82C59A's sole responsibility is the management of interrupts. It accepts interrupt requests from attached modules, determines which interrupt has the highest priority, and then signals the processor

by raising the INTR line. The processor acknowledges via the INTA line. This prompts the 82C59A to place the appropriate vector information on the data bus. The processor can then proceed to process the interrupt and to communicate directly with the I/O module to read or write data.

The 82C59A is programmable. The 80386 determines the priority scheme to be used by setting a control word in the 82C59A. The following interrupt modes are possible:

- **Fully nested:** The interrupt requests are ordered in priority from 0 (IR0) through 7 (IR7).
- **Rotating:** In some applications a number of interrupting devices are of equal priority. In this mode a device, after being serviced, receives the lowest priority in the group.
- **Special mask:** This allows the processor to inhibit interrupts from certain devices.

The Intel 8255A Programmable Peripheral Interface

As an example of an I/O module used for programmed I/O and interrupt-driven I/O, we consider the Intel 8255A Programmable Peripheral Interface. The 8255A is a single-chip, general-purpose I/O module originally designed for use with the Intel 80386 processor. It has since been cloned by other manufacturers and is a widely used peripheral controller chip. Its uses include as a controller for simple I/O devices for microprocessors and in embedded systems, including microcontroller systems.

ARCHITECTURE AND OPERATION

Figure 8.9 shows a general block diagram plus the pin assignment for the 40-pin package in which it is housed. As shown on the pin layout, the 8255A includes the following lines:

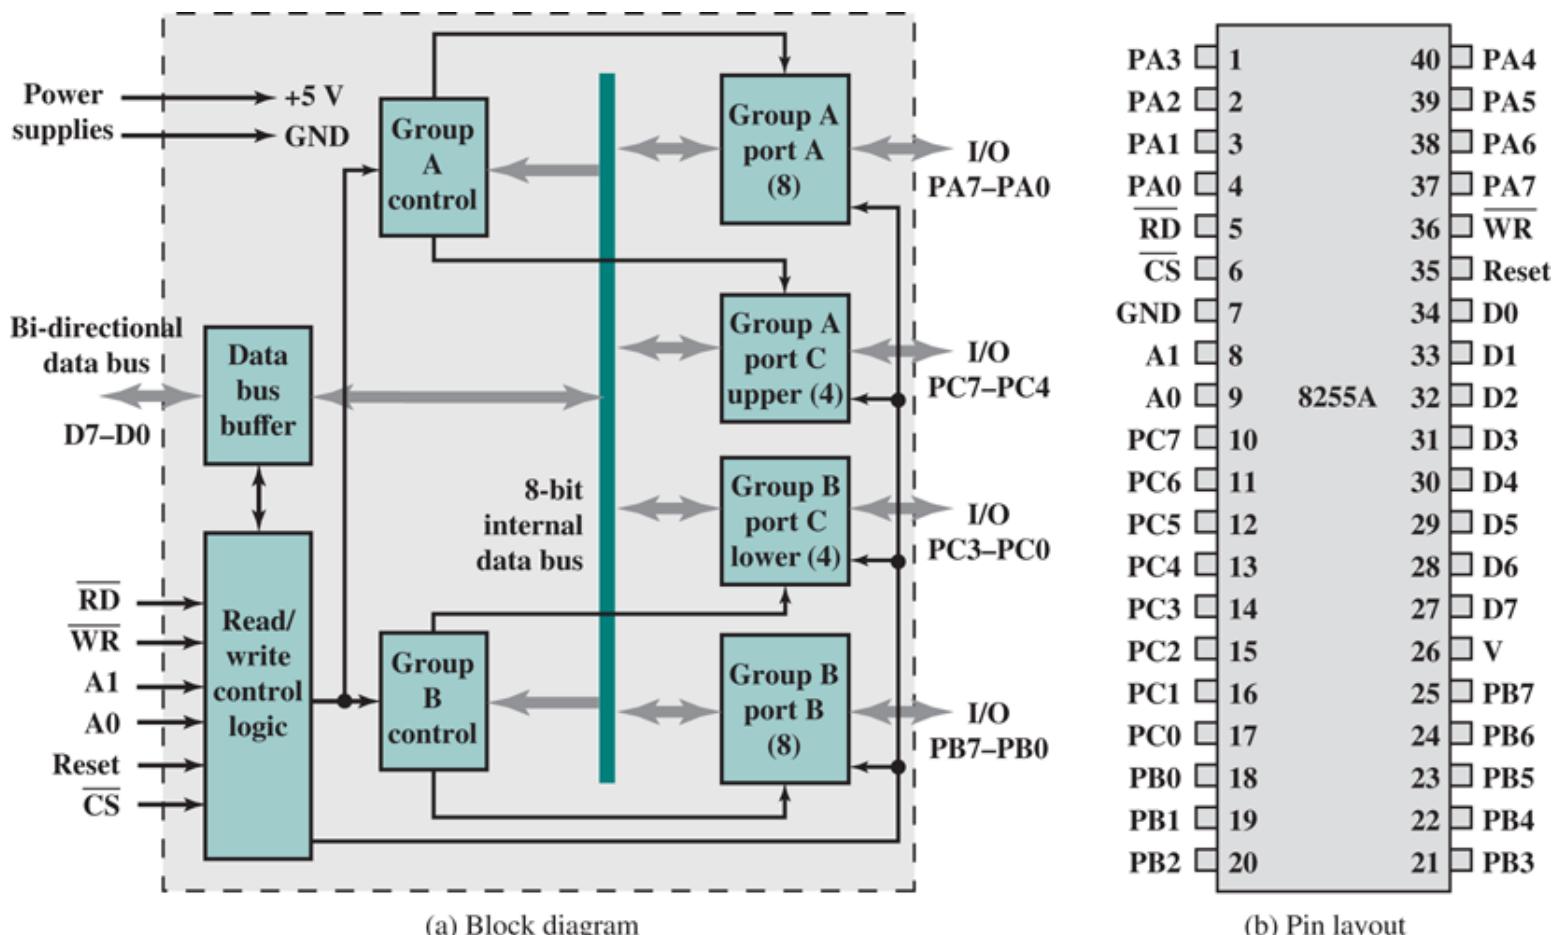

Figure 8.9 The Intel 8255A Programmable Peripheral Interface

- **D0–D7:** These are the data I/O lines for the device. All information read from and written to the

8255A occurs via these eight data lines.

- **CS (Chip Select Input):** If this line is a logical 0, the microprocessor can read and write to the 8255A.
- **RD (Read Input):** If this line is a logical 0 and the CS input is a logical 0, the 8255A data outputs are enabled onto the system data bus.
- **WR (Write Input):** If this input line is a logical 0 and the CS input is a logical 0, data are written to the 8255A from the system data bus.
- **RESET:** The 8255A is placed into its reset state if this input line is a logical 1. All peripheral ports are set to the input mode.
- **PA0–PA7, PB0–PB7, PC0–PC7:** These signal lines are used as 8-bit I/O ports. They can be connected to peripheral devices.
- **A0, A1:** The logical combination of these two input lines determines which internal register of the 8255A data are written to or read from.

The right side of the block diagram of [Figure 8.9a](#) is the external interface of the 8255A. The 24 I/O lines are divided into three 8-bit groups (A, B, C). Each group can function as an 8-bit I/O port, thus providing connection for three peripheral devices. In addition, group C is subdivided into 4-bit groups (C_A and C_B), which may be used in conjunction with the A and B I/O ports. Configured in this manner, group C lines carry control and status signals.

The left side of the block diagram is the internal interface to the microprocessor system bus. It includes an 8-bit bidirectional data bus (D0 through D7), used to transfer data between the microprocessor and the I/O ports and to transfer control information.

The processor controls the 8255A by means of an 8-bit control register in the processor. The processor can set the value of the control register to specify a variety of operating modes and configurations. From the processor point of view, there is a control port, and the control register bits are set in the processor and then sent to the control port over lines D0–D7. The two address lines specify one of the three I/O ports or the control register, as follows:

A1	A2	Selects
0	0	Port A
0	1	Port B
1	0	Port C
1	1	Control register

Thus, when the processor sets both A1 and A2 to 1, the 8255A interprets the 8-bit value on the data bus as a control word. When the processor transfers an 8-bit control word with line D7 set to 1 ([Figure 8.10a](#)), the control word is used to configure the operating mode of the 24 I/O lines. The three modes are:

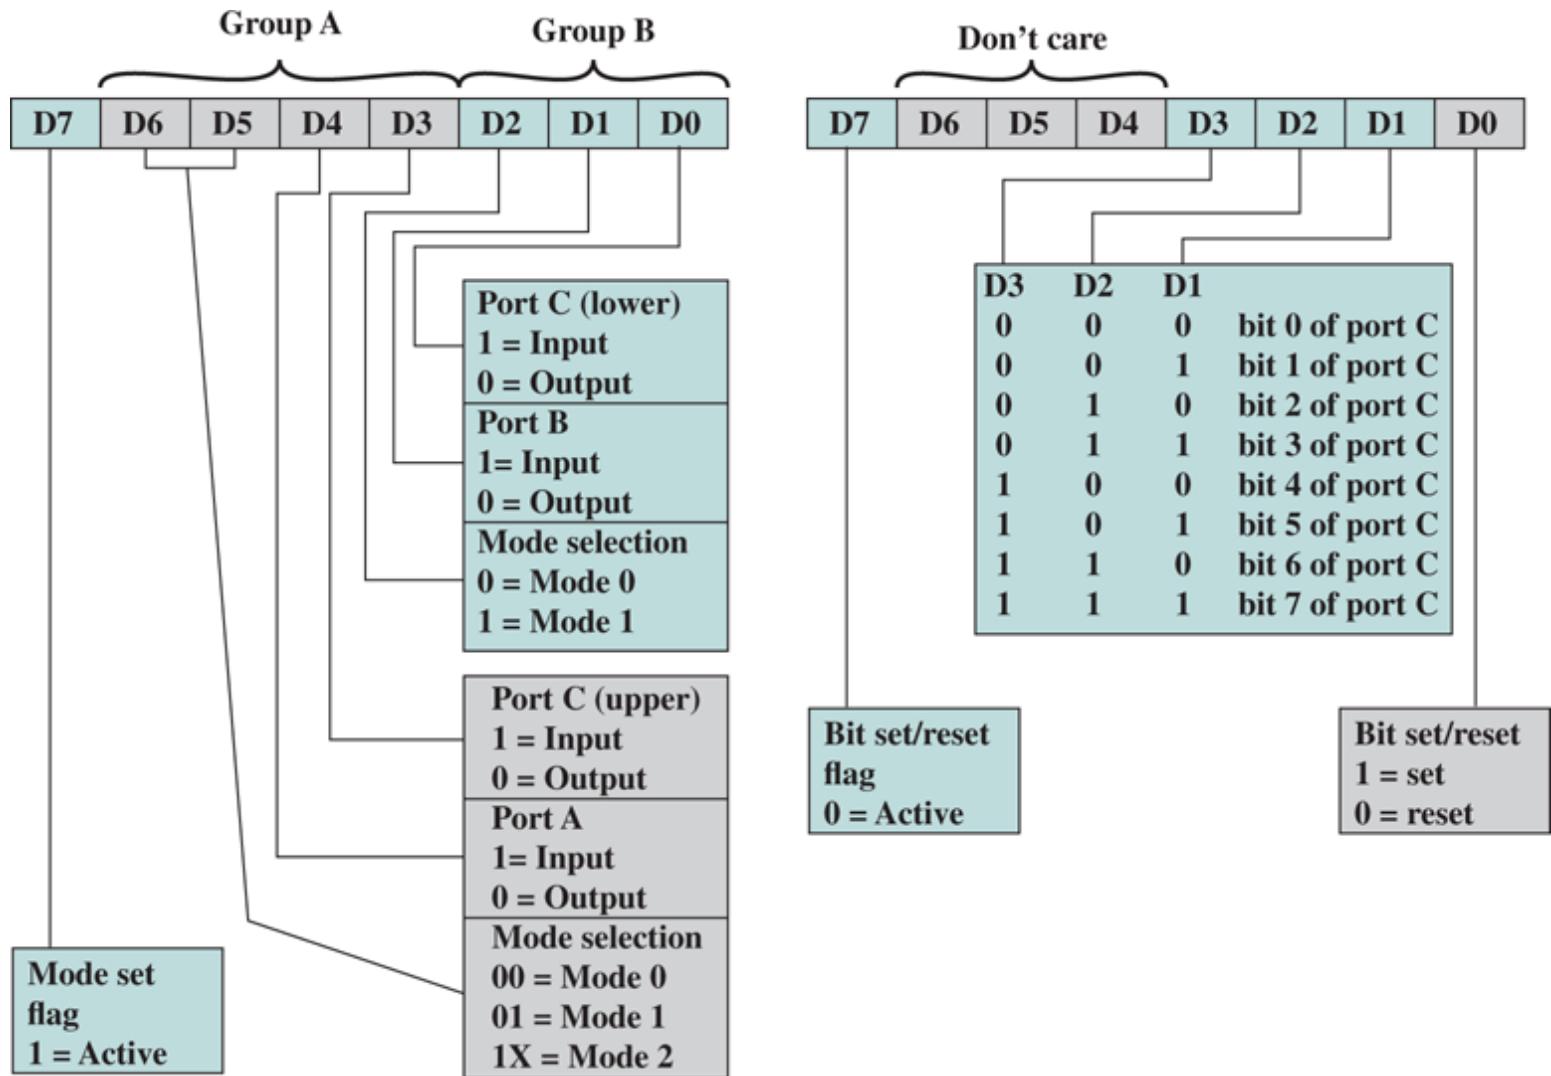

Figure 8.10 The Intel 8255A Control Word

- **Mode 0:** This is the basic I/O mode. The three groups of eight external lines function as three 8-bit I/O ports. Each port can be designated as input or output. Data may only be sent to a port if the port is defined as output, and data may only be read from a port if the port is set to input.
- **Mode 1:** In this mode, ports A and B can be configured as either input or output, and lines from port C serve as control lines for A and B. The control signals serve two principal purposes: “handshaking” and interrupt request. Handshaking is a simple timing mechanism. One control line is used by the sender as a DATA READY line, to indicate when the data are present on the I/O data lines. Another line is used by the receiver as an ACKNOWLEDGE, indicating that the data have been read and the data lines may be cleared. Another line may be designated as an INTERRUPT REQUEST line and tied back to the system bus.
- **Mode 2:** This is a bidirectional mode. In this mode, port A can be configured as either the input or output lines for bidirectional traffic on port B, with the port B lines providing the opposite direction. Again, port C lines are used for control signaling.

When the processor sets D7 to 0 ([Figure 8.10b](#)), the control word is used to program the bit values of port C individually. This feature is rarely used.

Because the 8255A is programmable via the control register, it can be used to control a variety of simple peripheral devices. **Figure 8.11** illustrates its use to control a keyboard/display terminal. The keyboard provides 8 bits of input. Two of these bits, SHIFT and CONTROL, have special meaning to the keyboard-handling program executing in the processor. However, this interpretation is transparent to the 8255A, which simply accepts the 8 bits of data and presents them on the system data bus. Two handshaking control lines are provided for use with the keyboard.

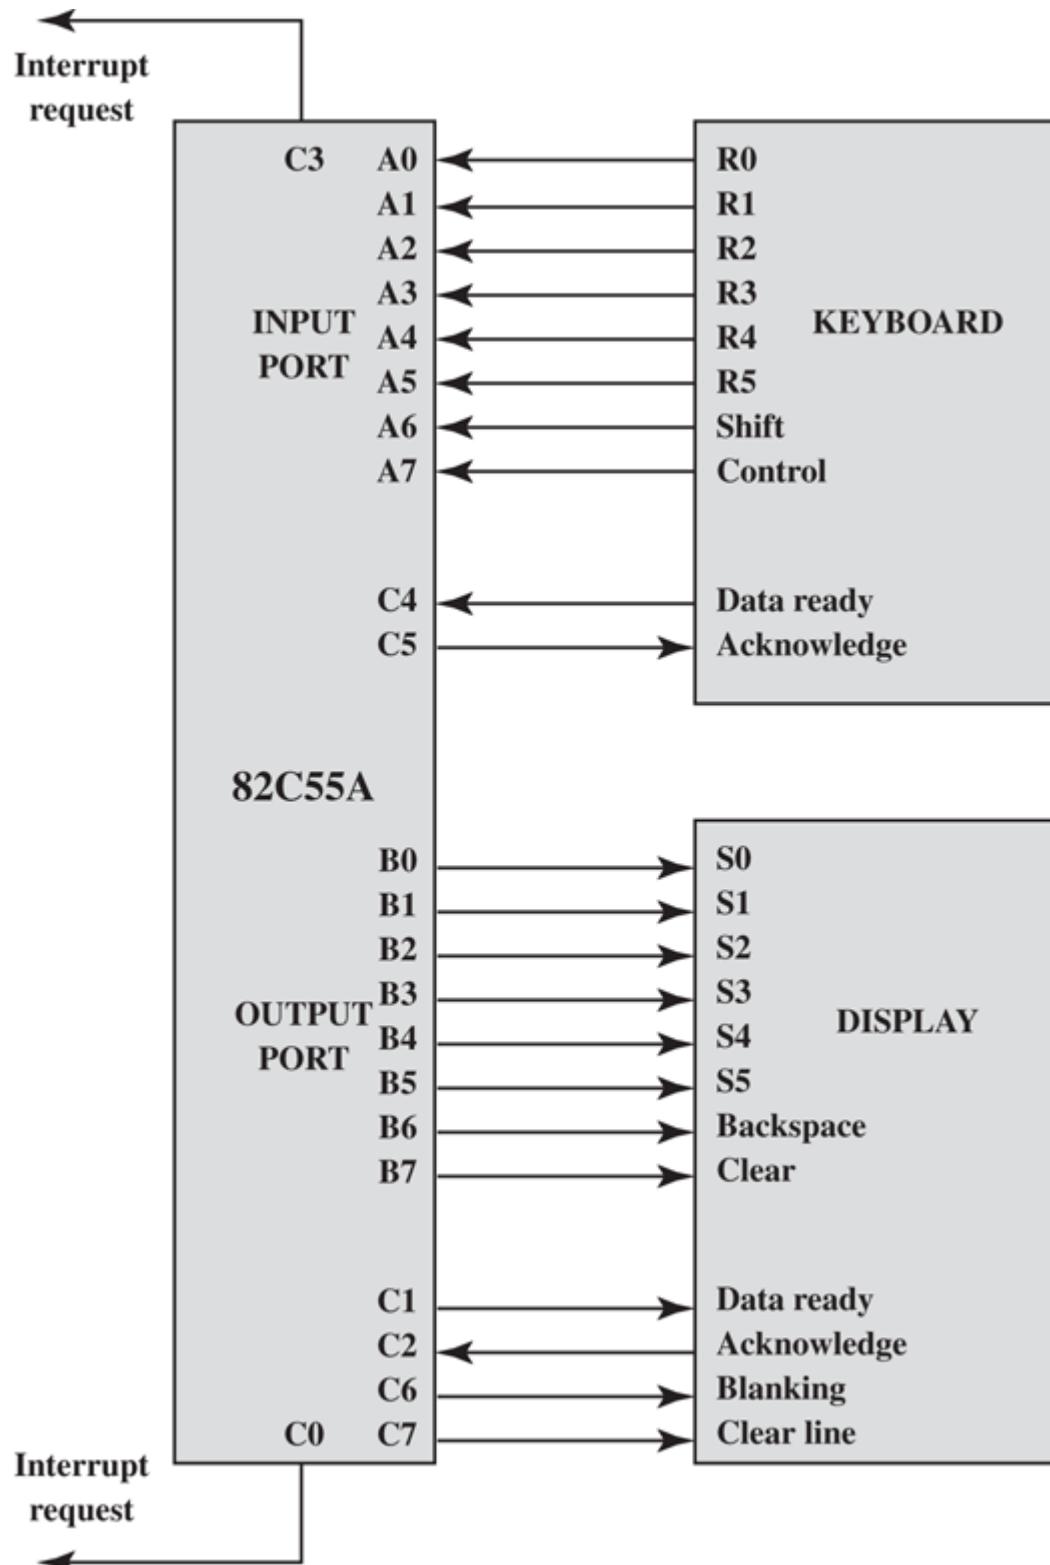

Figure 8.11 Keyboard/Display Interface to 8255A

The display is also linked by an 8-bit data port. Again, two of the bits have special meanings that are transparent to the 8255A. In addition to two handshaking lines, two lines provide additional control functions.

8.5 Direct Memory Access

Drawbacks of Programmed and Interrupt-Driven I/O

Interrupt-driven I/O, though more efficient than simple programmed I/O, still requires the active intervention of the processor to transfer data between memory and an I/O module, and any data transfer must traverse a path through the processor. Thus, both these forms of I/O suffer from two inherent drawbacks:

1. The I/O transfer rate is limited by the speed with which the processor can test and service a device.
2. The processor is tied up in managing an I/O transfer; a number of instructions must be executed for each I/O transfer (e.g., [Figure 8.5](#)).

There is somewhat of a trade-off between these two drawbacks. Consider the transfer of a block of data. Using simple programmed I/O, the processor is dedicated to the task of I/O and can move data at a rather high rate, at the cost of doing nothing else. Interrupt I/O frees up the processor to some extent at the expense of the I/O transfer rate. Nevertheless, both methods have an adverse impact on both processor activity and I/O transfer rate.

When large volumes of data are to be moved, a more efficient technique is required: direct memory access (DMA).

DMA Function

DMA involves an additional module on the system bus. The DMA module ([Figure 8.12](#)) is capable of mimicking the processor and, indeed, of taking over control of the system from the processor. It needs to do this to transfer data to and from memory over the system bus. For this purpose, the DMA module must use the bus only when the processor does not need it, or it must force the processor to suspend operation temporarily. The latter technique is more common and is referred to as *cycle stealing*, because the DMA module in effect steals a bus cycle.

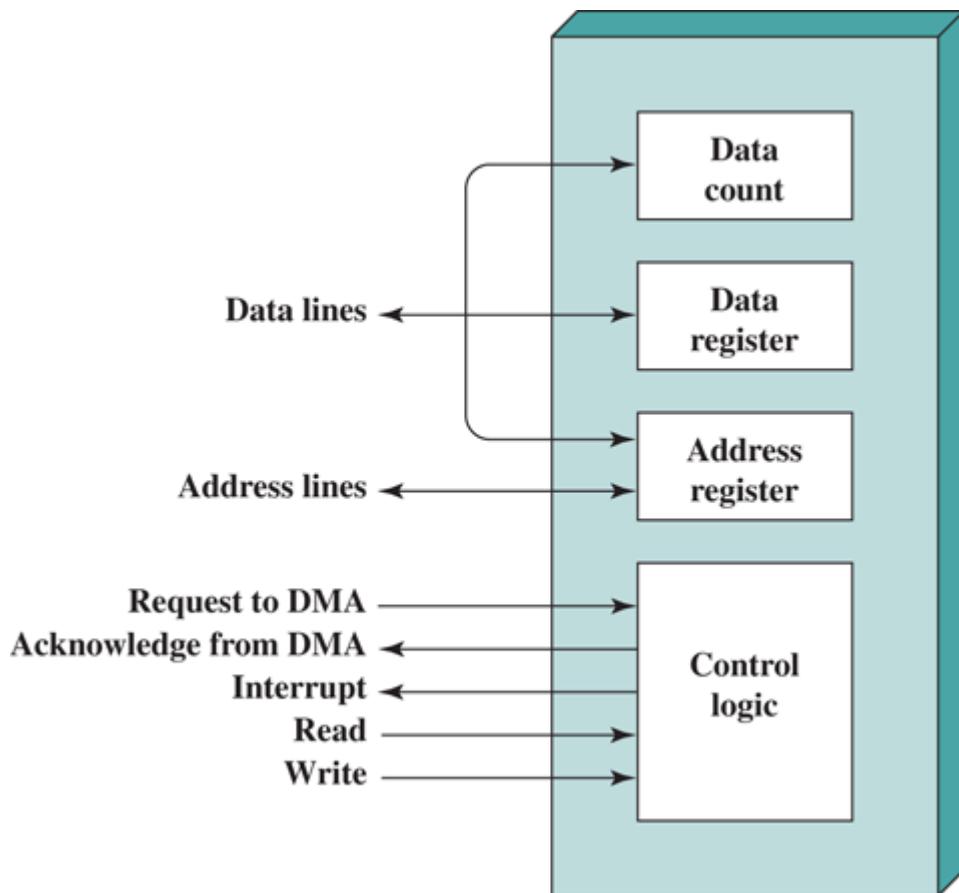

Figure 8.12 Typical DMA Block Diagram

When the processor wishes to read or write a block of data, it issues a command to the DMA module, by sending to the DMA module the following information:

- Whether a read or write is requested, using the read or write control line between the processor and the DMA module.
- The address of the I/O device involved, communicated on the data lines.
- The starting location in memory to read from or write to, communicated on the data lines and stored by the DMA module in its address register.
- The number of words to be read or written, again communicated via the data lines and stored in the data count register.

The processor then continues with other work. It has delegated this I/O operation to the DMA module. The DMA module transfers the entire block of data, one word at a time, directly to or from memory, without going through the processor. When the transfer is complete, the DMA module sends an interrupt signal to the processor. Thus, the processor is involved only at the beginning and end of the transfer ([Figure 8.4c](#)).

[Figure 8.13](#) shows where in the instruction cycle the processor may be suspended. In each case, the processor is suspended just before it needs to use the bus. The DMA module then transfers one word and returns control to the processor. Note that this is not an interrupt; the processor does not save a context and do something else. Rather, the processor pauses for one bus cycle. The overall effect is to cause the processor to execute more slowly. Nevertheless, for a multiple-word I/O transfer, DMA is far more efficient than interrupt-driven or programmed I/O.

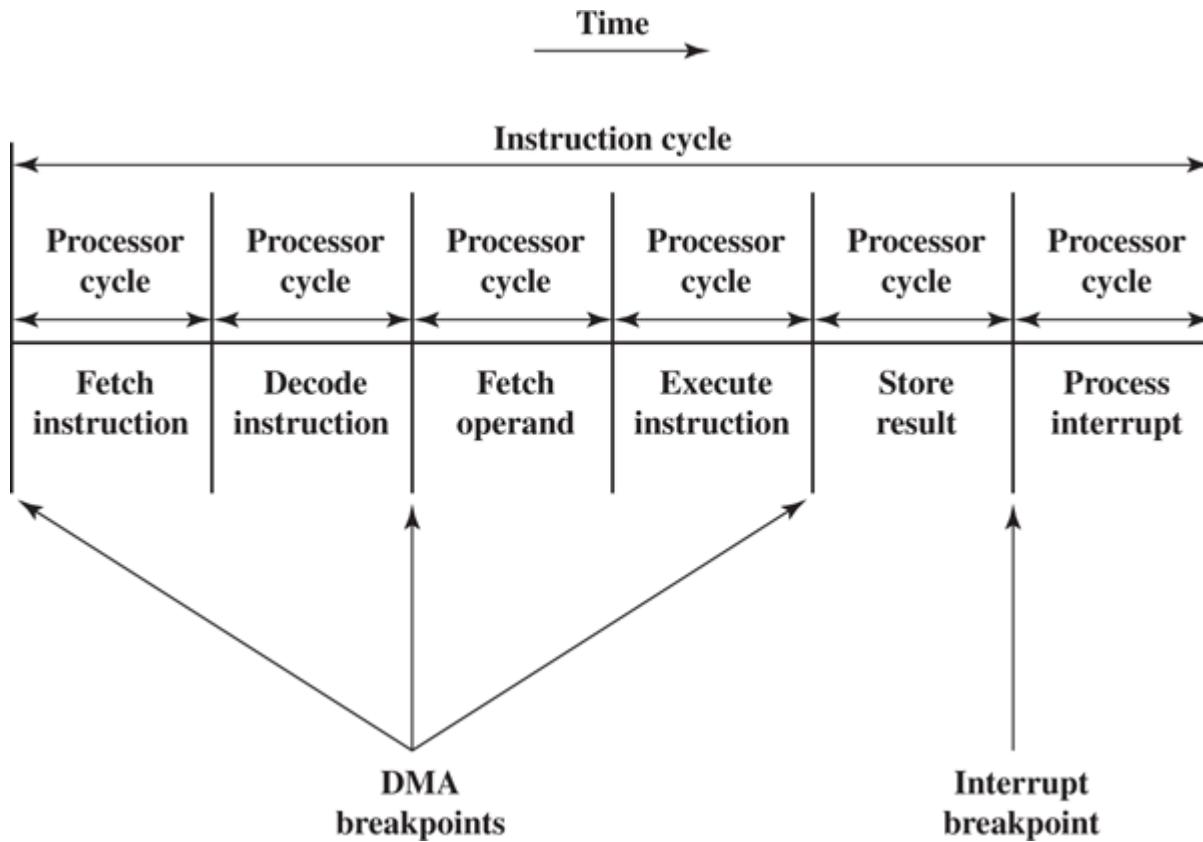

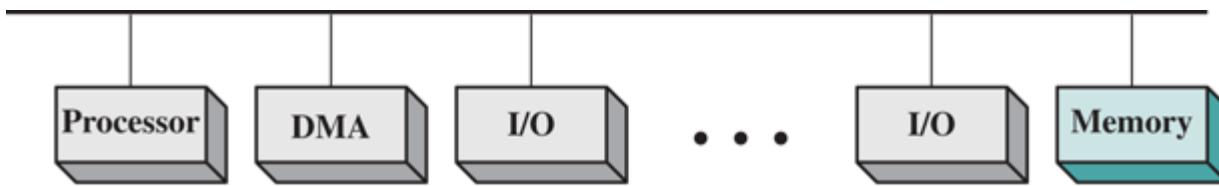

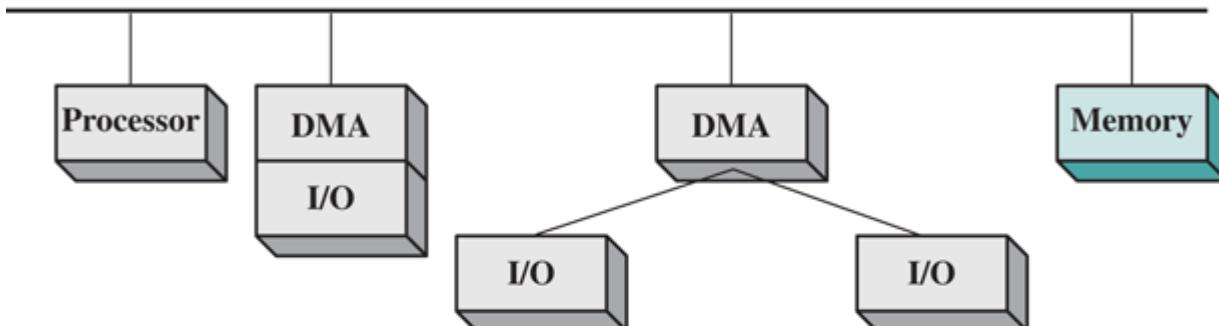

Figure 8.13 DMA and Interrupt Breakpoints during an Instruction Cycle

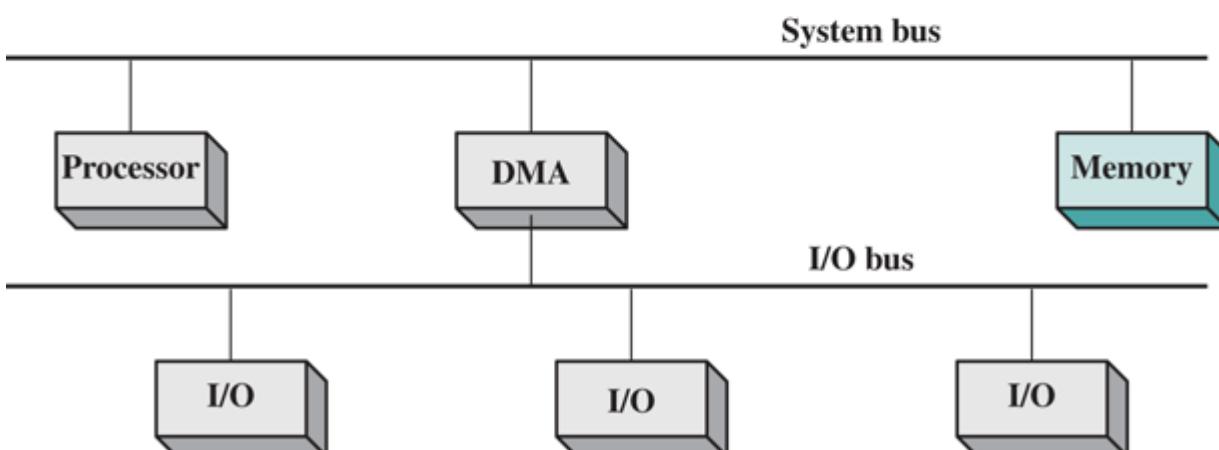

The DMA mechanism can be configured in a variety of ways. Some possibilities are shown in [Figure 8.14](#). In the first example, all modules share the same system bus. The DMA module, acting as a surrogate processor, uses programmed I/O to exchange data between memory and an I/O module through the DMA module. This configuration, while it may be inexpensive, is clearly inefficient. As with processor-controlled programmed I/O, each transfer of a word consumes two bus cycles.

(a) Single-bus, detached DMA

(b) Single-bus, integrated DMA-I/O

(c) I/O bus

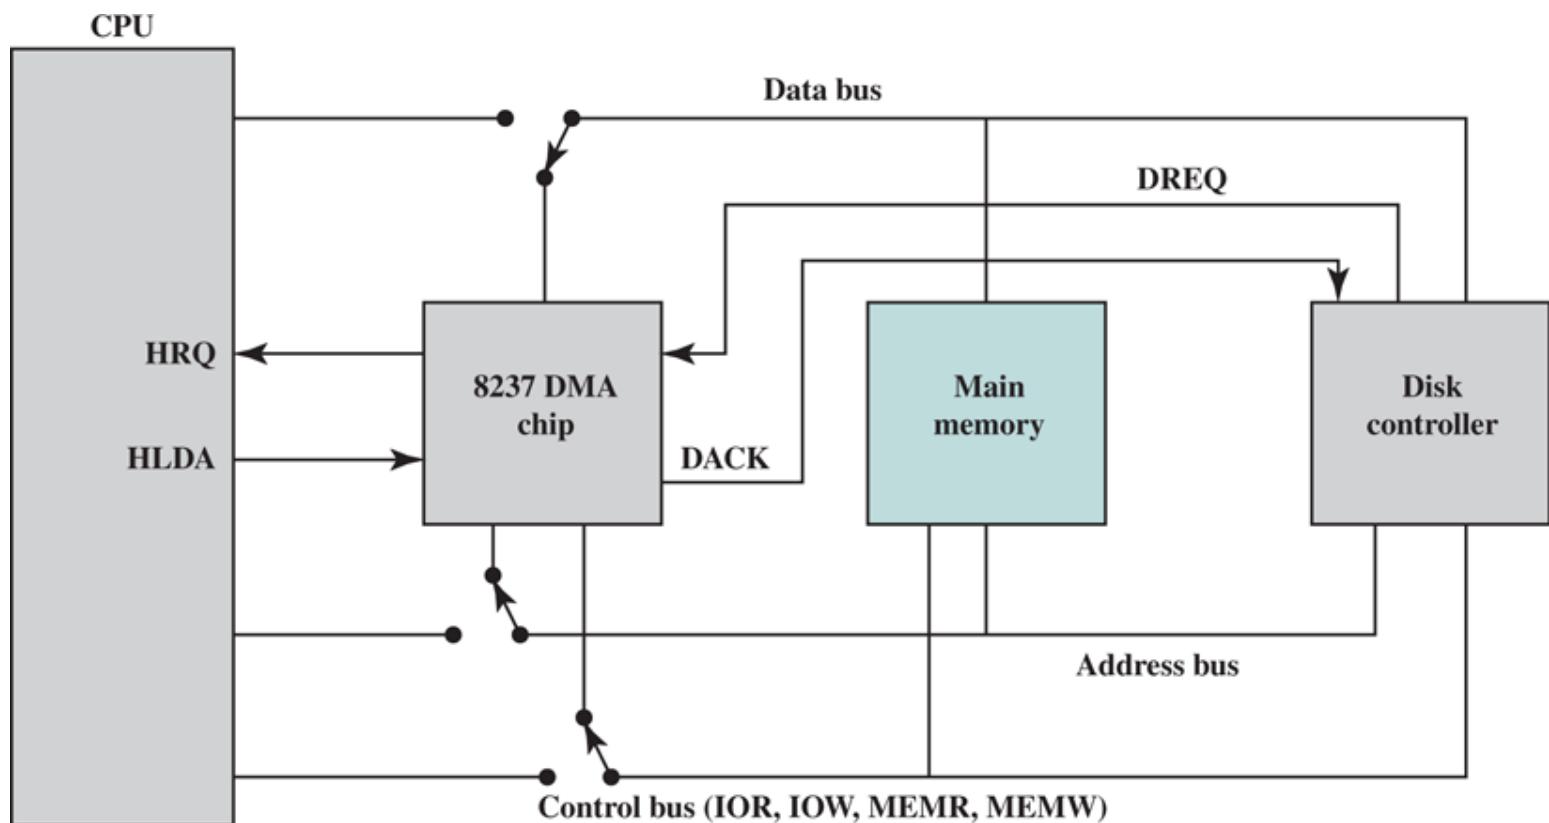

Figure 8.14 Alternative DMA Configurations

The number of required bus cycles can be cut substantially by integrating the DMA and I/O functions. As [Figure 8.14b](#) indicates, this means that there is a path between the DMA module and one or more I/O modules that does not include the system bus. The DMA logic may actually be a part of an I/O module, or it may be a separate module that controls one or more I/O modules. This concept can be taken one step further by connecting I/O modules to the DMA module using an I/O bus ([Figure 8.14c](#)). This reduces the number of I/O interfaces in the DMA module to one and provides for an easily expandable configuration. In both of these cases ([Figures 8.14b](#) and [c](#)), the system bus that the DMA module shares with the processor and memory is used by the DMA module only to exchange data with memory. The exchange of data between the DMA and I/O modules takes place off the system bus.

Intel 8237A DMA Controller

The Intel 8237A DMA controller interfaces to the 80×86 family of processors and to DRAM memory to provide a DMA capability. [Figure 8.15](#) indicates the location of the DMA module. When the DMA

module needs to use the system buses (data, address, and control) to transfer data, it sends a signal called HOLD to the processor. The processor responds with the HLDA (hold acknowledge) signal, indicating that the DMA module can use the buses. For example, if the DMA module is to transfer a block of data from memory to disk, it will do the following:

DACK = DMA acknowledge
DREQ = DMA request
HLDA = HOLD acknowledge
HRQ = HOLD request

Figure 8.15 8237 DMA Usage of System Bus

1. The peripheral device (such as the disk controller) will request the service of the DMA by pulling DREQ (DMA request) high.
2. The DMA will put a high on its HRQ (hold request), signaling the CPU through its HOLD pin that it needs to use the buses.
3. The CPU will finish the present bus cycle (not necessarily the present instruction) and respond to the DMA request by putting high on its HLDA (hold acknowledge), thus telling the 8237 DMA that it can go ahead and use the buses to perform its task. HOLD must remain active high as long as DMA is performing its task.
4. DMA will activate DACK (DMA acknowledge), which tells the peripheral device that it will start to transfer the data.
5. DMA starts to transfer the data from memory to peripheral by putting the address of the first byte of the block on the address bus and activating MEMR, thereby reading the byte from memory into the data bus; it then activates IOW to write it to the peripheral. Then DMA decrements the counter and increments the address pointer and repeats this process until the count reaches zero and the task is finished.
6. After the DMA has finished its job it will deactivate HRQ, signaling the CPU that it can regain control over its buses.

While the DMA is using the buses to transfer data, the processor is idle. Similarly, when the processor

is using the bus, the DMA is idle. The 8237 DMA is known as a *fly-by* DMA controller. This means that the data being moved from one location to another does not pass through the DMA chip and is not stored in the DMA chip. Therefore, the DMA can only transfer data between an I/O port and a memory address, and not between two I/O ports or two memory locations. However, as explained subsequently, the DMA chip can perform a memory-to-memory transfer via a register.

The 8237 contains four DMA channels that can be programmed independently, and any one of the channels may be active at any moment. These channels are numbered 0, 1, 2, and 3.

The 8237 has a set of five control/command registers to program and control DMA operation over one of its channels (**Table 8.2**):

Table 8.2 Intel 8237A Registers

E7D = enable/disable

TC = terminal count

Bit	Command	Status	Mode	Single Mask	All Mask		
D0	Memory-to-memory E/D	Channel 0 has reached TC	Channel select	Select channel mask bit	Clear/set channel 0 mask bit		
D1	Channel 0 address hold E/D	Channel 1 has reached TC			Clear/set channel 1 mask bit		
D2	Controller E/D	Channel 2 has reached TC	Verify/write/read transfer	Clear/set mask bit	Clear/set channel 2 mask bit		
D3	Normal/compressed timing	Channel 3 has reached TC	Auto-initialization E/D	Not used	Clear/set channel 3 mask bit		
D4	Fixed/rotating priority	Channel 0 request			Not used		
D5	Late/extended write selection	Channel 0 request	Address increment/decrement select				
D6	DREQ sense active high/low	Channel 0 request					
D7	DACK sense active high/low	Channel 0 request	Demand/single/block/cascade mode select				

- **Command:** The processor loads this register to control the operation of the DMA. D0 enables a memory-to-memory transfer, in which channel 0 is used to transfer a byte into an 8237 temporary register and channel 1 is used to transfer the byte from the register to memory. When memory-to-memory is enabled, D1 can be used to disable increment/decrement on channel 0 so that a fixed value can be written into a block of memory. D2 enables or disables DMA.
- **Status:** The processor reads this register to determine DMA status. Bits D0–D3 are used to indicate if channels 0–3 have reached their TC (terminal count). Bits D4–D7 are used by the processor to determine if any channel has a DMA request pending.
- **Mode:** The processor sets this register to determine the mode of operation of the DMA. Bits D0 and D1 are used to select a channel. The other bits select various operation modes for the selected channel. Bits D2 and D3 determine if the transfer is from an I/O device to memory (write) or from memory to I/O (read), or a verify operation. If D4 is set, then the memory address register and the count register are reloaded with their original values at the end of a DMA data transfer. Bits D6 and D7 determine the way in which the 8237 is used. In single mode, a single byte of data is transferred. Block and demand modes are used for a block transfer, with the demand mode allowing for premature ending of the transfer. Cascade mode allows multiple 8237s to be cascaded to expand the number of channels to more than 4.
- **Single Mask:** The processor sets this register. Bits D0 and D1 select the channel. Bit D2 clears or sets the mask bit for that channel. It is through this register that the DREQ input of a specific channel can be masked (disabled) or unmasked (enabled). While the command register can be used to disable the whole DMA chip, the single mask register allows the programmer to disable or enable a specific channel.
- **All Mask:** This register is similar to the single mask register except that all four channels can be masked or unmasked with one write operation.

In addition, the 8237A has eight data registers: one memory address register and one count register for each channel. The processor sets these registers to indicate the location of size of main memory to be affected by the transfers.

8.6 Direct Cache Access

DMA has proved an effective means of enhancing performance of I/O with peripheral devices and network I/O traffic. However, for the dramatic increases in data rates for network I/O, DMA is not able to scale to meet the increased demand. This demand is coming primarily from the widespread deployment of 10-Gbps and 100-Gbps Ethernet switches to handle massive amounts of data transfer to and from database servers and other high-performance systems [STAL16]. A secondary but increasingly important source of traffic comes from Wi-Fi in the gigabit range. Network Wi-Fi devices that handle 3.2 Gbps and 6.76 Gbps are becoming widely available and producing demand on enterprise systems [STAL16].

In this section, we will show how enabling the I/O function to have direct access to the cache can enhance performance, a technique known as **direct cache access (DCA)**. Throughout this section, we are concerned only with the cache that is closest to main memory, referred to as the **last-level cache**. In some systems, this will be an L2 cache, in others an L3 cache.

To begin, we describe the way in which contemporary multicore systems use on-chip shared cache to enhance DMA performance. This approach involves enabling the DMA function to have direct access to the last-level cache. Next we examine cache-related performance issues that manifest when high-speed network traffic is processed. From there, we look at several different strategies for DCA that are designed to enhance network protocol processing performance. Finally, this section describes a DCA approach implemented by Intel, referred to as Direct Data I/O.

DMA Using Shared Last-Level Cache

As was discussed in [Chapter 1](#) (see [Figure 1.2](#)), contemporary multicore systems include both cache dedicated to each core and an additional level of shared cache, either L2 or L3. With the increasing size of available last-level cache, system designers have enhanced the DMA function so that the DMA controller has access to the shared cache in a manner similar to the cores. To clarify the interaction of DMA and cache, it will be useful to first describe a specific system architecture. For this purpose, the following is an overview of the Intel Xeon system.

XEON MULTICORE PROCESSOR

Intel Xeon is Intel's high-end, high-performance processor family, used in servers, high-performance workstations, and supercomputers. Many of the members of the Xeon family use a ring interconnect system, as illustrated for the Xeon E5-2600/4600 in [Figure 8.16](#).

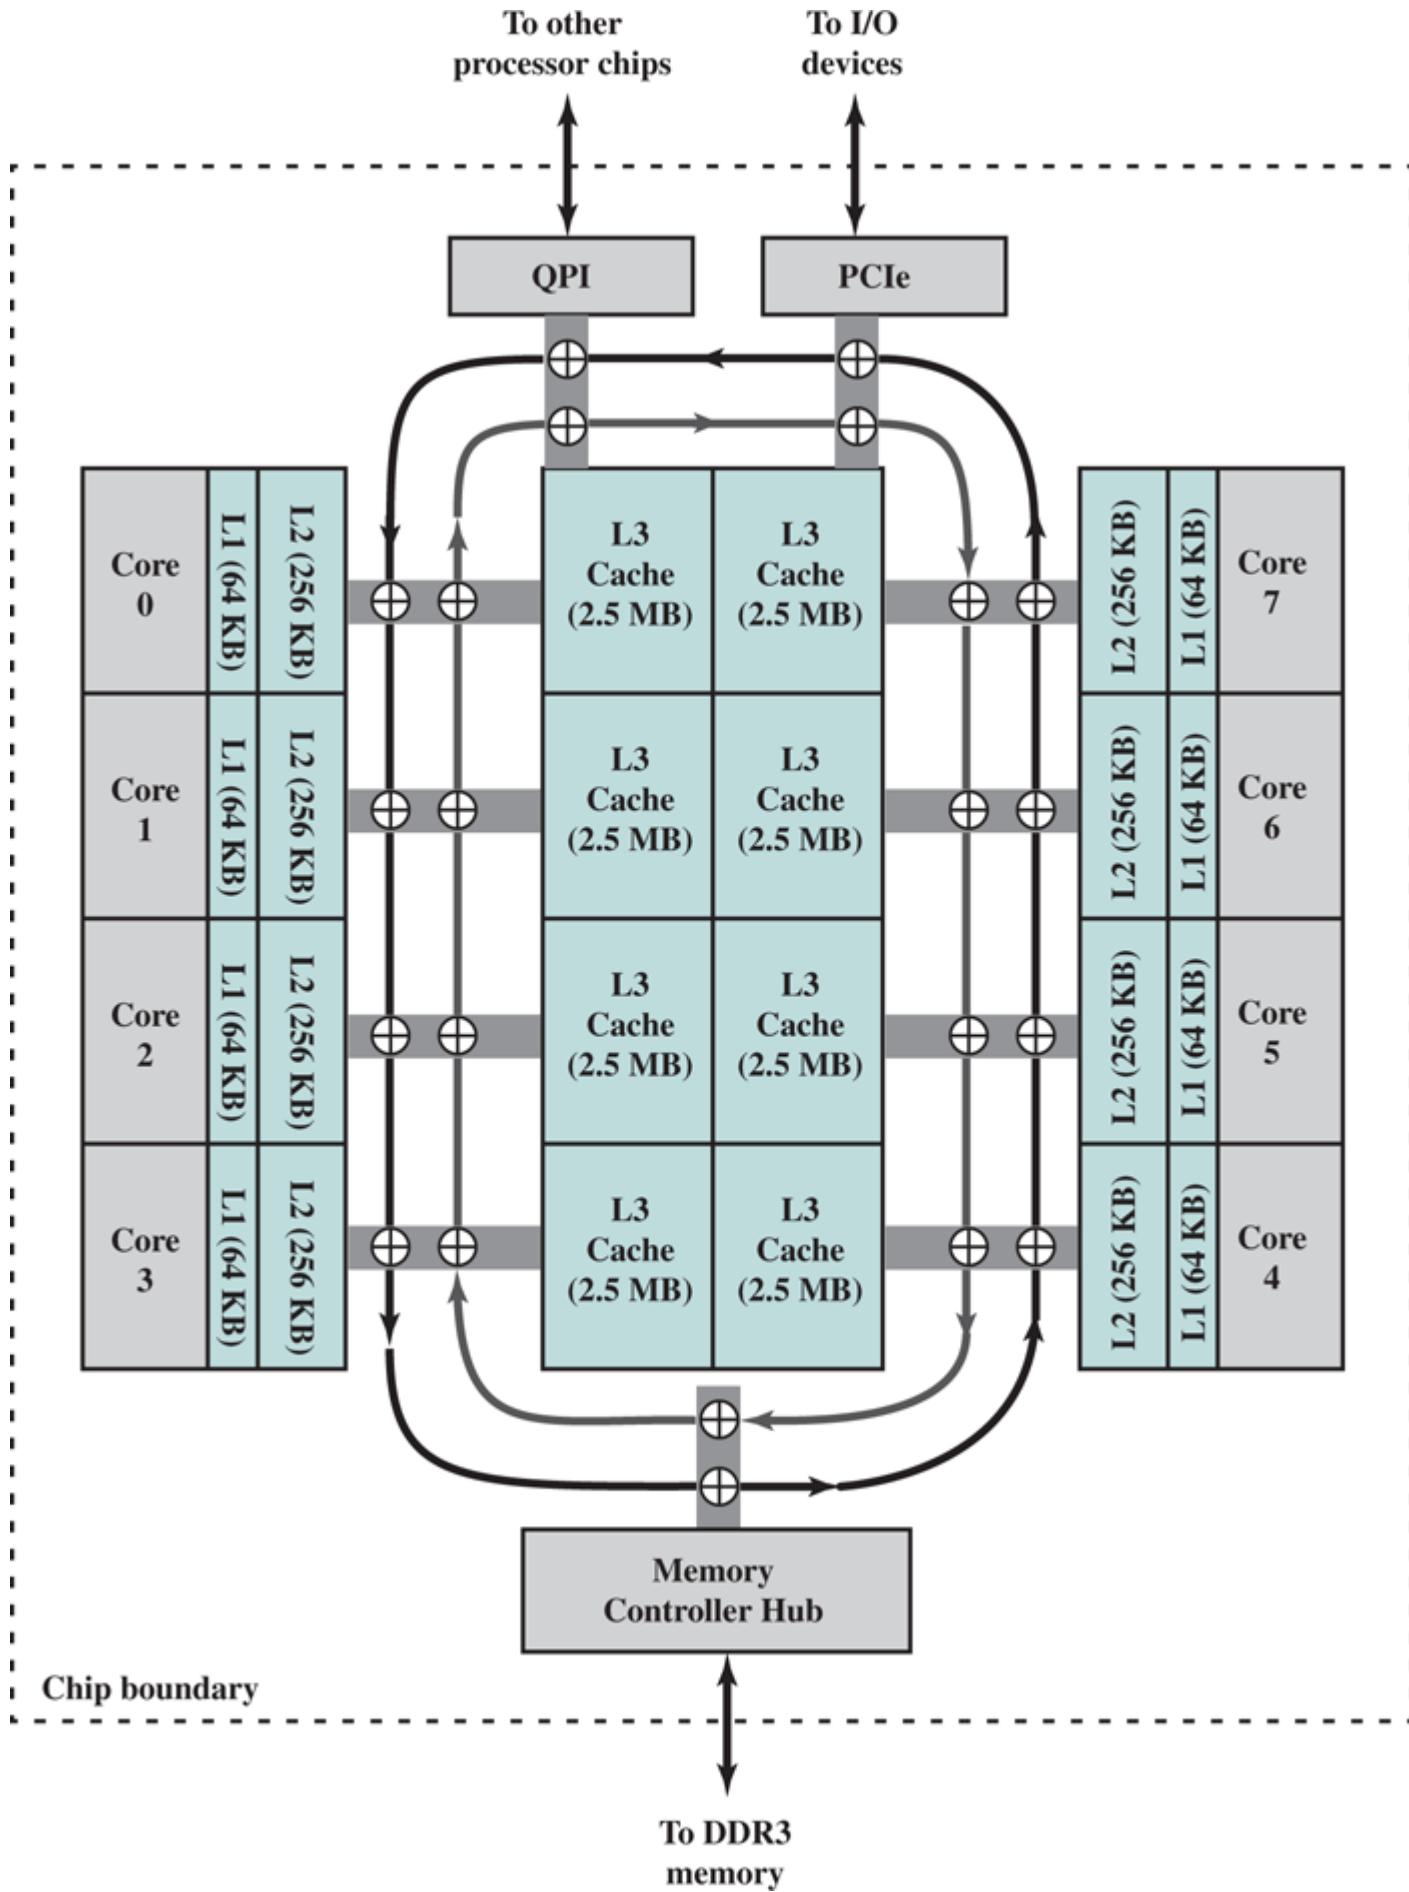

Figure 8.16 Xeon E5-2600/4600 Chip Architecture

The E5-2600/4600 can be configured with up to eight cores on a single chip. Each core has dedicated L1 and L2 caches. There is a shared L3 cache of up to 20 MB. The L3 cache is divided into slices,

one associated with each core although each core can address the entire cache. Further, each slice has its own cache pipeline, so that requests can be sent in parallel to the slices.

The bidirectional high-speed ring interconnect links cores, last-level cache, PCIe, and integrated memory controller (IMC).

In essence, the ring operates as follows:

1. Each component that attaches to the bidirectional ring (QPI, PCIe, L3 cache, L2 cache) is considered a ring agent, and implements ring agent logic.
2. The ring agents cooperate via a distributed protocol to request and allocate access to the ring, in the form of time slots.
3. When an agent has data to send, it chooses the ring direction that results in the shortest path to the destination and transmits when a scheduling slot is available.

The ring architecture provides good performance and scales well for multiple cores, up to a point. For systems with a greater number of cores, multiple rings are used, with each ring supporting some of the cores.

DMA USE OF THE CACHE

In traditional DMA operation, data are exchanged between main memory and an I/O device by means of the system interconnection structure, such as a bus, ring, or QPI point-to-point matrix. So, for example, if the Xeon E5-2600/4600 used a traditional DMA technique, output would proceed as follows. An I/O driver running on a core would send an I/O command to the I/O controller (labeled PCIe in [Figure 8.16](#)) with the location and size of the buffer in main memory containing the data to be transferred. The I/O controller issues a read request that is routed to the memory controller hub (MCH), which accesses the data on DDR3 memory and puts it on the system ring for delivery to the I/O controller. The L3 cache is not involved in this transaction and one or more off-chip memory reads are required. Similarly, for input, data arrive from the I/O controller and is delivered over the system ring to the MCH and written out to main memory. The MCH must also invalidate any L3 cache lines corresponding to the updated memory locations. In this case, one or more off-chip memory writes are required. Further, if an application wants to access the new data, a main memory read is required.

With the availability of large amounts of last-level cache, a more efficient technique is possible, and is used by the Xeon E5-2600/4600. For output, when the I/O controller issues a read request, the MCH first checks to see if the data are in the L3 cache. This is likely to be the case, if an application has recently written data into the memory block to be output. In that case, the MCH directs data from the L3 cache to the I/O controller; no main memory accesses are needed. However, it also causes the data to be evicted from cache, that is, the act of reading by an I/O device causes data to be evicted. Thus, the I/O operation proceeds efficiently because it does not require main memory access. But, if an application does need that data in the future, it must be read back into the L3 cache from main memory. The input operation on the Xeon E5-2600/4600 operates as described in the previous paragraph; the L3 cache is not involved. Thus, the performance improvement involves only output operations.

A final point. Although the output transfer is directly from cache to the I/O controller, the term *direct cache access* is not used for this feature. Rather, that term is reserved for the I/O protocol application, as described in the remainder of this section.

Cache-Related Performance Issues

Network traffic is transmitted in the form of a sequence of protocol blocks, called packets or protocol data units. The lowest, or link, level protocol is typically Ethernet, so that each arriving and departing block of data consists of an Ethernet packet containing as payload the higher-level protocol packet. The higher-level protocols are usually the Internet Protocol (IP), operating on top of Ethernet, and the Transmission Control Protocol (TCP), operating on top of IP. Accordingly, the Ethernet payload consists of a block of data with a TCP header and an IP header. For outgoing data, Ethernet packets are formed in a peripheral component, such as an I/O controller or network interface controller (NIC). Similarly, for incoming traffic, the I/O controller strips off the Ethernet information and delivers the TCP/IP packet to the host CPU.

For both outgoing and incoming traffic, the core, main memory, and cache are all involved. In a DMA scheme, when an application wishes to transmit data, it places that data in an application-assigned buffer in main memory. The core transfers this to a system buffer in main memory and creates the necessary TCP and IP headers, which are also buffered in system memory. The packet is then picked up via DMA for transfer via the NIC. This activity engages not only main memory but also the cache. For incoming traffic, similar transfers between system and application buffers are required.

When large volumes of protocol traffic are processed, two factors in this scenario degrade performance. First, the core consumes valuable clock cycles in copying data between system and application buffers. Second, because memory speeds have not kept up with CPU speeds, the core loses time waiting on memory reads and writes. In this traditional way of processing protocol traffic, the cache does not help because the data and protocol headers are constantly changing and thus the cache must constantly be updated.

To clarify the performance issue and to explain the benefit of DCA as a way of improving performance, let us look at the processing of protocol traffic in more detail for incoming traffic. In general terms, the following steps occur:

1. **Packet arrives:** The NIC receives an incoming Ethernet packet. The NIC processes and strips off the Ethernet control information. This includes doing an error detection calculation. The remaining TCP/IP packet is then transferred to the system's DMA module, which generally is part of the NIC. The NIC also creates a packet descriptor with information about the packet, such as its buffer location in memory.
2. **DMA:** The DMA module transfers data, including the packet descriptor, to main memory. It must also invalidate the corresponding cache lines, if any.
3. **NIC interrupts host:** After a number of packets have been transferred, the NIC issues an interrupt to the host processor.
4. **Retrieve descriptors and headers:** The core processes the interrupt, invoking an interrupt handling procedure, which reads the descriptor and header of the received packets.
5. **Cache miss occurs:** Because this is new data coming in, the cache lines corresponding to the system buffer containing the new data are invalidated. Thus, the core must stall to read the data from main memory into cache, and then to core registers.
6. **Header is processed:** The protocol software executes on the core to analyze the contents of the TCP and IP headers. This will likely include accessing a transport control block (TCB), which contains context information related to TCP. The TCB access may or may not trigger a cache miss, necessitating a main memory access.
7. **Payload transferred:** The data portion of the packet is transferred from the system buffer to the appropriate application buffer.

A similar sequence of steps occurs for outgoing packet traffic, but there are some differences that affect how the cache is managed. For outgoing traffic, the following steps occur:

1. **Packet transfer requested:** When an application has a block of data to transfer to a remote

- system, it places the data in an application buffer and alerts the OS with some type of system call.
2. **Packet created:** The OS invokes a TCP/IP process to create the TCP/IP packet for transmission. The TCP/IP process accesses the TCB (which may involve a cache miss) and creates the appropriate headers. It also reads the data from the application buffer, and then places the completed packet (headers plus data) in a system buffer. Note that the data that is written into the system buffer also exists in the cache. The TCP/IP process also creates a packet descriptor that is placed in memory shared with the DMA module.
 3. **Output operation invoked:** This uses a device driver program to signal the DMA module that output is ready for the NIC.
 4. **DMA transfer:** The DMA module reads the packet descriptor, then a DMA transfer is performed from main memory or the last-level cache to the NIC. Note that DMA transfers invalidate the cache line in cache even in the case of a read (by the DMA module). If the line is modified, this causes a write back. The core does not do the invalidates. The invalidates happen when the DMA module reads the data.
 5. **NIC signals completion:** After the transfer is complete, the NIC signals the driver on the core that originated the send signal.
 6. **Driver frees buffer:** Once the driver receives the completion notice, it frees up the buffer space for reuse. The core must also invalidate the cache lines containing the buffer data.

As can be seen, network I/O involves a number of accesses to cache and main memory and the movement of data between an application buffer and a system buffer. The heavy involvement of main memory becomes a bottleneck, as both core and network performance outstrip gains in memory access times.

Direct Cache Access Strategies

Several strategies have been proposed for making more efficient use of caches for network I/O, with the general term *direct cache access* applied to all of these strategies.

The simplest strategy is one that was implemented as a prototype on a number of Intel Xeon processors between 2006 and 2010 [KUMA07, INTE08]. This form of DCA applies only to incoming network traffic. The DCA function in the memory controller sends a prefetch hint to the core as soon as the data are available in system memory. This enables the core to prefetch the data packet from the system buffer, thus avoiding cache misses and the associated waste of core cycles.

While this simple form of DCA does provide some improvement, much more substantial gains can be realized by avoiding the system buffer in main memory altogether. For the specific function of protocol processing, note that the packet and packet descriptor information are accessed only once in the system buffer by the core. For incoming packets, the core reads the data from the buffer and transfers the packet payload to an application buffer. It has no need to access that data in the system buffer again. Similarly, for outgoing packets, once the core has placed the data in the system buffer, it has no need to access that data again. Suppose, therefore, that the I/O system were equipped not only with the capability of directly accessing main memory, but also of accessing the cache, both for input and output operations. Then it would be possible to use the last-level cache instead of the main memory to buffer packets and descriptors of incoming and outgoing packets.

This last approach, which is a true DCA, was proposed in [HUGG05]. It has also been described as **cache injection** [LEON06]. A version of this more complete form of DCA is implemented in Intel's Xeon processor line, referred to as **Direct Data I/O** [INTE12].

Direct Data I/O

Intel Direct Data I/O (DDIO) is implemented on all of the Xeon E5 family of processors. Its operation is best explained with a side-by-side comparison of transfers with and without DDIO.

PACKET INPUT

First, we look at the case of a packet arriving at the NIC from the network. **Figure 8.17a** shows the steps involved for a DMA operation. The NIC initiates a memory write (1). Then the NIC invalidates the cache lines corresponding to the system buffer (2). Next, the DMA operation is performed, depositing the packet directly into main memory (3). Finally, after the appropriate core receives a DMA interrupt signal, the core can read the packet data from memory through the cache (4).

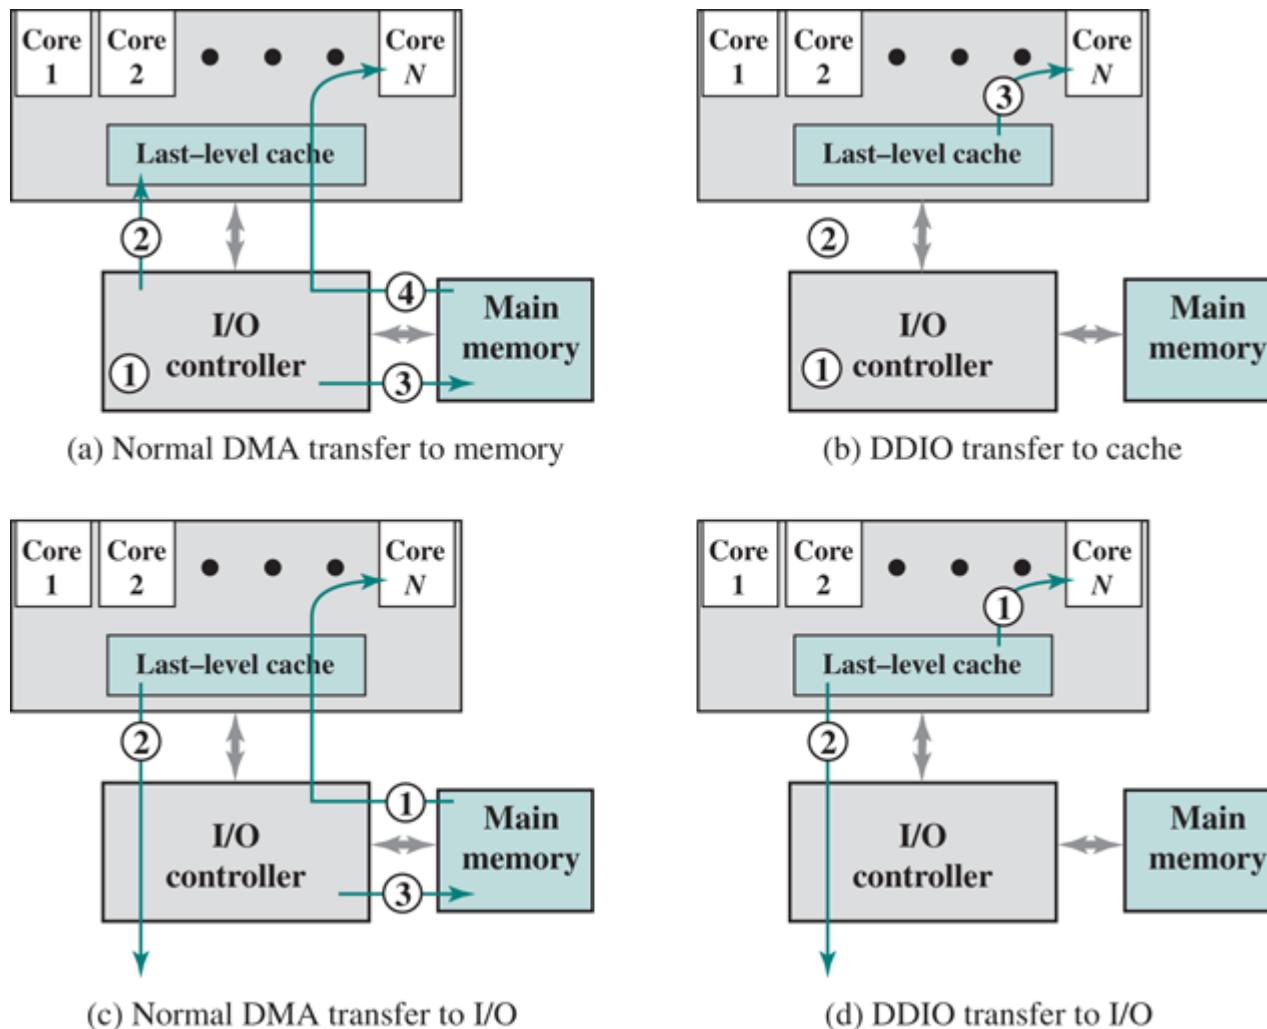

Figure 8.17 Comparison of DMA and DDIO

Before discussing the processing of an incoming packet using DDIO, we need to summarize the discussion of cache write policy from [Chapter 5](#), and introduce a new technique. For the following discussion, there are issues relating to cache coherency that arise in a multiprocessor or multicore environment. These details are discussed in [Chapter 19](#), but the details need not concern us here. Recall that there are two techniques for dealing with an update to a cache line:

- **Write through:** All write operations are made to main memory as well as to the cache, ensuring that main memory is always valid. Any other core–cache module can monitor traffic to main memory to maintain consistency within its own local cache.
- **Write back:** Updates are made only in the cache. When an update occurs, a dirty bit associated with the line is set. Then, when a block is replaced, it is written back to main memory if and only if the dirty bit is set.

DDIO uses the write-back strategy in the L3 cache.

A cache write operation may encounter a cache miss, which is dealt with by one of two strategies:

- **Write allocate:** The required line is loaded into the cache from main memory. Then, the line in the cache is updated by the write operation. This scheme is typically used with the write-back method.
- **Non-write allocate:** The block is modified directly in main memory. No change is made to the cache. This scheme is typically used with the write-through method.

With the above in mind, we can describe the DDIO strategy for inbound transfers initiated by the NIC.

1. If there is a cache hit, the cache line is updated, but not main memory; this is simply the write-back strategy for a cache hit. The Intel literature refers to this as **write update**.
2. If there is a cache miss, the write operation occurs to a line in the cache that will not be written back to main memory. Subsequent writes update the cache line, again with no reference to main memory or no future action that writes this data to main memory. The Intel documentation [INTE12] refers to this as *write allocate*, which unfortunately is not the same meaning for the term in the general cache literature.

The DDIO strategy is effective for a network protocol application because the incoming data need not be retained for future use. The protocol application is going to write the data to an application buffer, and there is no need to temporarily store it in a system buffer.

Figure 8.17b shows the operation for DDIO input. The NIC initiates a memory write (1). Then the NIC invalidates the cache lines corresponding to the system buffer and deposits the incoming data in the cache (2). Finally, after the appropriate core receives a DCA interrupt signal, the core can read the packet data from the cache (3).

PACKET OUTPUT

Figure 8.17c shows the steps involved for a DMA operation for outbound packet transmission. The TCP/IP protocol handler executing on the core reads data in from an application buffer and writes it out to a system buffer. These data access operations result in cache misses and cause data to be read from memory and into the L3 cache (1). When the NIC receives notification for starting a transmit operation, it reads the data from the L3 cache and transmits it (2). The cache access by the NIC causes the data to be evicted from the cache and written back to main memory (3).

Figure 8.17d shows the steps involved for a DDIO operation for packet transmission. The TCP/IP protocol handler creates the packet to be transmitted and stores it in allocated space in the L3 cache (1), but not in main memory (2). The read operation initiated by the NIC is satisfied by data from the cache, without causing evictions to main memory.

It should be clear from these side-by-side comparisons that DDIO is more efficient than DMA for both incoming and outgoing packets, and is therefore better able to keep up with a high packet traffic rate.

8.7 I/O Channels and Processors

The Evolution of the I/O Function

As computer systems have evolved, there has been a pattern of increasing complexity and sophistication of individual components. Nowhere is this more evident than in the I/O function. We have already seen part of that evolution. The evolutionary steps can be summarized as follows:

1. The CPU directly controls a peripheral device. This is seen in simple microprocessor-controlled devices.
2. A controller or I/O module is added. The CPU uses programmed I/O without interrupts. With this step, the CPU becomes somewhat divorced from the specific details of external device interfaces.
3. The same configuration as in step 2 is used, but now interrupts are employed. The CPU need not spend time waiting for an I/O operation to be performed, thus increasing efficiency.
4. The I/O module is given direct access to memory via DMA. It can now move a block of data to or from memory without involving the CPU, except at the beginning and end of the transfer.
5. The I/O module is enhanced to become a processor in its own right, with a specialized instruction set tailored for I/O. The CPU directs the I/O processor to execute an I/O program in memory. The I/O processor fetches and executes these instructions without CPU intervention. This allows the CPU to specify a sequence of I/O activities and to be interrupted only when the entire sequence has been performed.
6. The I/O module has a local memory of its own and is, in fact, a computer in its own right. With this architecture, a large set of I/O devices can be controlled, with minimal CPU involvement. A common use for such an architecture has been to control communication with interactive terminals. The I/O processor takes care of most of the tasks involved in controlling the terminals.

As one proceeds along this evolutionary path, more and more of the I/O function is performed without CPU involvement. The CPU is increasingly relieved of I/O-related tasks, improving performance. With the last two steps (5–6), a major change occurs with the introduction of the concept of an I/O module capable of executing a program. For step 5, the I/O module is often referred to as an *I/O channel*. For step 6, the term *I/O processor* is often used. However, both terms are on occasion applied to both situations. In what follows, we will use the term *I/O channel*.

Characteristics of I/O Channels

The I/O channel represents an extension of the DMA concept. An I/O channel has the ability to execute I/O instructions, which gives it complete control over I/O operations. In a computer system with such devices, the CPU does not execute I/O instructions. Such instructions are stored in main memory to be executed by a special-purpose processor in the I/O channel itself. Thus, the CPU initiates an I/O transfer by instructing the I/O channel to execute a program in memory. The program will specify the device or devices, the area or areas of memory for storage, priority, and actions to be taken for certain error conditions. The I/O channel follows these instructions and controls the data transfer.

Two types of I/O channels are common, as illustrated in [Figure 8.18](#). A *selector channel* controls multiple high-speed devices and, at any one time, is dedicated to the transfer of data with one of those devices. Thus, the I/O channel selects one device and effects the data transfer. Each device, or a small set of devices, is handled by a *controller*, or I/O module, that is much like the I/O modules we

have been discussing. Thus, the I/O channel serves in place of the CPU in controlling these I/O controllers. A *multiplexor channel* can handle I/O with multiple devices at the same time. For low-speed devices, a *byte multiplexor* accepts or transmits characters as fast as possible to multiple devices. For example, the resultant character stream from three devices with different rates and individual streams $A_1A_2A_3A_4 \dots , B_1B_2B_3B_4 \dots , \text{ and } C_1C_2C_3C_4 \dots$ might be $A_1B_1C_1A_2C_2A_3B_2C_3A_4$, and so on. For high-speed devices, a *block multiplexor* interleaves blocks of data from several devices.

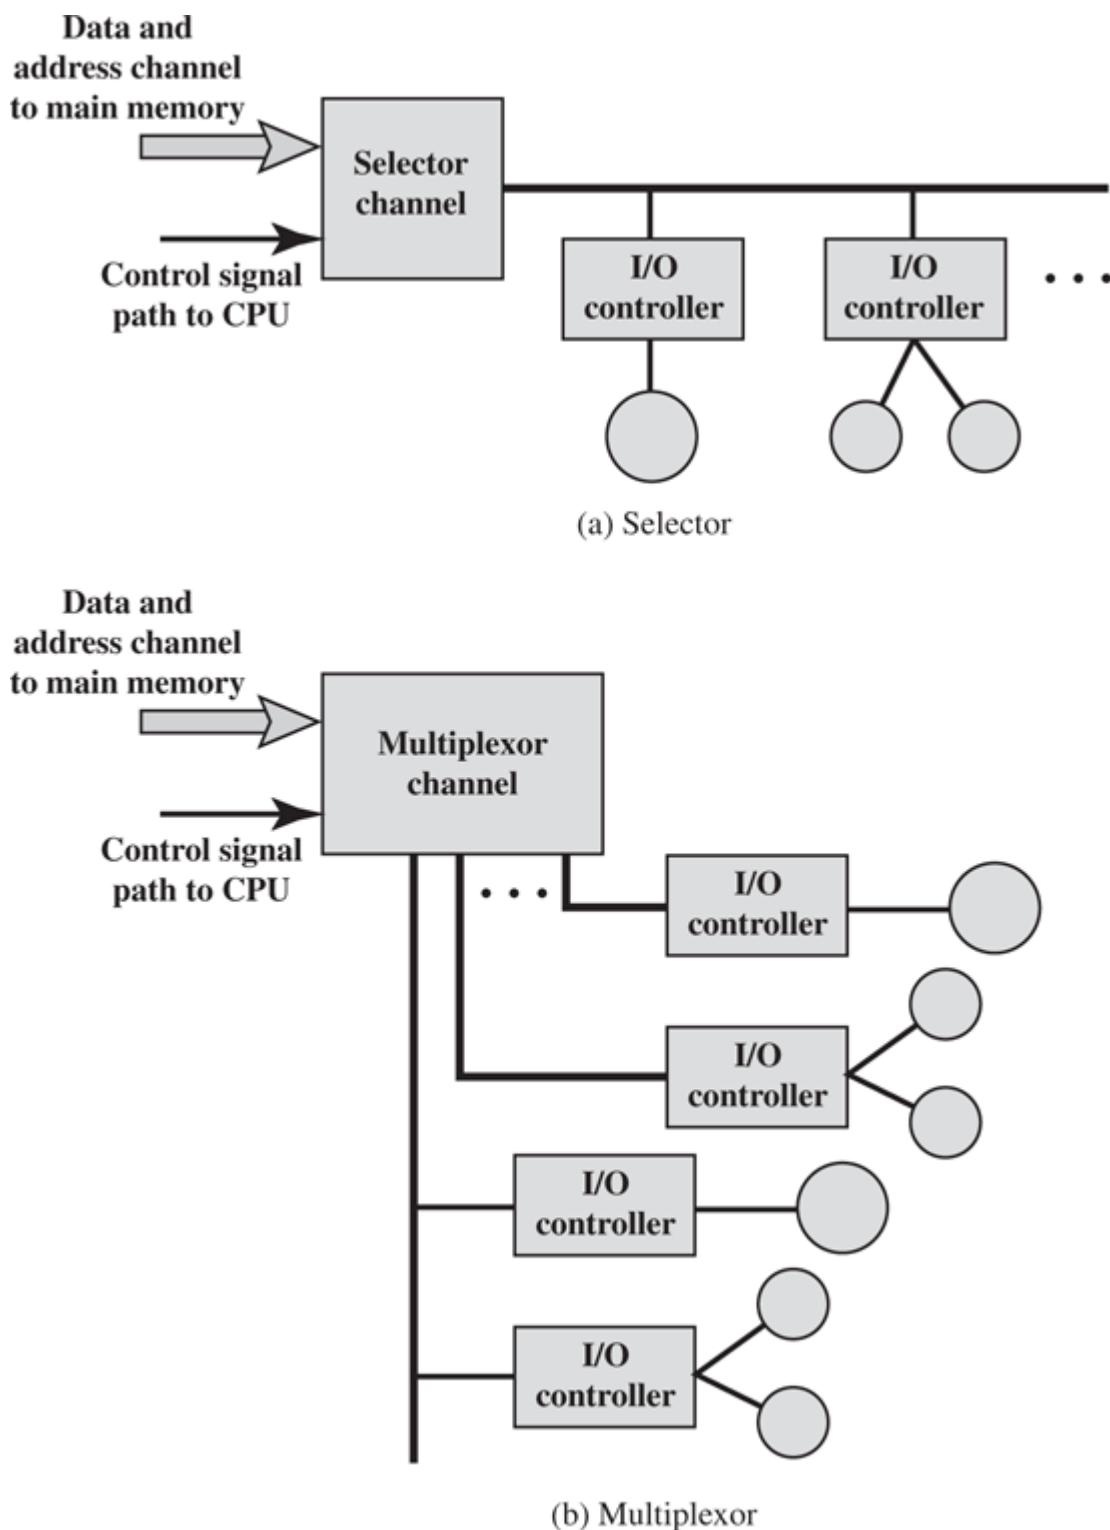

Figure 8.18 I/O Channel Architecture

8.8 External Interconnection Standards

In this section, we provide a brief overview of the most widely used external interface standards to support I/O.

Universal Serial Bus (USB)

USB is widely used for peripheral connections. It is the default interface for slower- speed devices, such as keyboard and pointing devices, but is also commonly used for high-speed I/O, including printers, disk drives, and network adapters.

USB has gone through multiple generations. The first version, USB 1.0, defined a *Low Speed* data rate of 1.5 Mbps and a *Full Speed* rate of 12 Mbps. USB 2.0 provides a data rate of 480 Mbps. USB 3.0 includes a new, higher speed bus called *SuperSpeed* in parallel with the USB 2.0 bus. The signaling speed of SuperSpeed is 5 Gbps, but due to signaling overhead, the usable data rate is up to 4 Gbps. The most recent specification is USB 3.1, which includes a faster transfer mode called *SuperSpeed+*. This transfer mode achieves a signaling rate of 10 Gbps and a theoretical usable data rate of 9.7 Gbps.

A USB system is controlled by a root host controller, which attaches to devices to create a local network with a hierarchical tree topology.

FireWire Serial Bus

FireWire was developed as an alternative to the small computer system interface (SCSI) to be used on smaller systems, such as personal computers, workstations, and servers. The objective was to meet the increasing demands for high I/O rates on these systems, while avoiding the bulky and expensive I/O channel technologies developed for mainframe and supercomputer systems. The result is the IEEE standard 1394, for a High Performance Serial Bus, commonly known as FireWire.

FireWire uses a daisy-chain configuration, with up to 63 devices connected off a single port. Moreover, up to 1022 FireWire buses can be interconnected using bridges, enabling a system to support as many peripherals as required.

FireWire provides for what is known as hot plugging, which makes it possible to connect and disconnect peripherals without having to power the computer system down or reconfigure the system. Also, FireWire provides for automatic configuration; it is not necessary manually to set device IDs or to be concerned with the relative position of devices. With FireWire, there are no terminations, and the system automatically performs a configuration function to assign addresses. A FireWire bus need not be a strict daisy chain. Rather, a tree-structured configuration is possible.

An important feature of the FireWire standard is that it specifies a set of three layers of protocols to standardize the way in which the host system interacts with the peripheral devices over the serial bus. The physical layer defines the transmission media that are permissible under FireWire and the electrical and signaling characteristics of each. Data rates from 25 Mbps to 3.2 Gbps are defined. The link layer describes the transmission of data in the packets. The transaction layer defines a request-response protocol that hides the lower-layer details of FireWire from applications.

Small Computer System Interface (SCSI)

SCSI is a once common standard for connecting peripheral devices (disks, modems, printers, etc.) to small and medium-sized computers. Although SCSI has evolved to higher data rates, it has lost popularity to such competitors as USB and FireWire in smaller systems. However, high-speed versions of SCSI remain popular for mass memory support on enterprise systems. For example, the IBM zEnterprise EC12 and other IBM mainframes offer support for SCSI, and a number of Seagate hard drive systems use SCSI.

The physical organization of SCSI is a shared bus, which can support up to 16 or 32 devices, depending on the generation of the standard. The bus provides for parallel transmission rather than serial, with a bus width of 16 bits on earlier generations and 32 bits on later generations. Speeds range from 5 Mbps on the original SCSI-1 specification to 160 Mbps on SCSI-3 U3.

Thunderbolt

The most recent, and one of fastest, peripheral connection technology to become available for general-purpose use is Thunderbolt, developed by Intel with collaboration from Apple. One Thunderbolt cable can manage the work previously required of multiple cables. The technology combines data, video, audio, and power into a single high-speed connection for peripherals such as hard drives, RAID (Redundant Array of Independent Disks) arrays, video-capture boxes, and network interfaces. It provides up to 10 Gbps throughput in each direction and up to 10 watts of power to connected peripherals.

InfiniBand

InfiniBand is an I/O specification aimed at the high-end server market. The first version of the specification was released in early 2001 and has attracted numerous vendors. For example, IBM zEnterprise series of mainframes has relied heavily on InfiniBand for a number of years. The standard describes an architecture and specifications for data flow among processors and intelligent I/O devices. InfiniBand has become a popular interface for storage area networking and other large storage configurations. In essence, InfiniBand enables servers, remote storage, and other network devices to be attached in a central fabric of switches and links. The switch-based architecture can connect up to 64,000 servers, storage systems, and networking devices.

PCI Express

PCI Express is a high-speed bus system for connecting peripherals of a wide variety of types and speeds. [Chapter 3](#) discusses PCI Express in detail.

SATA

Serial ATA (Serial Advanced Technology Attachment) is an interface for disk storage systems. It provides data rates of up to 6 Gbps, with a maximum per device of 300 Mbps. SATA is widely used in desktop computers, and in industrial and embedded applications.

Ethernet

Ethernet is the predominant wired networking technology, used in homes, offices, data centers, enterprises, and wide-area networks. As Ethernet has evolved to support data rates up to 100 Gbps and distances from a few meters to tens of km, it has become essential for supporting personal computers, workstations, servers, and massive data storage devices in organizations large and small.

Ethernet began as an experimental bus-based 3-Mbps system. With a bus system, all of the attached devices, such as PCs, connect to a common coaxial cable, much like residential cable TV systems. The first commercially-available Ethernet, and the first version of IEEE 802.3, were bus-based systems operating at 10 Mbps. As technology has advanced, Ethernet has moved from bus-based to switch-based, and the data rate has periodically increased by an order of magnitude. With switch-based systems, there is a central switch, with all of the devices connected directly to the switch. Currently, Ethernet systems are available at speeds up to 100 Gbps. Here is a brief chronology.

- 1983: 10 Mbps (megabit per second, million bits per second)
- 1995: 100 Mbps
- 1998: 1 Gbps (gigabit per second, billion bits per second)
- 2003: 10 Gbps
- 2010: 40 Gbps and 100 Gbps

Wi-Fi

Wi-Fi is the predominant wireless Internet access technology, used in homes, offices, and public spaces. Wi-Fi in the home now connects computers, tablets, smart phones, and a host of electronic devices, such as video cameras, TVs, and thermostats. Wi-Fi in the enterprise has become an essential means of enhancing worker productivity and network effectiveness. And public Wi-Fi hotspots have expanded dramatically to provide free Internet access in most public places.

As the technology of antennas, wireless transmission techniques, and wireless protocol design has evolved, the IEEE 802.11 committee has been able to introduce standards for new versions of Wi-Fi at ever-higher speeds. Once the standard is issued, industry quickly develops the products. Here is a brief chronology, starting with the original standard, which was simply called IEEE 802.11, and showing the maximum data rate for each version:

- 802.11 (1997): 2 Mbps (megabit per second, million bits per second)
- 802.11a (1999): 54 Mbps
- 802.11b (1999): 11 Mbps
- 802.11n (1999): 600 Mbps
- 802.11g (2003): 54 Mbps
- 802.11ad (2012): 6.76 Gbps (billion bits per second)
- 802.11ac (2014): 3.2 Gbps

8.9 IBM z13 I/O Structure

The z13 is IBM's latest mainframe computer offering (at the time of this writing). The system is based on the use of a 5-GHz multicore chip with eight cores. The z13 architecture can have a maximum of 168 processor chips, or processor units (PU), for a total of 1344 cores, and it supports up to a total of 10 TB of real memory. In this section, we look at the I/O structure of the z13.

Channel Structure

The z13 has a dedicated I/O subsystem that manages all I/O operations, completely off-loading this processing and memory burden from the main processors. [Figure 8.19](#) shows the logical structure of the I/O subsystem. Of the 168 core processors, up to 24 of these can be dedicated for I/O use, creating 46 channel subsystems (CSS). Each CSS is made up of the following elements:

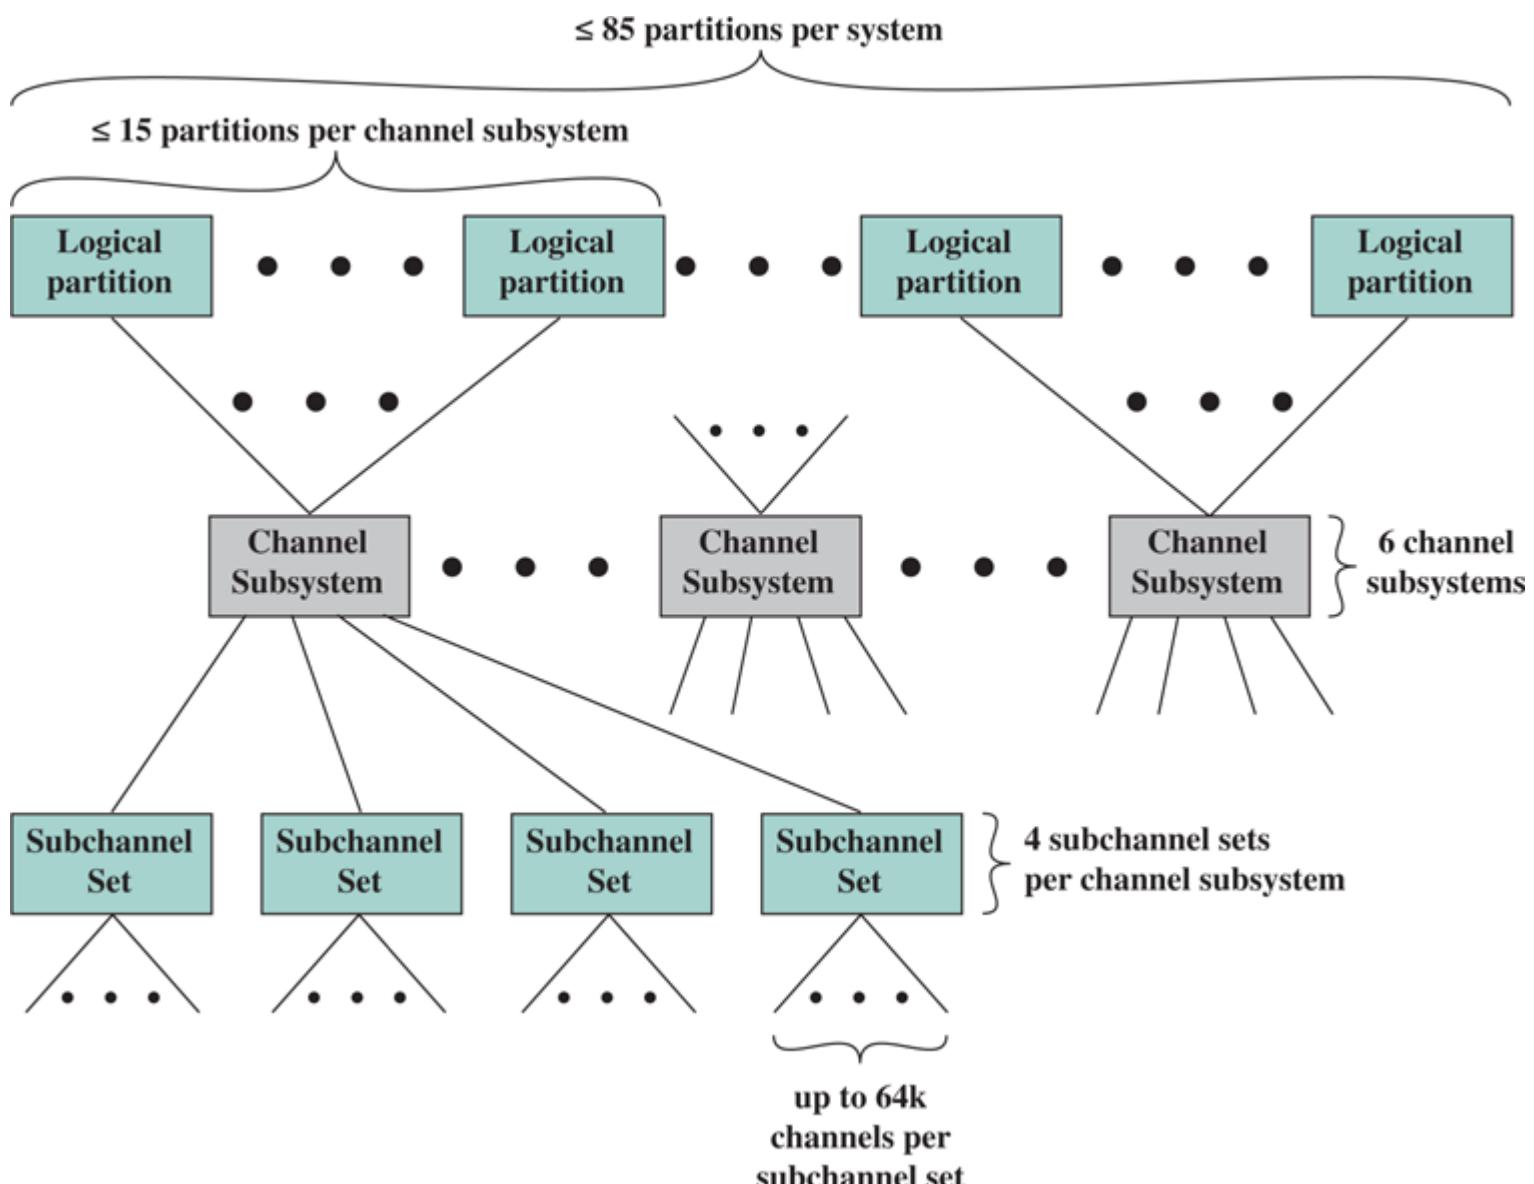

Figure 8.19 IBM z13 I/O Channel Structure

- **System assist processor (SAP):** The SAP is a core processor configured for I/O operation. Its role is to offload I/O operations and manage channels and the I/O operations queues. It relieves the other processors of all I/O tasks, allowing them to be dedicated to application logic.
- **Hardware system area (HSA):** The HSA is a reserved part of the system memory containing the

I/O configuration. It is used by SAPs. A fixed amount of 96 GB is reserved, which is not part of the customer-purchased memory. This provides for greater configuration flexibility and higher availability by eliminating planned and preplanned outages.

- **Logical partitions:** A logical partition is a form of virtual machine, which is in essence a logical processor defined at the operating system level.³ Each CSS supports up to 16 logical partitions.
³ A virtual machine is an instance of an operating system along with one or more applications running in an isolated memory partition within the computer. It enables different operating systems to run in the same computer at the same time, as well as prevents applications from interfering with each other. See [STAL18] for a discussion of virtual machines.
- **Subchannels:** A subchannel appears to a program as a logical device and contains the information required to perform an I/O operation. One subchannel exists for each I/O device addressable by the CSS. A subchannel is used by the channel subsystem code running on a partition to pass an I/O request to the channel subsystem. A subchannel is assigned for each device defined to the logical partition. Up to 196k subchannels are supported per CSS.
- **Subchannel set:** This is a collection of subchannels within a channel subsystem. The maximum number of subchannels of a subchannel set determines how many devices are accessible to a channel subsystem.
- **Channel path:** A channel path is a single interface between a channel subsystem and one or more control units, via a channel. Commands and data are sent across a channel path to perform I/O requests. Each CSS can have up to 256 channel paths.
- **Channel:** Channels are small processors that communicate with the I/O control units (CUs). They manage the data transfer between memory and the external devices.

This elaborate structure enables the mainframe to manage a massive number of I/O devices and communication links. All I/O processing is offloaded from the application and server processors, enhancing performance. The channel subsystem processors are somewhat general in configuration, enabling them to manage a wide variety of I/O duties and to keep up with evolving requirements. The channel processors are specifically programmed for the I/O control units to which they interface.

I/O System Organization

To explain the I/O system organization, we need to first briefly explain the physical layout of the z13. The system has the following characteristics:

- Weight: 2567 kg (5657 lbs)
- Width: 1.847 m (6.06 ft)
- Depth: 1.806 m (5.9 ft)
- Height: 2.154 m (7.1 ft)

Not exactly a laptop.

The system consists of two large bays called frames bolted together, that house the various components of the z13. The A frame houses four processor drawers interconnected via Ethernet, and one PCIe I/O drawer, which contains I/O hardware, including multiplexors and channels. The A frame also includes two support servers used by a system manager for platform management, battery backup, and a cooling unit (water or air).

The Z frame houses up to four I/O drawers, which can be a combination of PCIe drawers and customer-selected I/O drawers. The Z frame also includes battery backup and a keyboard/display tray, which contains the keyboards and the displays that are connected to the support servers.

With this background, we now show a typical configuration of the z13 I/O system structure ([Figure 8.20](#)). Each z13 processor drawer supports two types of internal (i.e., internal to the A and Z frames) I/O infrastructures: PCI Express (PCIe) and Infiniband. Each processor drawer includes a card containing the channel controller which provides connectivity to the I/O drawers. These channel controllers are referred to as **fanouts**.

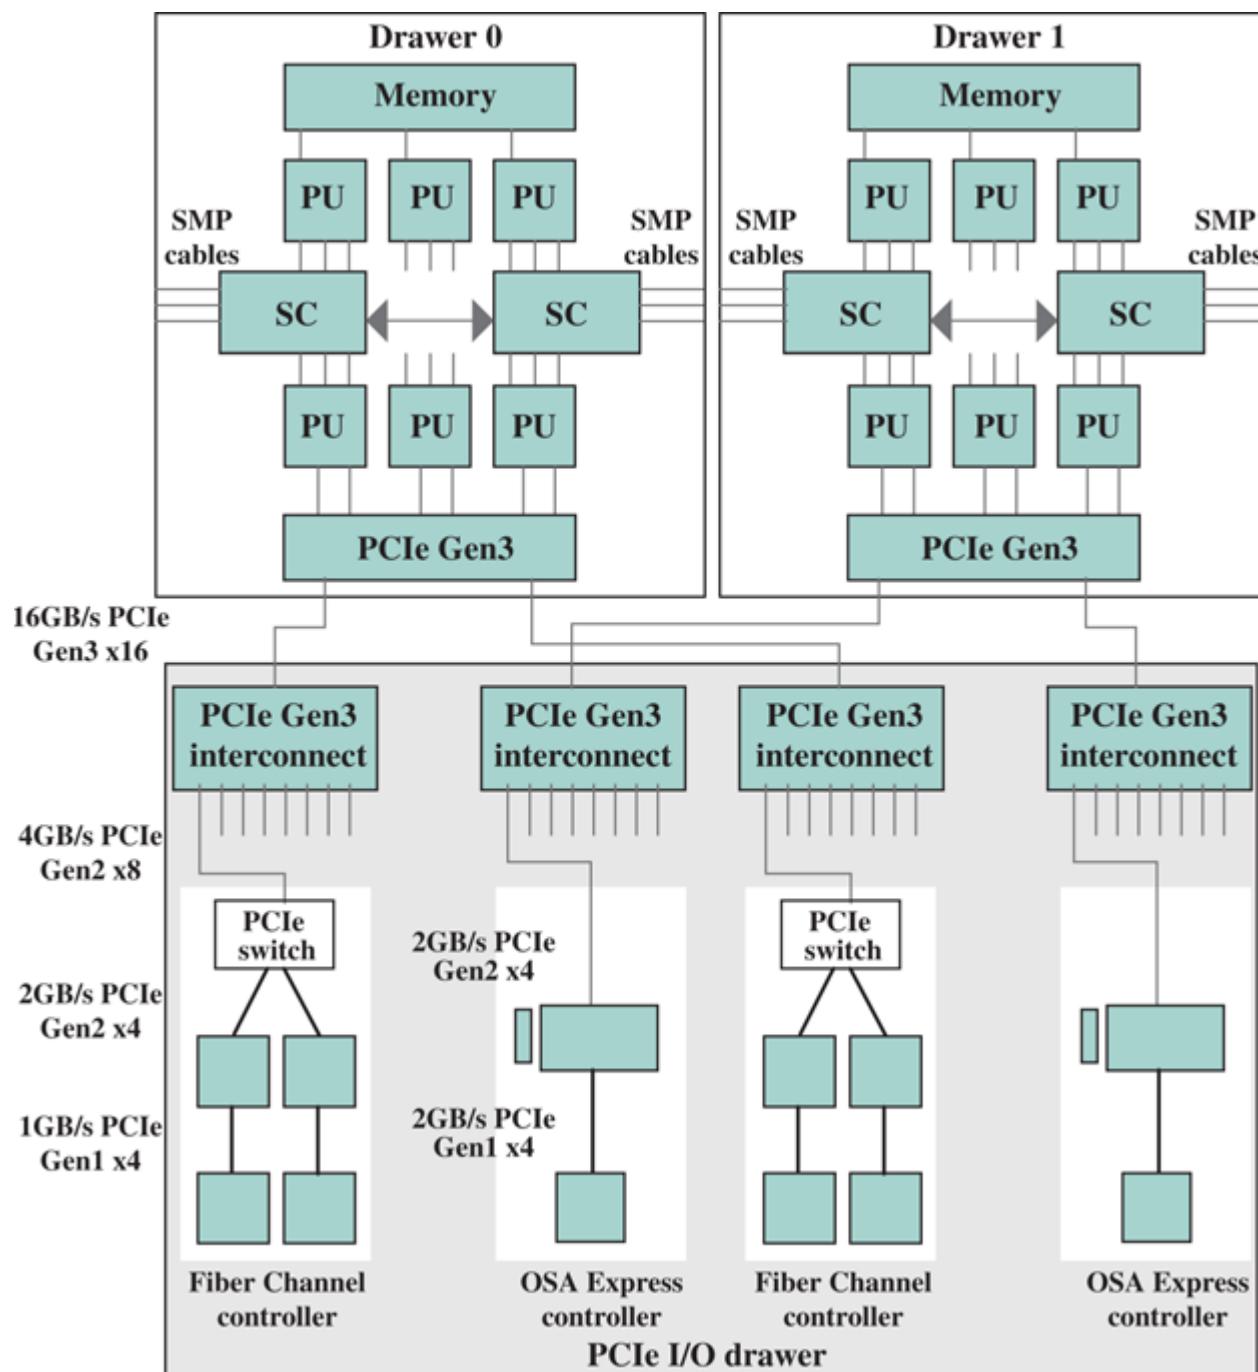

Figure 8.20 IBM z13 I/O System Structure

The InfiniBand connections from the processor book to the I/O drawers are via a Host Channel Adapter (HCA) fanout, which has InfiniBand links to InfiniBand multiplexors in the I/O drawer. The InfiniBand multiplexors are used to interconnect servers, communications infrastructure equipment, storage, and embedded systems. In addition to using InfiniBand to interconnect systems, all of which use InfiniBand, the InfiniBand multiplexor supports other I/O technologies, such as Ethernet. Ethernet connections provide 1-Gbps and 10-Gbps connections to a variety of devices that support this popular local area network technology. One noteworthy use of Ethernet is to construct large server farms, particularly to interconnect blade servers with each other and with other mainframes.⁴

⁴ A blade server is a server architecture that houses multiple server modules (blades) in a single chassis. It is widely used in data centers to save space and improve system management. Either self-standing or rack mounted, the chassis provides the power supply, and each blade has its own CPU, memory, and hard disk.

The PCIe connections from the processor book to the I/O drawers are via a PCIe fanout to PCIe switches. The PCIe switches can connect to a number of I/O device controllers. Typical examples for z13 are 1-Gbps and 10-Gbps Ethernet, Fiber Channel, and (OSA) Express Controller. OSA is an I/O adapter technology that provides streamlined, high-speed transfer between system memory and a high-speed network interface, such as Ethernet.

Review Questions

- 8.1 List three broad classifications of external, or peripheral, devices.
- 8.2 What is the International Reference Alphabet?
- 8.3 What are the major functions of an I/O module?
- 8.4 List and briefly define three techniques for performing I/O.
- 8.5 What is the difference between memory-mapped I/O and isolated I/O?
- 8.6 When a device interrupt occurs, how does the processor determine which device issued the interrupt?
- 8.7 When a DMA module takes control of a bus, and while it retains control of the bus, what does the processor do?

Problems

- 8.1 On a typical microprocessor, a distinct I/O address is used to refer to the I/O data registers and a distinct address for the control and status registers in an I/O controller for a given device. Such registers are referred to as **ports**. In the Intel 8088, two I/O instruction formats are used. In one format, the 8-bit opcode specifies an I/O operation; this is followed by an 8-bit port address. Other I/O opcodes imply that the port address is in the 16-bit DX register. How many ports can the 8088 address in each I/O addressing mode?
- 8.2 A similar instruction format is used in the Zilog Z8000 microprocessor family. In this case, there is a direct port addressing capability, in which a 16-bit port address is part of the instruction, and an indirect port addressing capability, in which the instruction references one of the 16-bit general purpose registers, which contains the port address. How many ports can the Z8000 address in each I/O addressing mode?
- 8.3 The Z8000 also includes a block I/O transfer capability that, unlike DMA, is under the direct control of the processor. The block transfer instructions specify a port address register (Rp), a count register (Rc), and a destination register (Rd). Rd contains the main memory address at which the first byte read from the input port is to be stored. Rc is any of the 16-bit general purpose registers. How large a data block can be transferred?
- 8.4 Consider a microprocessor that has a block I/O transfer instruction such as that found on the Z8000. Following its first execution, such an instruction takes five clock cycles to re-execute. However, if we employ a nonblocking I/O instruction, it takes a total of 20 clock cycles for fetching and execution. Calculate the increase in speed with the block I/O instruction when transferring blocks of 128 bytes.
- 8.5 A system is based on an 8-bit microprocessor and has two I/O devices. The I/O controllers for this system use separate control and status registers. Both devices handle data on a 1-byte-at-a-time basis. The first device has two status lines and three control lines. The second device has three status lines and four control lines.
 - a. How many 8-bit I/O control module registers do we need for status reading and control of each device?
 - b. What is the total number of needed control module registers given that the first device is an output-only device?
 - c. How many distinct addresses are needed to control the two devices?
- 8.6 For programmed I/O, **Figure 8.5** indicates that the processor is stuck in a wait loop doing status checking of an I/O device. To increase efficiency, the I/O software could be written so that the processor periodically checks the status of the device. If the device is not ready, the processor can jump to other tasks. After some timed interval, the processor comes back to check status again.
 - a. Consider the above scheme for outputting data one character at a time to a printer that operates at 10 characters per second (cps). What will happen if its status is scanned every 200 ms?

- b. Next consider a keyboard with a single character buffer. On average, characters are entered at a rate of 10 cps. However, the time interval between two consecutive key depressions can be as short as 60 ms. At what frequency should the keyboard be scanned by the I/O program?

8.7 A microprocessor scans the status of an output I/O device every 20 ms. This is accomplished by means of a timer alerting the processor every 20 ms. The interface of the device includes two ports: one for status and one for data output. How long does it take to scan and service the device, given a clocking rate of 8 MHz? Assume for simplicity that all pertinent instruction cycles take 12 clock cycles.

8.8 In [Section 8.3](#), one advantage and one disadvantage of memory-mapped I/O, compared with isolated I/O, were listed. List two more advantages and two more disadvantages.

8.9 A particular system is controlled by an operator through commands entered from a keyboard. The average number of commands entered in an 8-hour interval is 60.

- Suppose the processor scans the keyboard every 100 ms. How many times will the keyboard be checked in an 8-hour period?
- By what fraction would the number of processor visits to the keyboard be reduced if interrupt-driven I/O were used?

8.10 Suppose that the 8255A shown in [Figure 8.9](#) is configured as follows: port A as input, port B as output, and all the bits of port C as output. Show the bits of the control register to define this configuration.

8.11 Consider a system employing interrupt-driven I/O for a particular device that transfers data at an average of 8 KB/s on a continuous basis.

- Assume that interrupt processing takes about $100\mu s$ (i.e., the time to jump to the interrupt service routine (ISR), execute it, and return to the main program). Determine what fraction of processor time is consumed by this I/O device if it interrupts for every byte.
- Now assume that the device has two 16-byte buffers and interrupts the processor when one of the buffers is full. Naturally, interrupt processing takes longer, because the ISR must transfer 16 bytes. While executing the ISR, the processor takes about $8\mu s$ for the transfer of each byte. Determine what fraction of processor time is consumed by this I/O device in this case.
- Now assume that the processor is equipped with a block transfer I/O instruction such as that found on the Z8000. This permits the associated ISR to transfer each byte of a block in only $2\mu s$. Determine what fraction of processor time is consumed by this I/O device in this case.

8.12 In virtually all systems that include DMA modules, DMA to main memory is given higher priority than CPU access to main memory. Why?

8.13 A DMA module is transferring characters to memory using [cycle stealing](#), from a device transmitting at 9600 bps. The processor is fetching instructions at the rate of 1 million instructions per second (1 MIPS). By how much will the processor be slowed down due to the DMA activity?

8.14 Consider a system in which bus cycles takes 500 ns. Transfer of bus control in either direction, from processor to I/O device or vice versa, takes 250 ns. One of the I/O devices has a data transfer rate of 50 KB/s and employs DMA. Data are transferred 1 byte at a time.

- Suppose we employ DMA in a burst mode. That is, the DMA interface gains bus mastership prior to the start of a block transfer and maintains control of the bus until the whole block is transferred. For how long would the device tie up the bus when transferring a block of 128 bytes?
- Repeat the calculation for cycle-stealing mode.

8.15 Examination of the timing diagram of the 8237A indicates that once a block transfer begins, it takes three bus clock cycles per DMA cycle. During the DMA cycle, the 8237A transfers one byte of information between memory and I/O device.

- a. Suppose we clock the 8237A at a rate of 5 MHz. How long does it take to transfer one byte?
- b. What would be the maximum attainable data transfer rate?
- c. Assume that the memory is not fast enough and we have to insert two wait states per DMA cycle. What will be the actual data transfer rate?

8.16 Assume that in the system of the preceding problem, a memory cycle takes 750 ns. To what value could we reduce the clocking rate of the bus without effect on the attainable data transfer rate?

8.17 A DMA controller serves four receive-only telecommunication links (one per DMA channel) having a speed of 64 Kbps each.

- a. Would you operate the controller in burst mode or in cycle-stealing mode?
- b. What priority scheme would you employ for service of the DMA channels?

8.18 A 32-bit computer has two selector channels and one multiplexor channel. Each selector channel supports two magnetic disk and two magnetic tape units. The multiplexor channel has two line printers, two card readers, and 10 VDT terminals connected to it. Assume the following transfer rates:

Disk drive	800 Kbytes/s
Magnetic tape drive	200 Kbytes/s
Line printer	6.6 Kbytes/s
Card reader	1.2 Kbytes/s
VDT	1 Kbyte/s

Estimate the maximum aggregate I/O transfer rate in this system.

8.19 A computer consists of a processor and an I/O device D connected to main memory M via a shared bus with a data bus width of one word. The processor can execute a maximum of 10^6 instructions per second. An average instruction requires five machine cycles, three of which use the memory bus. A memory read or write operation uses one machine cycle. Suppose that the processor is continuously executing “background” programs that require 95% of its instruction execution rate but not any I/O instructions. Assume that one processor cycle equals one bus cycle. Now suppose the I/O device is to be used to transfer very large blocks of data between M and D.

- a. If programmed I/O is used and each one-word I/O transfer requires the processor to execute two instructions, estimate the maximum I/O data-transfer rate, in words per second, possible through D.
- b. Estimate the same rate if DMA is used.

8.20 A data source produces 7-bit IRA characters, to each of which is appended a parity bit. Derive an expression for the maximum effective data rate (rate of IRA data bits) over an R-bps line for the following:

- a.

- Asynchronous transmission, with a 1.5-unit stop bit;
- b. Bit-synchronous transmission, with a frame consisting of 48 control bits and 128 information bits;
 - c. Same as (b), with a 1024-bit information field;
 - d. Character-synchronous, with nine control characters per frame and 16 information characters;
 - e. Same as (d), with 128 information characters.

8.21 Two women are on either side of a high fence. One of the women, named Apple-server, has a beautiful apple tree loaded with delicious apples growing on her side of the fence; she is happy to supply apples to the other woman whenever needed. The other woman, named Apple-eater, loves to eat apples but has none. In fact, she must eat her apples at a fixed rate (an apple a day keeps the doctor away). If she eats them faster than that rate, she will get sick. If she eats them slower, she will suffer malnutrition. Neither woman can talk, and so the problem is to get apples from Apple-server to Apple-eater at the correct rate.

- a. Assume that there is an alarm clock sitting on top of the fence and that the clock can have multiple alarm settings. How can the clock be used to solve the problem? Draw a timing diagram to illustrate the solution.
- b. Now assume that there is no alarm clock. Instead Apple-eater has a flag that she can wave whenever she needs an apple. Suggest a new solution. Would it be helpful for Apple-server also to have a flag? If so, incorporate this into the solution. Discuss the drawbacks of this approach.
- c. Now take away the flag and assume the existence of a long piece of string. Suggest a solution that is superior to that of (b) using the string.

8.22 Assume that one 16-bit and two 8-bit microprocessors are to be interfaced to a system bus. The following details are given:

- 1. All microprocessors have the hardware features necessary for any type of data transfer: programmed I/O, interrupt-driven I/O, and DMA.
- 2. All microprocessors have a 16-bit address bus.
- 3. Two memory boards, each of 64-Kbytes capacity, are interfaced with the bus. The designer wishes to use a shared memory that is as large as possible.
- 4. The system bus supports a maximum of four interrupt lines and one DMA line. Make any other assumptions necessary, and:
 - a. Give the system bus specifications in terms of number and types of lines.
 - b. Describe a possible protocol for communicating on the bus (i.e., read-write, interrupt, and DMA sequences).
 - c. Explain how the aforementioned devices are interfaced to the system bus.

Learning Objectives

After studying this chapter, you should be able to:

- Summarize, at a top level, the key functions of an **operating system (OS)** .
- Discuss the evolution of operating systems for early simple batch systems to modern complex systems.
- Explain the differences among long-, medium-, and short-term scheduling.
- Understand the reason for memory **partitioning** and explain the various techniques that are used.
- Assess the relative advantages of paging and segmentation.

Define virtual memory.

Although the focus of this text is computer hardware, there is one area of software that needs to be addressed: the computer's OS. The OS is a program that manages the computer's resources, provides services for programmers, and schedules the execution of other programs. Some understanding of operating systems is essential to appreciate the mechanisms by which the CPU controls the computer system. In particular, explanations of the effect of interrupts and of the management of the memory hierarchy are best explained in this context.

The chapter begins with an overview and brief history of operating systems. The bulk of the chapter looks at the two OS functions that are most relevant to the study of computer organization and architecture: scheduling and memory management.

9.1 Operating System Overview

Operating System Objectives and Functions

An OS is a program that controls the execution of application programs and acts as an interface between applications and the computer hardware. It can be thought of as having two objectives:

- **Convenience:** An OS makes a computer more convenient to use.
- **Efficiency:** An OS allows the computer system resources to be used in an efficient manner.

Let us examine these two aspects of an OS in turn.

THE OPERATING SYSTEM AS A USER/COMPUTER INTERFACE

The hardware and software used in providing applications to a user can be viewed in a layered or hierarchical fashion, as depicted in **Figure 9.1**. The user of those applications, the end user, generally is not concerned with the computer's architecture. Thus the end user views a computer system in terms of an application. That application can be expressed in a programming language and is developed by an application programmer. To develop an application program as a set of processor instructions that is completely responsible for controlling the computer hardware would be an overwhelmingly complex task. To ease this task, a set of system programs is provided. Some of these programs are referred to as **utilities**. These implement frequently used functions that assist in program creation, the management of files, and the control of I/O devices. A programmer makes use of these facilities in developing an application, and the application, while it is running, invokes the utilities to perform certain functions. The most important system program is the OS. The OS masks the details of the hardware from the programmer and provides the programmer with a convenient interface for using the system. It acts as mediator, making it easier for the programmer and for application programs to access and use those facilities and services.

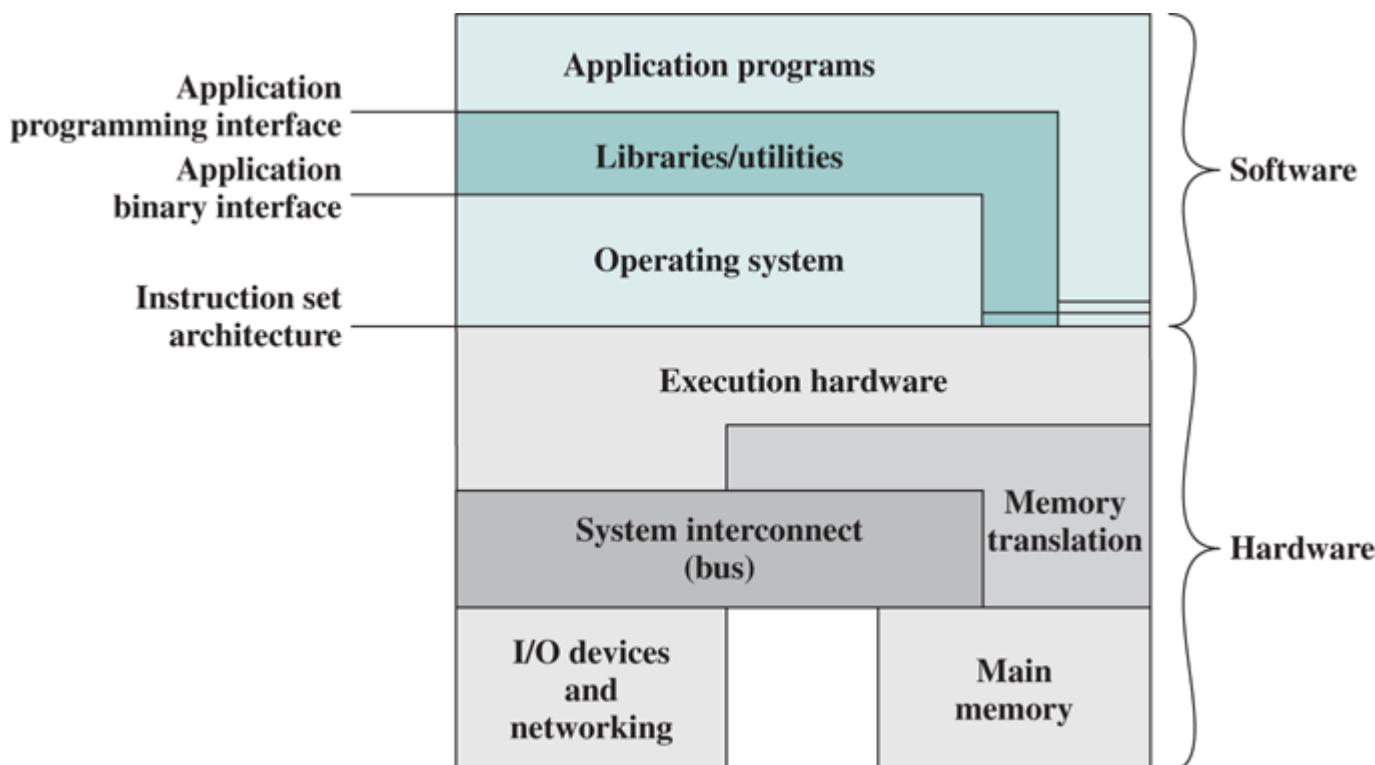

Figure 9.1 Computer Hardware and Software Structure

Briefly, the OS typically provides services in the following areas:

- **Program creation:** The OS provides a variety of facilities and services, such as editors and debuggers, to assist the programmer in creating programs. Typically, these services are in the form of **utility** programs that are not actually part of the OS but are accessible through the OS.
- **Program execution:** A number of steps need to be performed to execute a program. Instructions and data must be loaded into main memory, I/O devices and files must be initialized, and other resources must be prepared. The OS handles all of this for the user.
- **Access to I/O devices:** Each I/O device requires its own specific set of instructions or control signals for operation. The OS takes care of the details so that the programmer can think in terms of simple reads and writes.
- **Controlled access to files:** In the case of files, control must include an understanding of not only the nature of the I/O device (disk drive, tape drive) but also the file format on the storage medium. Again, the OS worries about the details. Further, in the case of a system with multiple simultaneous users, the OS can provide protection mechanisms to control access to the files.
- **System access:** In the case of a shared or public system, the OS controls access to the system as a whole and to specific system resources. The access function must provide protection of resources and data from unauthorized users and must resolve conflicts for resource contention.
- **Error detection and response:** A variety of errors can occur while a computer system is running. These include internal and external hardware errors, such as a memory error, or a device failure or malfunction; and various software errors, such as arithmetic overflow, attempt to access forbidden memory location, and inability of the OS to grant the request of an application. In each case, the OS must make the response that clears the error condition with the least impact on running applications. The response may range from ending the program that caused the error, to retrying the operation, to simply reporting the error to the application.
- **Accounting:** A good OS collects usage statistics for various resources and monitors performance parameters such as response time. On any system, this information is useful in anticipating the need for future enhancements and in tuning the system to improve performance. On a multiuser system, the information can be used for billing purposes. **Figure 9.1** also indicates three key interfaces in a typical computer system:
 - **Instruction set architecture (ISA):** The ISA defines the repertoire of machine language instructions that a computer can follow. This interface is the boundary between hardware and software. Note that both application programs and utilities may access the ISA directly. For these programs, a subset of the instruction repertoire is available (user ISA). The OS has access to additional machine language instructions that deal with managing system resources (system ISA).
 - **Application binary interface (ABI):** The ABI defines a standard for binary portability across programs. The ABI defines the system call interface to the operating system and the hardware resources and services available in a system through the user ISA.
 - **Application programming interface (API):** The API gives a program access to the hardware resources and services available in a system through the user ISA supplemented with **high-level language (HLL)** library calls. Any system calls are usually performed through libraries. Using an API enables application software to be ported easily, through recompilation, to other systems that support the same API.

THE OPERATING SYSTEM AS RESOURCE MANAGER

A computer is a set of resources for the movement, storage, and processing of data and for the control of these functions. The OS is responsible for managing these resources.

Can we say that the OS controls the movement, storage, and processing of data? From one point of view, the answer is yes: By managing the computer's resources, the OS is in control of the computer's basic functions. But this control is exercised in a curious way. Normally, we think of a control

mechanism as something external to that which is controlled, or at least as something that is a distinct and separate part of that which is controlled. (For example, a residential heating system is controlled by a thermostat, which is completely distinct from the heat-generation and heat-distribution apparatus.) This is not the case with the OS, which as a control mechanism is unusual in two respects:

- The OS functions in the same way as ordinary computer software; that is, it is a program executed by the processor.
- The OS frequently relinquishes control and must depend on the processor to allow it to regain control.

Like other computer programs, the OS provides instructions for the processor. The key difference is in the intent of the program. The OS directs the processor in the use of the other system resources and in the timing of its execution of other programs. But in order for the processor to do any of these things, it must cease executing the OS program and execute other programs. Thus, the OS relinquishes control for the processor to do some “useful” work and then resumes control long enough to prepare the processor to do the next piece of work. The mechanisms involved in all this should become clear as the chapter proceeds.

Figure 9.2 suggests the main resources that are managed by the OS. A portion of the OS is in main memory. This includes the **kernel**, or **nucleus** , which contains the most frequently used functions in the OS and, at a given time, other portions of the OS currently in use. The remainder of main memory contains user programs and data. The allocation of this resource (main memory) is controlled jointly by the OS and memory-management hardware in the processor, as we will see. The OS decides when an I/O device can be used by a program in execution, and controls access to and use of files. The processor itself is a resource, and the OS must determine how much processor time is to be devoted to the execution of a particular user program. In the case of a multiple-processor system, this decision must span all of the processors.

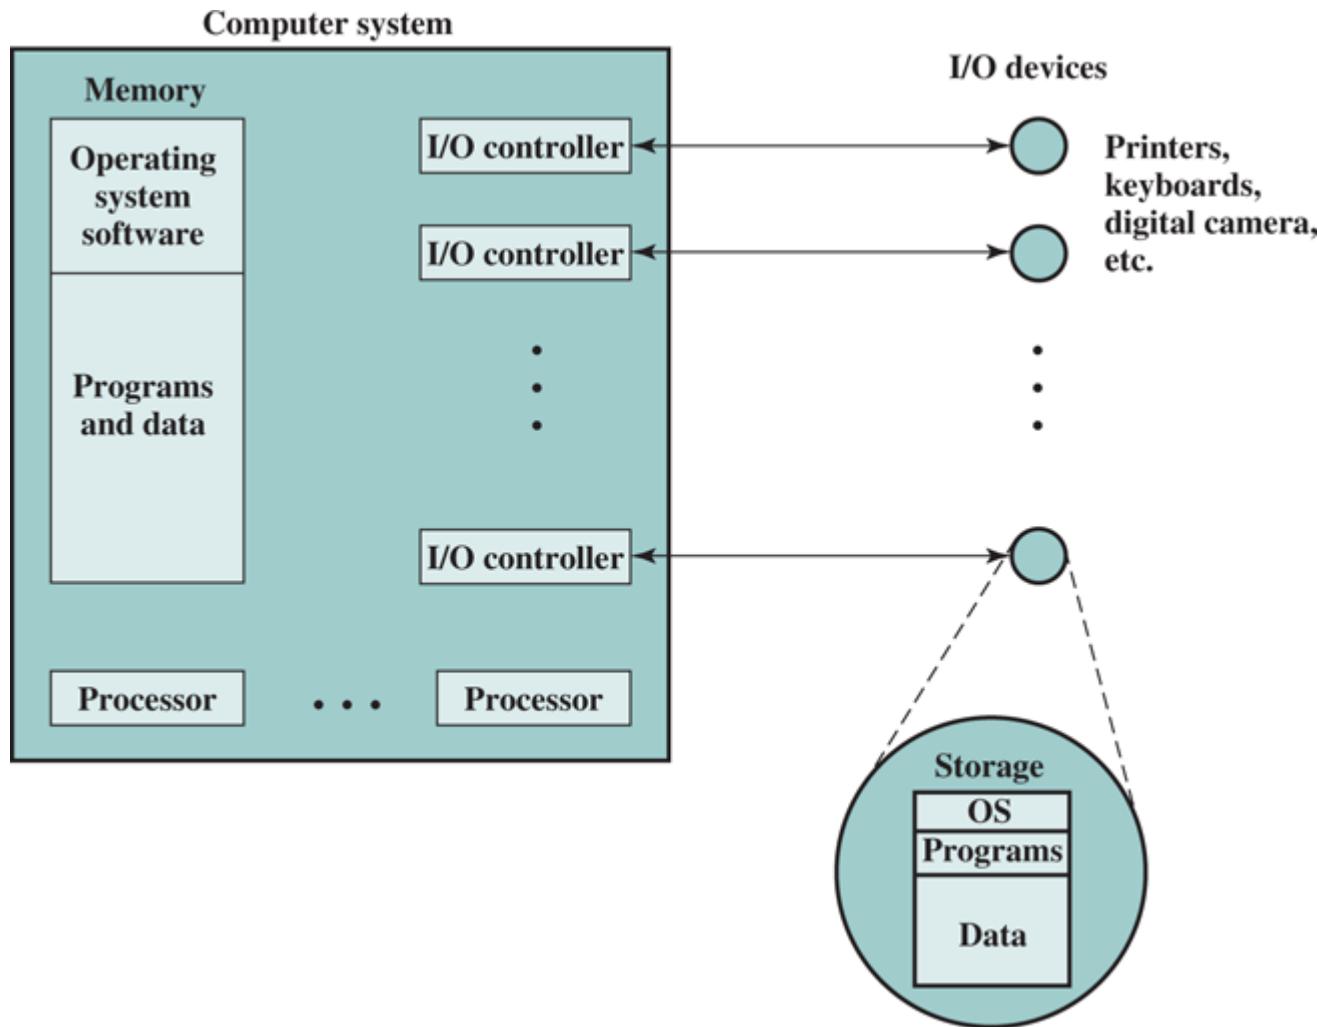

Figure 9.2 The Operating System as Resource Manager

Types of Operating Systems

Certain key characteristics serve to differentiate various types of operating systems. The characteristics fall along two independent dimensions. The first dimension specifies whether the system is batch or interactive. In an **interactive** system, the user/programmer interacts directly with the computer, usually through a keyboard/display terminal, to request the execution of a job or to perform a transaction. Furthermore, the user may, depending on the nature of the application, communicate with the computer during the execution of the job. A **batch system** is the opposite of interactive. The user's program is batched together with programs from other users and submitted by a computer operator. After the program is completed, results are printed out for the user. Pure batch systems are rare today, however, it will be useful to the description of contemporary operating systems to briefly examine batch systems.

An independent dimension specifies whether the system employs **multiprogramming** or not. With multiprogramming, the attempt is made to keep the processor as busy as possible, by having it work on more than one program at a time. Several programs are loaded into memory, and the processor switches rapidly among them. The alternative is a **uniprogramming** system that works only one program at a time.

EARLY SYSTEMS

With the earliest computers, from the late 1940s to the mid-1950s, the programmer interacted directly with the computer hardware; there was no OS. These processors were run from a console, consisting

of display lights, toggle switches, some form of input device, and a printer. Programs in processor code were loaded via the input device (e.g., a card reader). If an error halted the program, the error condition was indicated by the lights. The programmer could proceed to examine registers and main memory to determine the cause of the error. If the program proceeded to a normal completion, the output appeared on the printer.

These early systems presented two main problems:

- **Scheduling:** Most installations used a sign-up sheet to reserve processor time. Typically, a user could sign up for a block of time in multiples of a half hour or so. A user might sign up for an hour and finish in 45 minutes; this would result in wasted computer idle time. On the other hand, the user might run into problems, not finish in the allotted time, and be forced to stop before resolving the problem.
- **Setup time:** A single program, called a **job**, could involve loading the compiler plus the high-level language program (source program) into memory, saving the compiled program (object program), and then loading and linking together the object program and common functions. Each of these steps could involve mounting or dismounting tapes, or setting up card decks. If an error occurred, the hapless user typically had to go back to the beginning of the setup sequence. Thus a considerable amount of time was spent just in setting up the program to run.

This mode of operation could be termed serial processing, reflecting the fact that users have access to the computer in series. Over time, various system software tools were developed to attempt to make serial processing more efficient. These include libraries of common functions, linkers, loaders, debuggers, and I/O driver routines that were available as common software for all users.

SIMPLE BATCH SYSTEMS

Early processors were very expensive, and therefore it was important to maximize processor utilization. The wasted time due to scheduling and setup time was unacceptable.

To improve utilization, simple batch operating systems were developed. With such a system, also called a **monitor**, the user no longer has direct access to the processor. Rather, the user submits the job on cards or tape to a computer operator, who *batches* the jobs together sequentially and places the entire batch on an input device, for use by the monitor.

To understand how this scheme works, let us look at it from two points of view: that of the monitor and that of the processor. From the point of view of the monitor, the monitor controls the sequence of events. For this to be so, much of the monitor must always be in main memory and available for execution (**Figure 9.3**). That portion is referred to as the **resident monitor**. The rest of the monitor consists of utilities and common functions that are loaded as subroutines to the user program at the beginning of any job that requires them. The monitor reads in jobs one at a time from the input device (typically a card reader or magnetic tape drive). As it is read in, the current job is placed in the user program area, and control is passed to this job. When the job is completed, it returns control to the monitor, which immediately reads in the next job. The results of each job are printed out for delivery to the user.

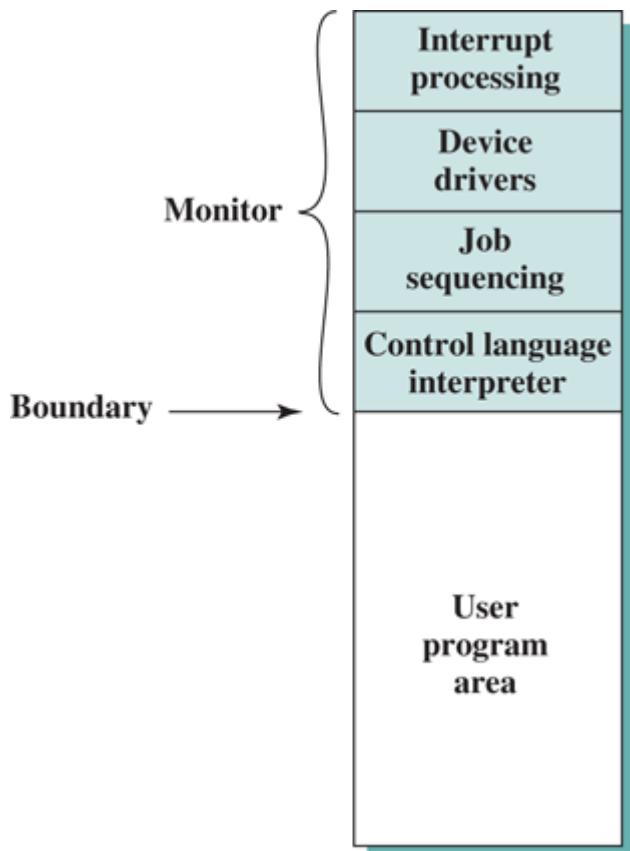

Figure 9.3 Memory Layout for a Resident Monitor

Now consider this sequence from the point of view of the processor. At a certain point in time, the processor is executing instructions from the portion of main memory containing the monitor. These instructions cause the next job to be read in to another portion of main memory. Once a job has been read in, the processor will encounter in the monitor a branch instruction that instructs the processor to continue execution at the start of the user program. The processor will then execute the instruction in the user's program until it encounters an ending or error condition. Either event causes the processor to fetch its next instruction from the monitor program. Thus the phrase "control is passed to a job" simply means that the processor is now fetching and executing instructions in a user program, and "control is returned to the monitor" means that the processor is now fetching and executing instructions from the monitor program.

It should be clear that the monitor handles the scheduling problem. A batch of jobs is queued up, and jobs are executed as rapidly as possible, with no intervening idle time.

How about the job setup time? The monitor handles this as well. With each job, instructions are included in a **job control language (JCL)**. This is a special type of programming language used to provide instructions to the monitor. A simple example is that of a user submitting a program written in FORTRAN plus some data to be used by the program. Each FORTRAN instruction and each item of data is on a separate punched card or a separate record on tape. In addition to FORTRAN and data lines, the job includes job control instructions, which are denoted by the beginning "\$". The overall format of the job looks like this:

```

$JOB
$FTN
:
}FORTRAN instructions
$LOAD
$RUN
:
}Data
$END

```

To execute this job, the monitor reads the \$FTN line and loads the appropriate compiler from its mass storage (usually tape). The compiler translates the user's program into object code, which is stored in memory or mass storage. If it is stored in memory, the operation is referred to as "compile, load, and go." If it is stored on tape, then the \$LOAD instruction is required. This instruction is read by the monitor, which regains control after the compile operation. The monitor invokes the loader, which loads the object program into memory in place of the compiler and transfers control to it. In this manner, a large segment of main memory can be shared among different subsystems, although only one such subsystem could be resident and executing at a time.

We see that the monitor, or batch OS, is simply a computer program. It relies on the ability of the processor to fetch instructions from various portions of main memory in order to seize and relinquish control alternately. Certain other hardware features are also desirable:

- **Memory protection:** While the user program is executing, it must not alter the memory area containing the monitor. If such an attempt is made, the processor hardware should detect an error and transfer control to the monitor. The monitor would then abort the job, print out an error message, and load the next job.
- **Timer:** A timer is used to prevent a single job from monopolizing the system. The timer is set at the beginning of each job. If the timer expires, an interrupt occurs, and control returns to the monitor.
- **Privileged instructions:** Certain instructions are designated privileged and can be executed only by the monitor. If the processor encounters such an instruction while executing a user program, an error interrupt occurs. Among the privileged instructions are I/O instructions, so that the monitor retains control of all I/O devices. This prevents, for example, a user program from accidentally reading job control instructions from the next job. If a user program wishes to perform I/O, it must request that the monitor perform the operation for it. If a privileged instruction is encountered by the processor while it is executing a user program, the processor hardware considers this an error and transfers control to the monitor.
- **Interrupts:** Early computer models did not have this capability. This feature gives the OS more flexibility in relinquishing control to and regaining control from user programs.

Processor time alternates between execution of user programs and execution of the monitor. There have been two sacrifices: Some main memory is now given over to the monitor and some processor time is consumed by the monitor. Both of these are forms of overhead. Even with this overhead, the simple batch system improves utilization of the computer.

MULTI/PROGRAMMED BATCH SYSTEMS

Even with the automatic job sequencing provided by a simple batch OS, the processor is often idle. The problem is that I/O devices are slow compared to the processor. [Figure 9.4](#) details a representative calculation. The calculation concerns a program that processes a file of records and performs, on average, 100 processor instructions per record. In this example the computer spends over 96% of its time waiting for I/O devices to finish transferring data! [Figure 9.5a](#) illustrates this situation. The processor spends a certain amount of time executing, until it reaches an I/O instruction. It must then wait until that I/O instruction concludes before proceeding.

Read one record from file	15 μs
Execute 100 instructions	1 μs
Write one record to file	15 μs
TOTAL	31 μs
 Percent CPU utilization = $\frac{1}{31} = 0.032 = 3.2\%$	

Figure 9.4 System Utilization Example

This inefficiency is not necessary. We know that there must be enough memory to hold the OS (resident monitor) and one user program. Suppose that there is room for the OS and two user programs. Now, when one job needs to wait for I/O, the processor can switch to the other job, which likely is not waiting for I/O ([Figure 9.5b](#)). Furthermore, we might expand memory to hold three, four, or more programs and switch among all of them ([Figure 9.5c](#)). This technique is known as **multiprogramming**, or **multitasking**¹. It is the central theme of modern operating systems.

¹ The term *multitasking* is sometimes reserved to mean multiple tasks within the same program that may be handled concurrently by the OS, in contrast to *multiprogramming*, which would refer to multiple processes from multiple programs. However, it is more common to equate the terms *multitasking* and *multiprogramming*, as is done in most standards dictionaries (e.g., IEEE Std 100-1992, *The New IEEE Standard Dictionary of Electrical and Electronics Terms*).

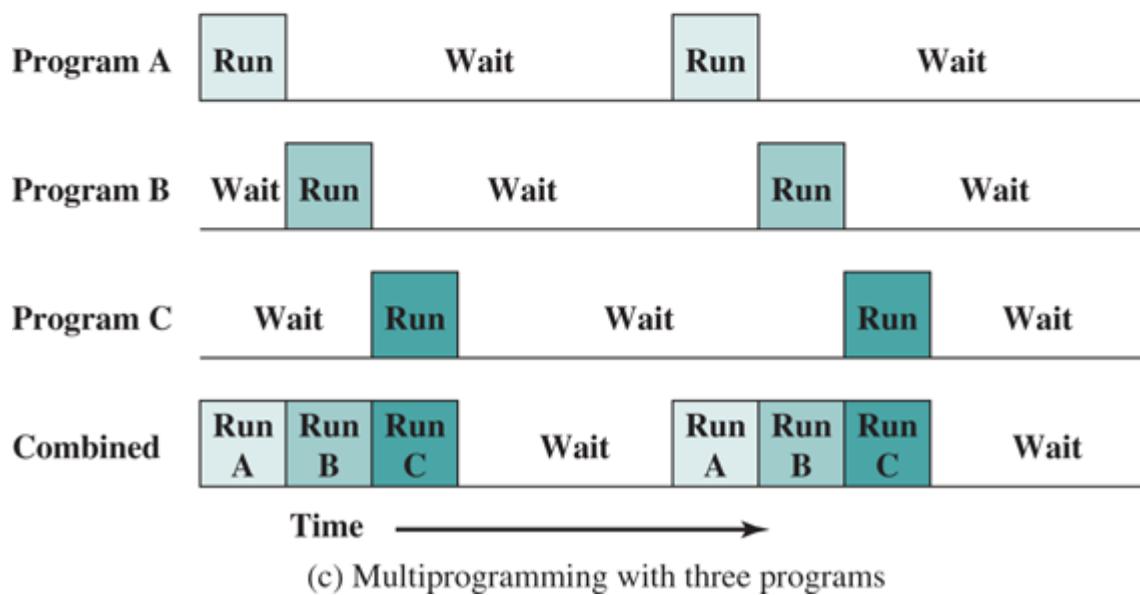

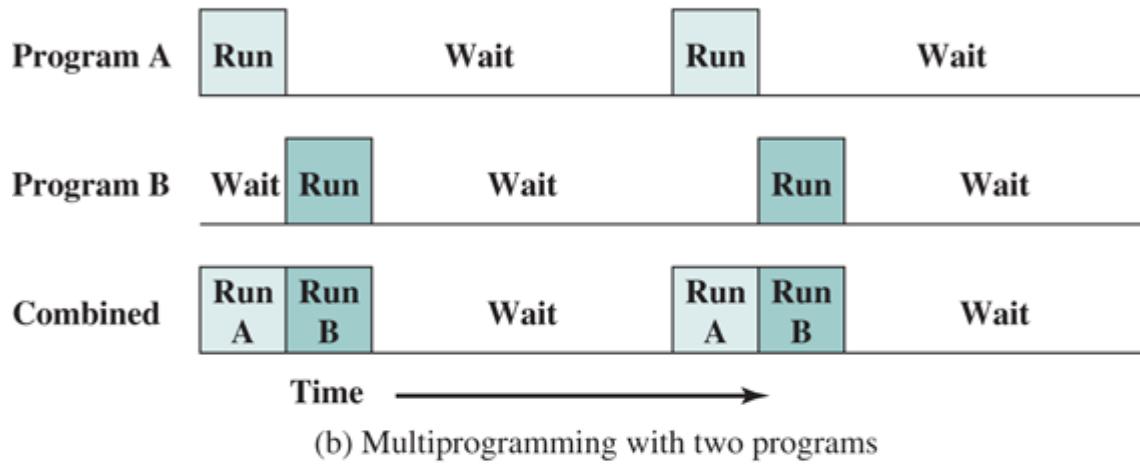

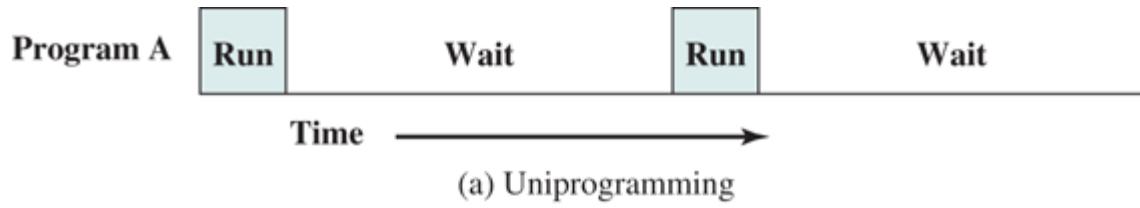

Figure 9.5 Multiprogramming Example

Example 9.1

This example illustrates the benefit of multiprogramming. Consider a computer with 250 Mbytes of available memory (not used by the OS), a disk, a terminal, and a printer. Three programs, JOB1, JOB2, and JOB3, are submitted for execution at the same time, with the attributes listed in [Table 9.1](#). We assume minimal processor requirements for JOB1 and JOB2 and continuous disk and printer use by JOB3. For a simple batch environment, these jobs will be executed in sequence. Thus, JOB1 completes in 5 minutes. JOB2 must wait until the 5 minutes is over and then completes 15 minutes after that. JOB3 begins after 20 minutes and completes at 30 minutes from the time it was initially submitted. The average resource utilization, throughput, and response times are shown in the uniprogramming column of [Table 9.2](#). Device-by-device utilization is illustrated in [Figure 9.6a](#). It is evident that there is gross underutilization for all resources when

averaged over the required 30-minute time period.

Table 9.1 Sample Program Execution Attributes

	JOB1	JOB2	JOB3
Type of job	Heavy compute	Heavy I/O	Heavy I/O
Duration (min)	5	15	10
Memory required (M)	50	100	80
Need disk?	No	No	Yes
Need terminal?	No	Yes	No
Need printer?	No	No	Yes

Table 9.2 Effects of Multiprogramming on Resource Utilization

	Uniprogramming	Multiprogramming
Processor use (%)	20	40
Memory use (%)	33	67
Disk use (%)	33	67
Printer use (%)	33	67
Elapsed time (min)	30	15
Throughput rate (jobs/hr)	6	12
Mean response time (min)	18	10

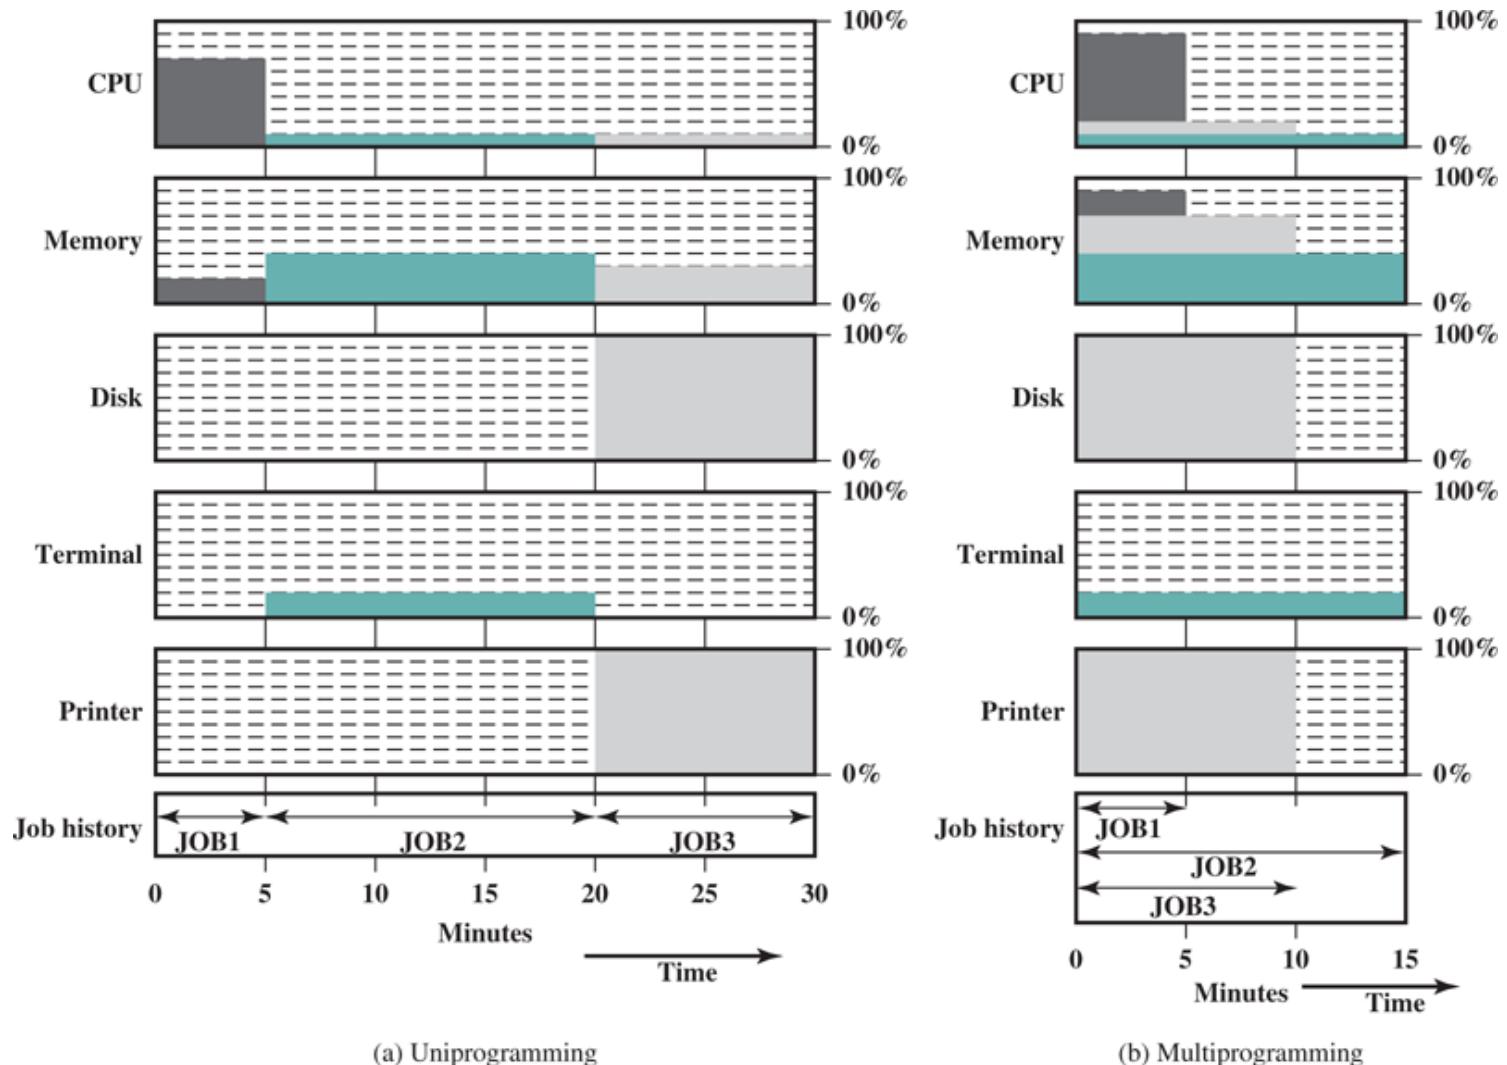

Figure 9.6 Utilization Histograms

Now suppose that the jobs are run concurrently under a multiprogramming OS. Because there is little resource contention between the jobs, all three can run in nearly minimum time while coexisting with the others in the computer (assuming that JOB2 and JOB3 are allotted enough processor time to keep their input and output operations active). JOB1 will still require 5 minutes to complete but at the end of that time, JOB2 will be one-third finished, and JOB3 will be half finished. All three jobs will have finished within 15 minutes. The improvement is evident when examining the multiprogramming column of **Table 9.2**, obtained from the histogram shown in **Figure 9.6b**.

As with a simple batch system, a multiprogramming batch system must rely on certain computer hardware features. The most notable additional feature that is useful for multiprogramming is the hardware that supports I/O interrupts and DMA. With interrupt-driven I/O or DMA, the processor can issue an I/O command for one job and proceed with the execution of another job while the I/O is carried out by the device controller. When the I/O operation is complete, the processor is interrupted and control is passed to an interrupt-handling program in the OS. The OS will then pass control to another job.

Multiprogramming operating systems are fairly sophisticated compared to single-program, or **uniprogramming**, systems. To have several jobs ready to run, the jobs must be kept in main memory, requiring some form of **memory management**. In addition, if several jobs are ready to run, the processor must decide which one to run, which requires some algorithm for scheduling. These concepts are discussed later in this chapter.

TIME-SHARING SYSTEMS

With the use of multiprogramming, batch processing can be quite efficient. However, for many jobs, it is desirable to provide a mode in which the user interacts directly with the computer. Indeed, for some jobs, such as transaction processing, an interactive mode is essential.

Today, the requirement for an interactive computing facility can be, and often is, met by the use of a dedicated microcomputer. That option was not available in the 1960s, when most computers were big and costly. Instead, time sharing was developed.

Just as multiprogramming allows the processor to handle multiple batch jobs at a time, multiprogramming can be used to handle multiple interactive jobs. In this latter case, the technique is referred to as time sharing, because the processor's time is shared among multiple users. In a **time-sharing system**, multiple users simultaneously access the system through terminals, with the OS interleaving the execution of each user program in a short burst or quantum of computation. Thus, if there are n users actively requesting service at one time, each user will only see on the average $1/n$ of the effective computer speed, not counting OS overhead. However, given the relatively slow human reaction time, the response time on a properly designed system should be comparable to that on a dedicated computer.

Both batch multiprogramming and time sharing use multiprogramming. The key differences are listed in **Table 9.3**.

Table 9.3 Batch Multiprogramming versus Time Sharing

	Batch Multiprogramming	Time Sharing
Principal objective	Maximize processor use	Minimize response time
Source of directives to operating system	Job control language commands provided with the job	Commands entered at the terminal

9.2 Scheduling

The key to multiprogramming is scheduling. In fact, four types of scheduling are typically involved (**Table 9.4**). We will explore these presently. But first, we introduce the concept of **process**. This term was first used by the designers of the Multics OS in the 1960s. It is a somewhat more general term than *job*. Many definitions have been given for the term *process*, including

Table 9.4 Types of Scheduling

Long-term scheduling	The decision to add to the pool of processes to be executed.
Medium-term scheduling	The decision to add to the number of processes that are partially or fully in main memory.
Short-term scheduling	The decision as to which available process will be executed by the processor.
I/O scheduling	The decision as to which process's pending I/O request shall be handled by an available I/O device.

- A program in execution
- The “animated spirit” of a program
- That entity to which a processor is assigned

This concept should become clearer as we proceed.

Long-Term Scheduling

The long-term scheduler determines which programs are admitted to the system for processing. Thus, it controls the degree of multiprogramming (number of processes in memory). Once admitted, a job or user program becomes a process and is added to the queue for the short-term scheduler. In some systems, a newly created process begins in a swapped-out condition, in which case it is added to a queue for the medium-term scheduler.

In a batch system, or for the batch portion of a general-purpose OS, newly submitted jobs are routed to disk and held in a batch queue. The long-term scheduler creates processes from the queue when it can. There are two decisions involved here. First, the scheduler must decide that the OS can take on one or more additional processes. Second, the scheduler must decide which job or jobs to accept and turn into processes. The criteria used may include priority, expected execution time, and I/O requirements.

For interactive programs in a time-sharing system, a process request is generated when a user attempts to connect to the system. Time-sharing users are not simply queued up and kept waiting until the system can accept them. Rather, the OS will accept all authorized comers until the system is saturated, using some predefined measure of saturation. At that point, a connection request is met with a message indicating that the system is full and the user should try again later.

Medium-Term Scheduling

Medium-term scheduling is part of the swapping function, described in [Section 9.3](#). Typically, the swapping-in decision is based on the need to manage the degree of multiprogramming. On a system that does not use virtual memory, memory management is also an issue. Thus, the swapping-in decision will consider the memory requirements of the swapped-out processes.

Short-Term Scheduling

The long-term scheduler executes relatively infrequently and makes the coarse-grained decision of whether or not to take on a new process, and which one to take. The short-term scheduler, also known as the [dispatcher](#), executes frequently and makes the fine-grained decision of which job to execute next.

PROCESS STATES

To understand the operation of the short-term scheduler, we need to consider the concept of a [process state](#). During the lifetime of a process, its status will change a number of times. Its status at any point in time is referred to as a *state*. The term *state* is used because it connotes that certain information exists that defines the status at that point. At minimum, there are five defined states for a process ([Figure 9.7](#)):

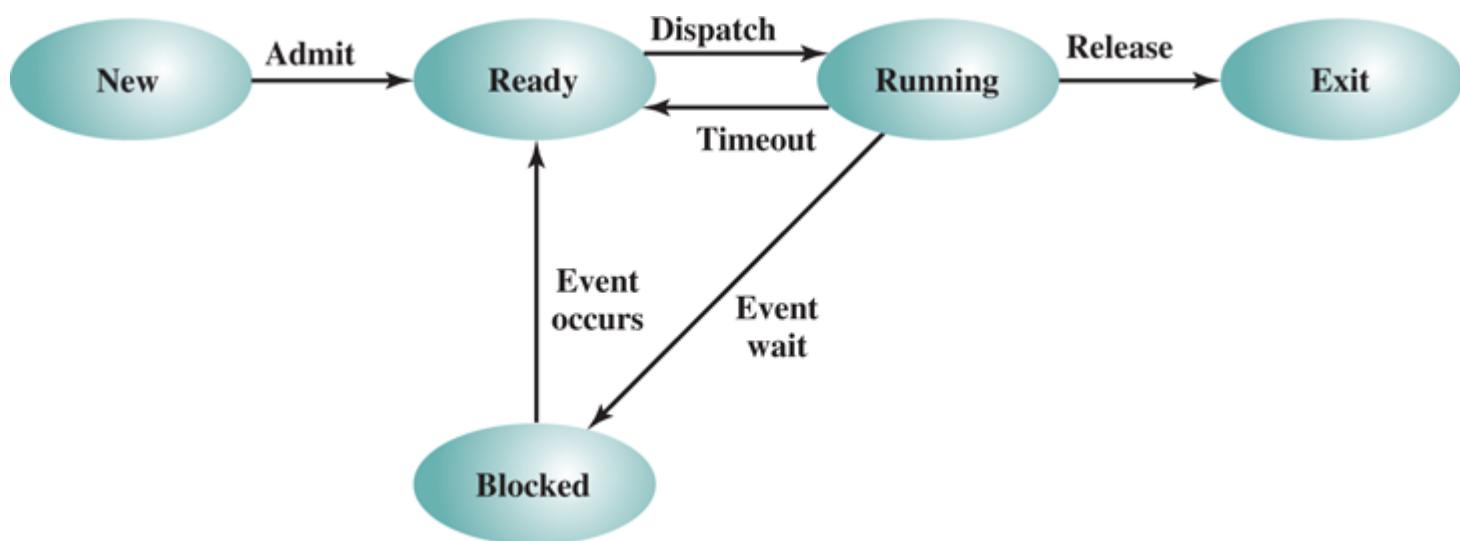

Figure 9.7 Five-State Process Model

- **New:** A program is admitted by the high-level scheduler but is not yet ready to execute. The OS will initialize the process, moving it to the ready state.
- **Ready:** The process is ready to execute and is awaiting access to the processor.
- **Running:** The process is being executed by the processor.
- **Waiting:** The process is suspended from execution waiting for some system resource, such as I/O.
- **Halted:** The process has terminated and will be destroyed by the OS.

For each process in the system, the OS must maintain information indicating the state of the process and other information necessary for process execution. For this purpose, each process is represented in the OS by a [process control block](#) ([Figure 9.8](#)), which typically contains:

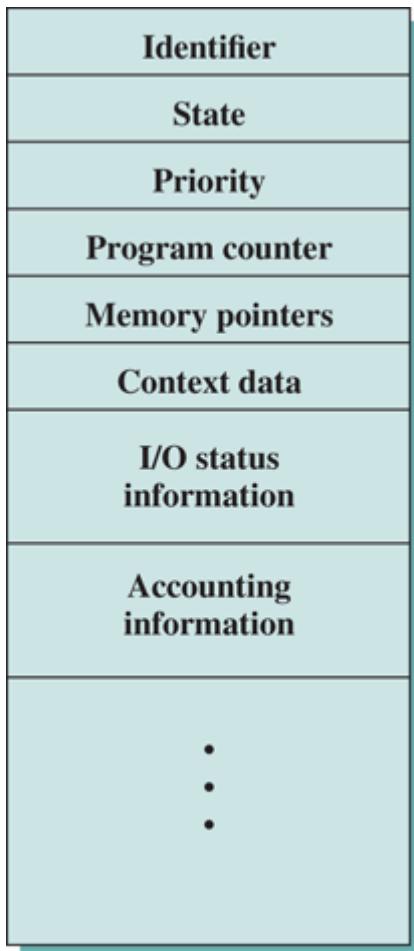

Figure 9.8 Process Control Block

- **Identifier:** Each current process has a unique identifier.
- **State:** The current state of the process (new, ready, and so on).
- **Priority:** Relative priority level.
- **Program counter:** The address of the next instruction in the program to be executed.
- **Memory pointers:** The starting and ending locations of the process in memory.
- **Context data:** These are data that are present in registers in the processor while the process is executing, and they will be discussed in Part Three. For now, it is enough to say that these data represent the “context” of the process. The context data plus the program counter are saved when the process leaves the running state. They are retrieved by the processor when it resumes execution of the process.
- **I/O status information:** Includes outstanding I/O requests, I/O devices (e.g., tape drives) assigned to this process, a list of files assigned to the process, and so on.
- **Accounting information:** May include the amount of processor time and clock time used, time limits, account numbers, and so on.

When the scheduler accepts a new job or user request for execution, it creates a blank process control block and places the associated process in the new state. After the system has properly filled in the process control block, the process is transferred to the ready state.

SCHEDULING TECHNIQUES

To understand how the OS manages the scheduling of the various jobs in memory, let us begin by considering the simple example in [Figure 9.9](#). The figure shows how main memory is partitioned at a given point in time. The kernel of the OS is, of course, always resident. In addition, there are a number of active processes, including **A** and **B**, each of which is allocated a portion of memory.

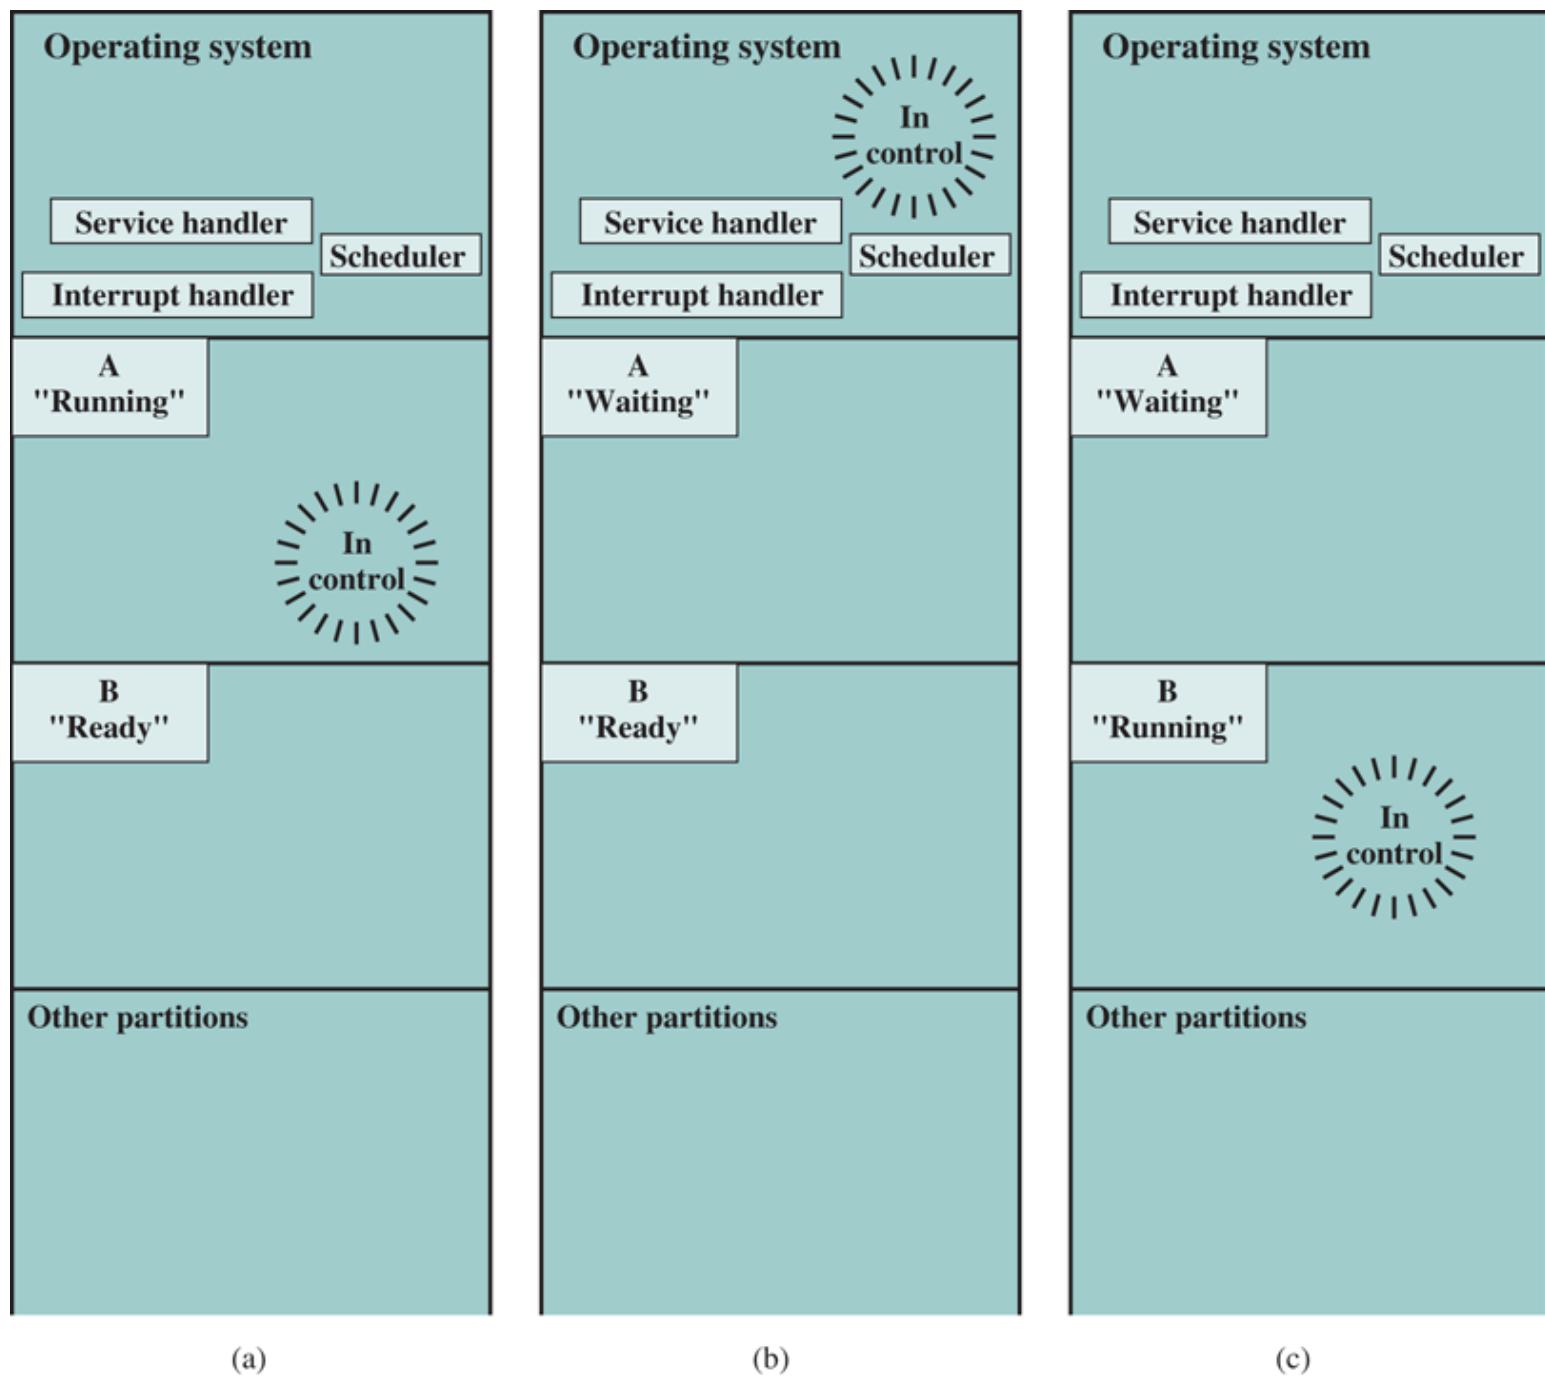

Figure 9.9 Scheduling Example

We begin at a point in time when process **A** is running. The processor is executing instructions from the program contained in **A**'s memory partition. At some later point in time, the processor ceases to execute instructions in **A** and begins executing instructions in the OS area. This will happen for one of three reasons:

1. Process **A** issues a service call (e.g., an I/O request) to the OS. Execution of **A** is suspended until this call is satisfied by the OS.
2. Process **A** causes an *interrupt*. An interrupt is a hardware-generated signal to the processor. When this signal is detected, the processor ceases to execute **A** and transfers to the interrupt handler in the OS. A variety of events related to **A** will cause an interrupt. One example is an error, such as attempting to execute a privileged instruction. Another example is a timeout; to prevent any one process from monopolizing the processor, each process is only granted the processor for a short period at a time.
3. Some event unrelated to process **A** that requires attention causes an interrupt. An example is the completion of an I/O operation.

In any case, the result is the following. The processor saves the current context data and the program counter for **A** in **A**'s process control block and then begins executing in the OS. The OS may perform some work, such as initiating an I/O operation. Then the short-term-scheduler portion of the OS decides which process should be executed next. In this example, **B** is chosen. The OS instructs the processor to restore **B**'s context data and proceed with the execution of **B** where it left off.

This simple example highlights the basic functioning of the short-term scheduler. [Figure 9.10](#) shows the major elements of the OS involved in the multiprogramming and scheduling of processes. The OS receives control of the processor at the interrupt handler if an interrupt occurs and at the service-call handler if a service call occurs. Once the interrupt or service call is handled, the short-term scheduler is invoked to select a process for execution.

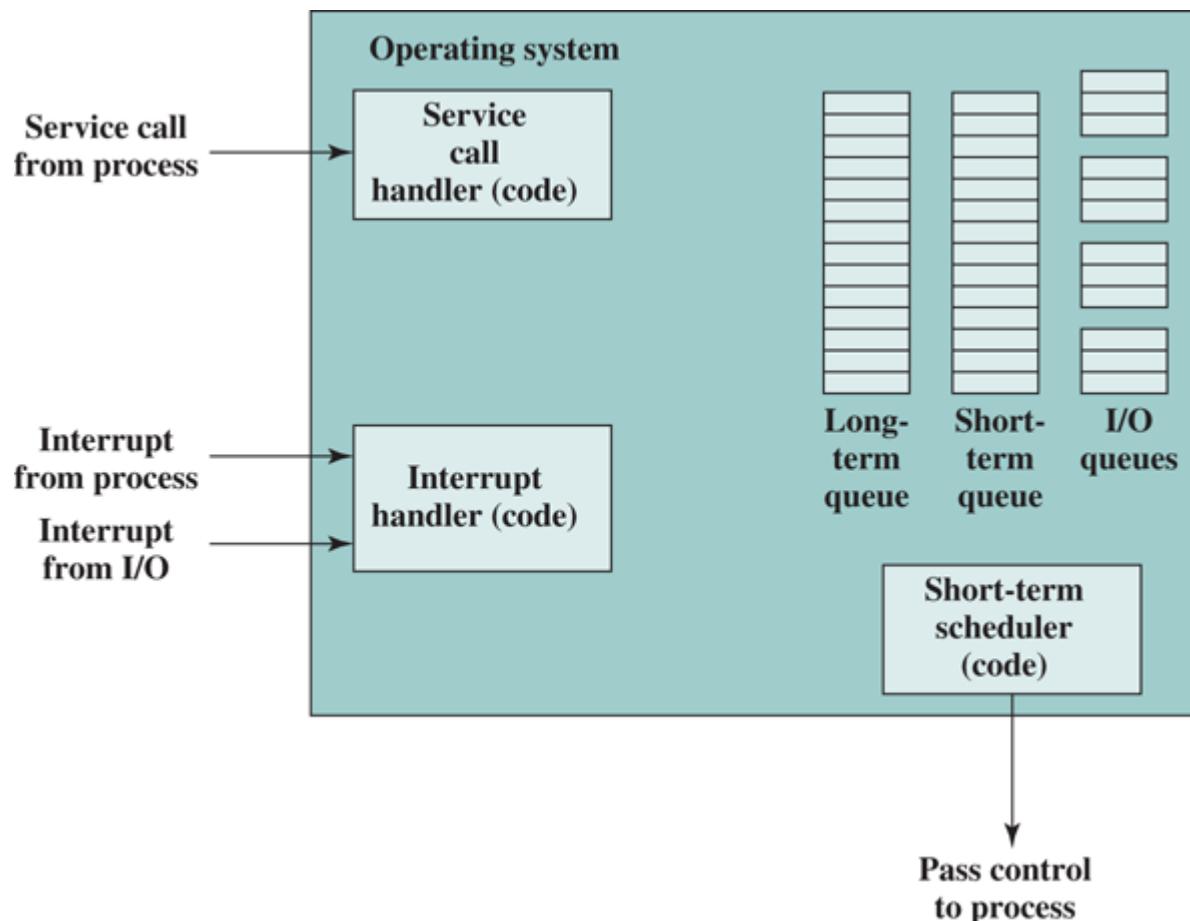

Figure 9.10 Key Elements of an Operating System for Multiprogramming

To do its job, the OS maintains a number of queues. Each queue is simply a waiting list of processes waiting for some resource. The **long-term queue** is a list of jobs waiting to use the system. As conditions permit, the high-level scheduler will allocate memory and create a process for one of the waiting items. The **short-term queue** consists of all processes in the ready state. Any one of these processes could use the processor next. It is up to the short-term scheduler to pick one. Generally, this is done with a round-robin algorithm, giving each process some time in turn. Priority levels may also be used. Finally, there is an **I/O queue** for each I/O device. More than one process may request the use of the same I/O device. All processes waiting to use each device are lined up in that device's queue.

[Figure 9.11](#) suggests how processes progress through the computer under the control of the OS. Each process request (batch job, user-defined interactive job) is placed in the long-term queue. As resources become available, a process request becomes a process and is then placed in the ready

state and put in the short-term queue. The processor alternates between executing OS instructions and executing user processes. While the OS is in control, it decides which process in the short-term queue should be executed next. When the OS has finished its immediate tasks, it turns the processor over to the chosen process.

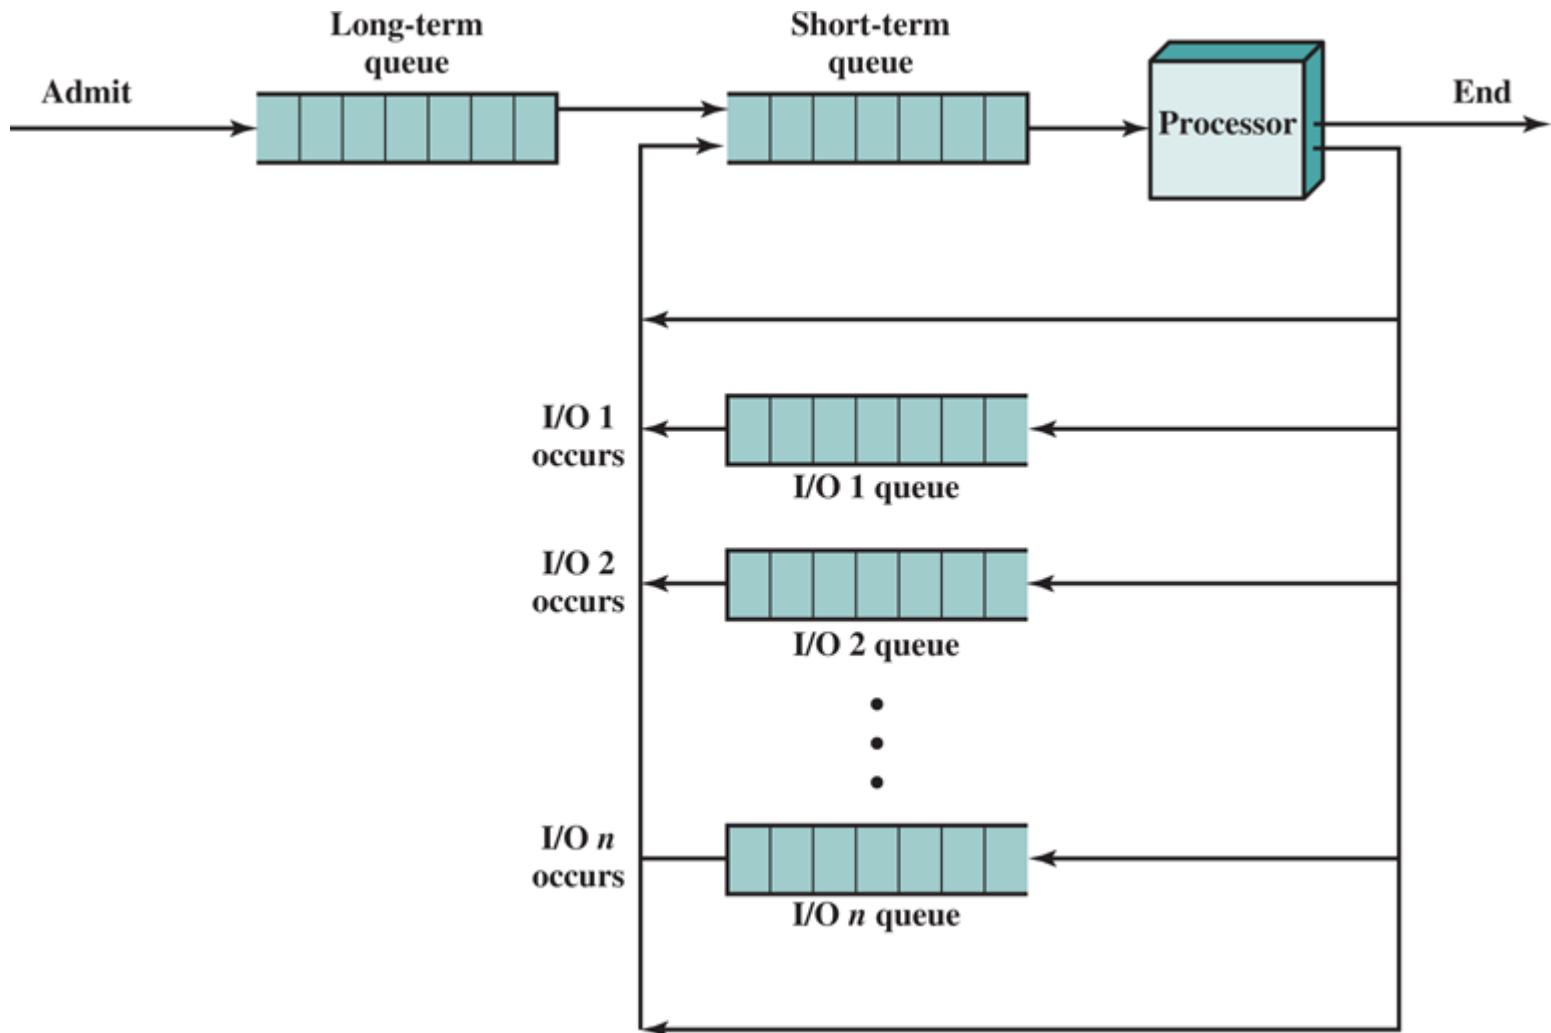

Figure 9.11 Queuing Diagram Representation of Processor Scheduling

As was mentioned earlier, a process being executed may be suspended for a variety of reasons. If it is suspended because the process requests I/O, then it is placed in the appropriate I/O queue. If it is suspended because of a timeout or because the OS must attend to pressing business, then it is placed in the ready state and put into the short-term queue.

Finally, we mention that the OS also manages the I/O queues. When an I/O operation is completed, the OS removes the satisfied process from that I/O queue and places it in the short-term queue. It then selects another waiting process (if any) and signals for the I/O device to satisfy that process's request.

9.3 Memory Management

In a uniprogramming system, main memory is divided into two parts: one part for the OS (resident monitor) and one part for the program currently being executed. In a multiprogramming system, the “user” part of memory is subdivided to accommodate multiple processes. The task of subdivision is carried out dynamically by the OS and is known as **memory management**.

Effective memory management is vital in a multiprogramming system. If only a few processes are in memory, then for much of the time all of the processes will be waiting for I/O and the processor will be idle. Thus, memory needs to be allocated efficiently to pack as many processes into memory as possible.

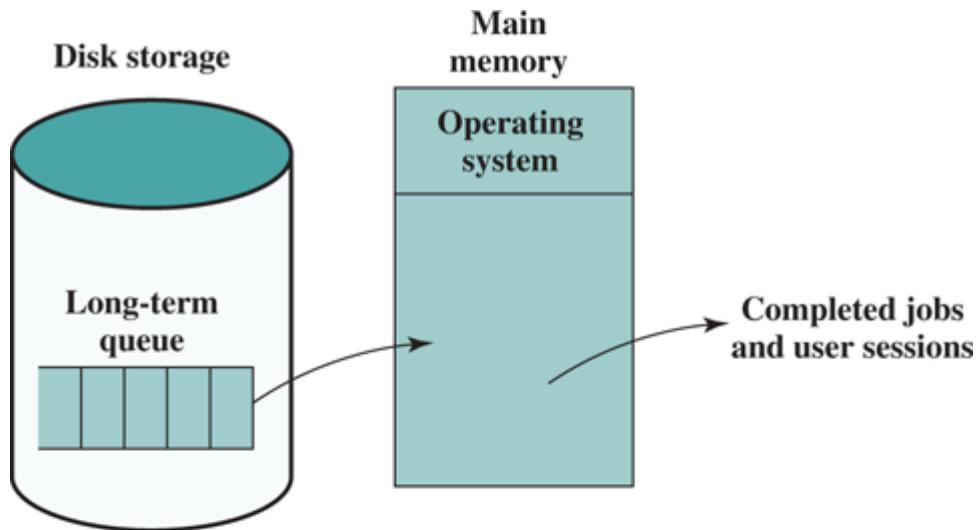

Swapping

Referring back to [Figure 9.11](#), we have discussed three types of queues: the long-term queue of requests for new processes, the short-term queue of processes ready to use the processor, and the various I/O queues of processes that are not ready to use the processor. Recall that the reason for this elaborate machinery is that I/O activities are much slower than computation and therefore the processor in a uniprogramming system is idle most of the time.

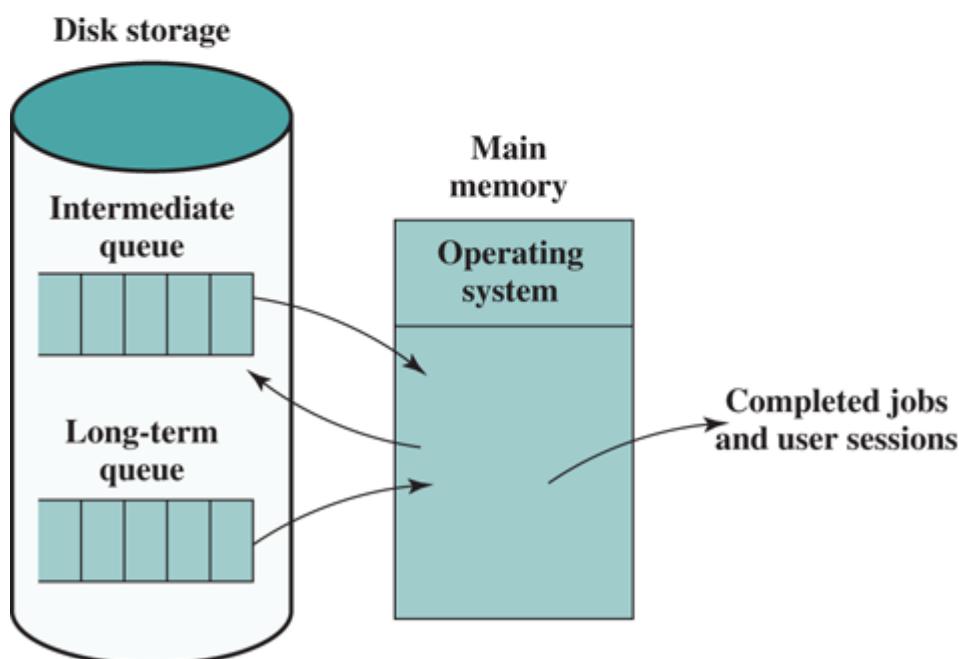

But the arrangement in [Figure 9.11](#) does not entirely solve the problem. It is true that, in this case, memory holds multiple processes and that the processor can move to another process when one process is waiting. But the processor is so much faster than I/O that it will be common for *all* the processes in memory to be waiting on I/O. Thus, even with multiprogramming, a processor could be idle most of the time.

What to do? Main memory could be expanded, and so be able to accommodate more processes. But there are two flaws in this approach. First, main memory is expensive, even today. Second, the appetite of programs for memory has grown as fast as the cost of memory has dropped. So larger memory results in larger processes, not more processes.

Another solution is **swapping**, depicted in [Figure 9.12](#). We have a long-term queue of process requests, typically stored on disk. These are brought in, one at a time, as space becomes available. As processes are completed, they are moved out of main memory. Now the situation will arise that none of the processes in memory are in the ready state (e.g., all are waiting on an I/O operation). Rather than remain idle, the processor swaps one of these processes back out to disk into an *intermediate queue*. This is a queue of existing processes that have been temporarily kicked out of memory. The OS then brings in another process from the intermediate queue, or it honors a new process request from the long-term queue. Execution then continues with the newly arrived process.

(a) Simple job scheduling

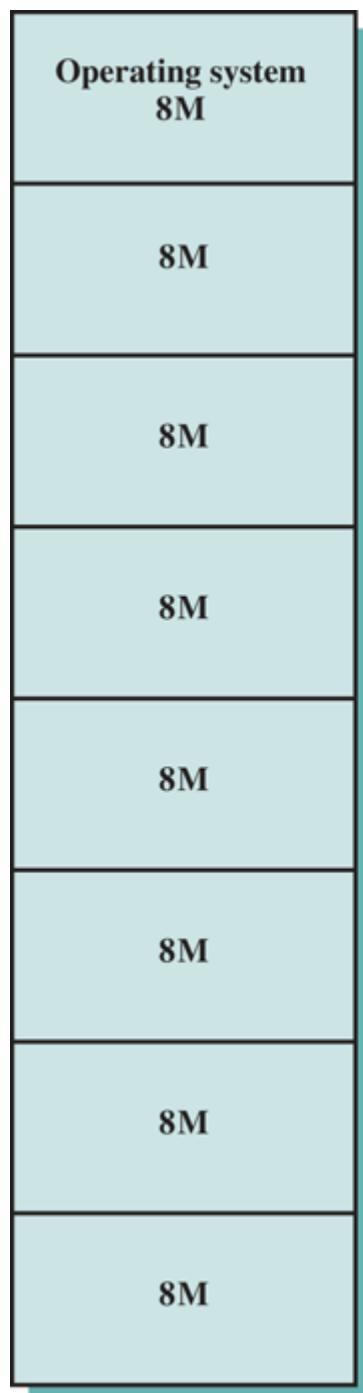

(b) Swapping

Figure 9.12 The Use of Swapping

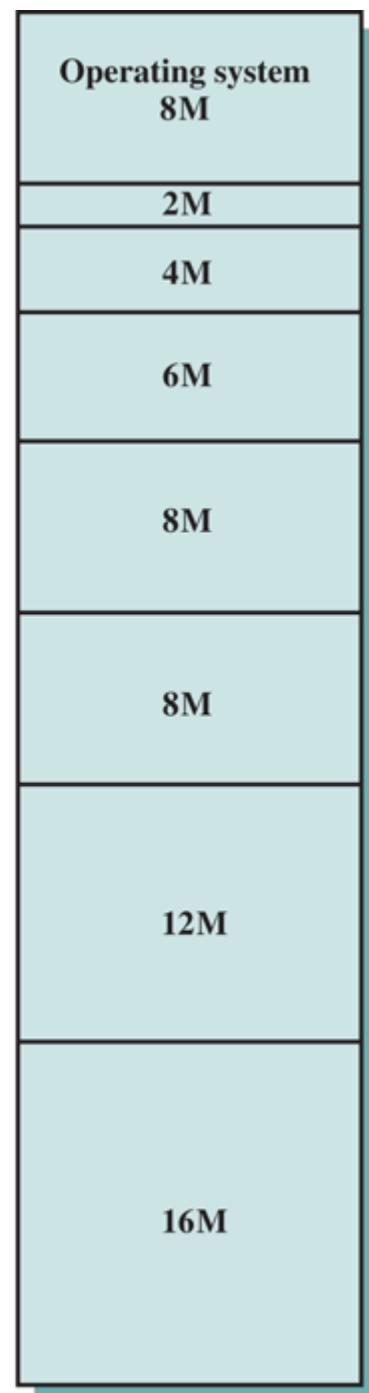

Swapping, however, is an I/O operation, and therefore there is the potential for making the problem worse, not better. But because disk I/O is generally the fastest I/O on a system (e.g., compared with tape or printer I/O), swapping will usually enhance performance. A more sophisticated scheme, involving virtual memory, improves performance over simple swapping. This will be discussed shortly. But first, we must prepare the ground by explaining partitioning and paging.

Partitioning

The simplest scheme for partitioning available memory is to use *fixed-size partitions*, as shown in **Figure 9.13**. Note that, although the partitions are of fixed size, they need not be of equal size. When a process is brought into memory, it is placed in the smallest available partition that will hold it.

(a) Equal-size partitions

(b) Unequal-size partitions

Figure 9.13 Example of Fixed Partitioning of a 64-Mbyte Memory

Even with the use of unequal fixed-size partitions, there will be wasted memory. In most cases, a process will not require exactly as much memory as provided by the partition. For example, a process that requires 3M bytes of memory would be placed in the 4M partition of [Figure 9.13b](#), wasting 1M that could be used by another process.

A more efficient approach is to use *variable-size partitions*. When a process is brought into memory, it is allocated exactly as much memory as it requires and no more.

Example 9.2

An example, using 64 Mbytes of main memory, is shown in [Figure 9.14](#). Initially, main memory is empty, except for the OS (a). The first three processes are loaded in, starting where the OS ends and occupying just enough space for each process (b, c, d). This leaves a “hole” at the end of

memory that is too small for a fourth process. At some point, none of the processes in memory is ready. The OS swaps out process 2 (e), which leaves sufficient room to load a new process, process 4 (f). Because process 4 is smaller than process 2, another small hole is created. Later, a point is reached at which none of the processes in main memory is ready, but process 2, in the ready-suspend state, is available. Because there is insufficient room in memory for process 2, the OS swaps process 1 out (g) and swaps process 2 back in (h).

As this example shows, this method starts out well, but eventually it leads to a situation in which there are a lot of small holes in memory. As time goes on, memory becomes more and more fragmented, and memory utilization declines. One technique for overcoming this problem is **compaction**: From time to time, the OS shifts the processes in memory to place all the free memory together in one block. This is a time-consuming procedure, wasteful of processor time.

Before we consider ways of dealing with the shortcomings of partitioning, we must clear up one loose end. Consider **Figure 9.14**; it should be obvious that a process is not likely to be loaded into the same place in main memory each time it is swapped in. Furthermore, if compaction is used, a process may be shifted while in main memory. A process in memory consists of instructions plus data. The instructions will contain addresses for memory locations of two types:

- Addresses of data items
- Addresses of instructions, used for branching instructions

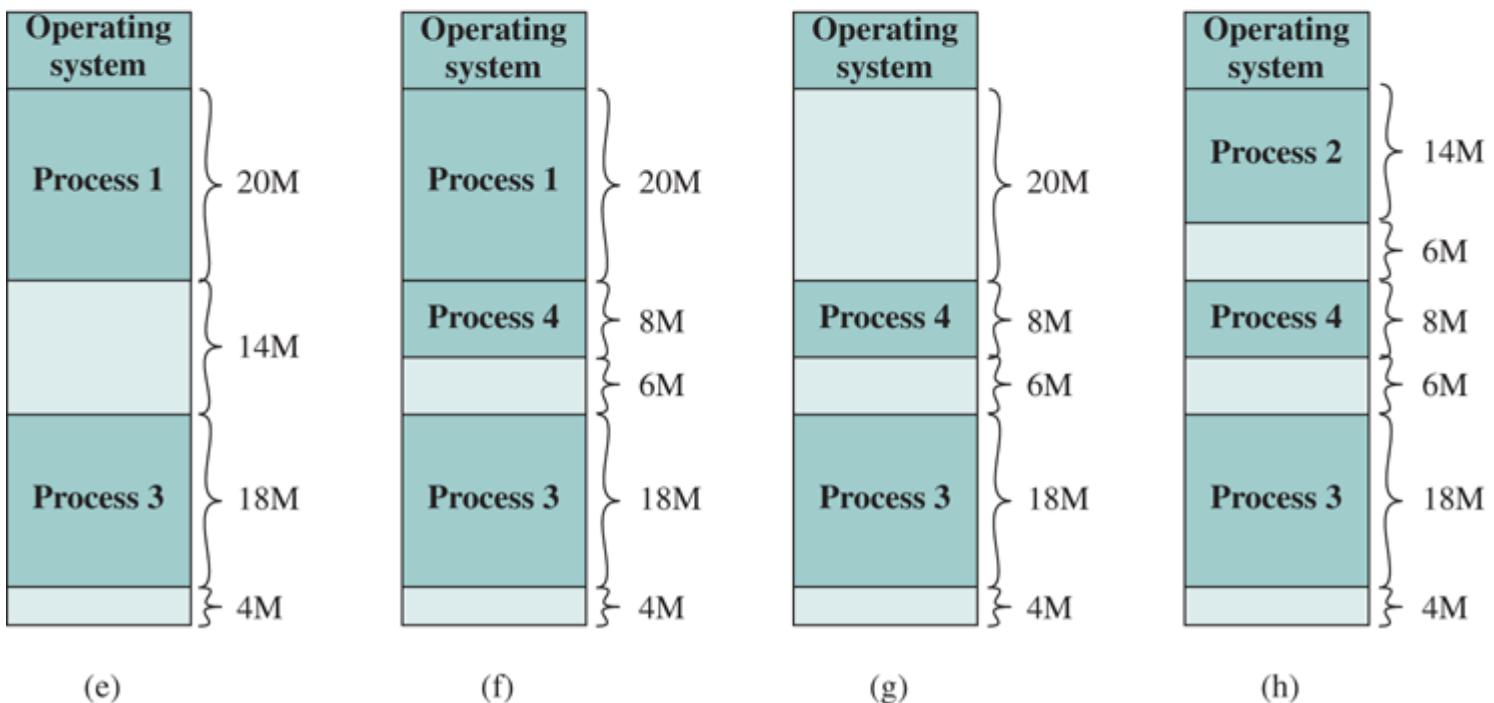

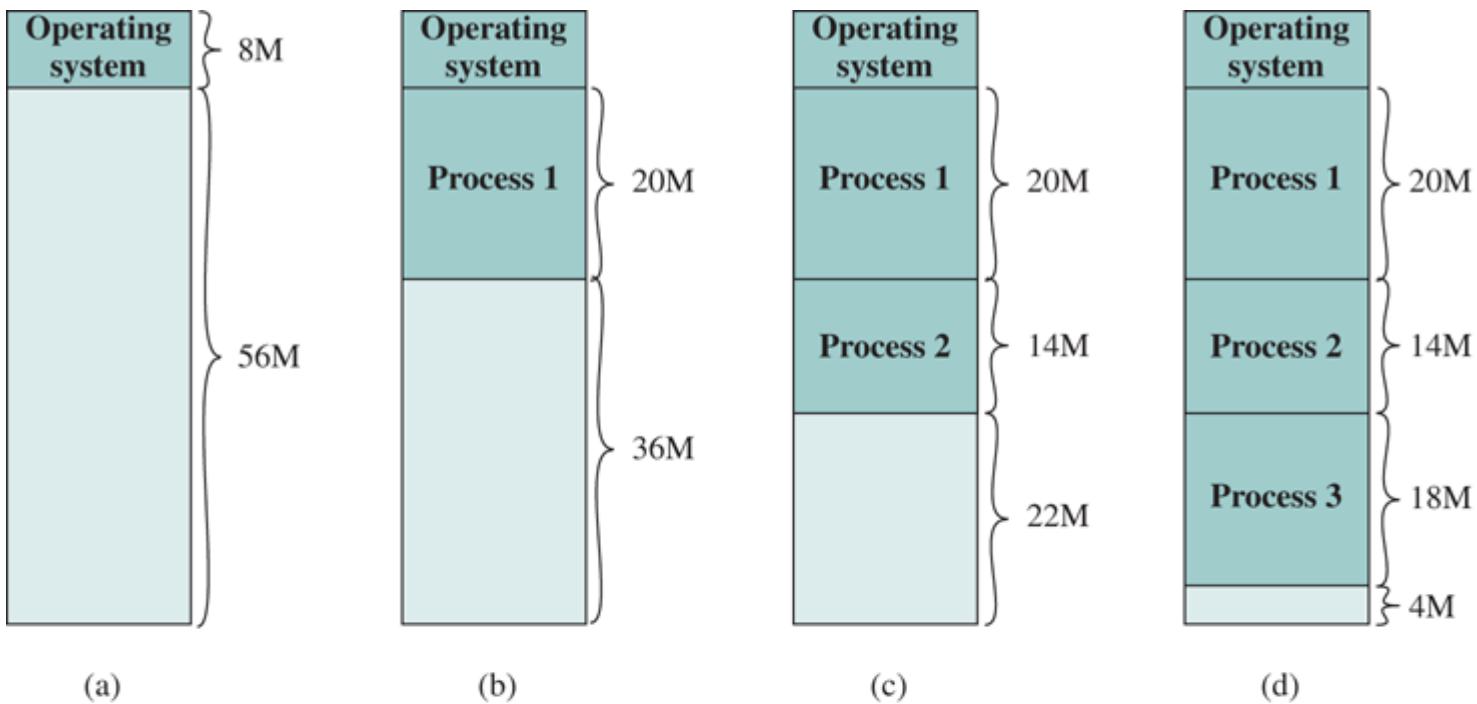

Figure 9.14 The Effect of Dynamic Partitioning

But these addresses are not fixed. They will change each time a process is swapped in. To solve this problem, a distinction is made between logical addresses and physical addresses. A **logical address** is expressed as a location relative to the beginning of the program. Instructions in the program contain only logical addresses. A **physical address** is an actual location in main memory. When the processor executes a process, it automatically converts from logical to physical address by adding the current starting location of the process, called its **base address**, to each logical address. This is another example of a processor hardware feature designed to meet an OS requirement. The exact nature of this hardware feature depends on the memory management strategy in use. We will see several examples later in this chapter.

Both unequal fixed-size and variable-size partitions are inefficient in the use of memory. Suppose, however, that memory is partitioned into equal fixed-size chunks that are relatively small, and that each process is also divided into small fixed-size chunks of some size. Then the chunks of a program, known as **pages**, could be assigned to available chunks of memory, known as **frames**, or page frames. At most, then, the wasted space in memory for that process is a fraction of the last page.

Figure 9.15 shows an example of the use of pages and frames. At a given point in time, some of the frames in memory are in use and some are free. The list of free frames is maintained by the OS. Process A, stored on disk, consists of four pages. When it comes time to load this process, the OS finds four free frames and loads the four pages of process A into the four frames.

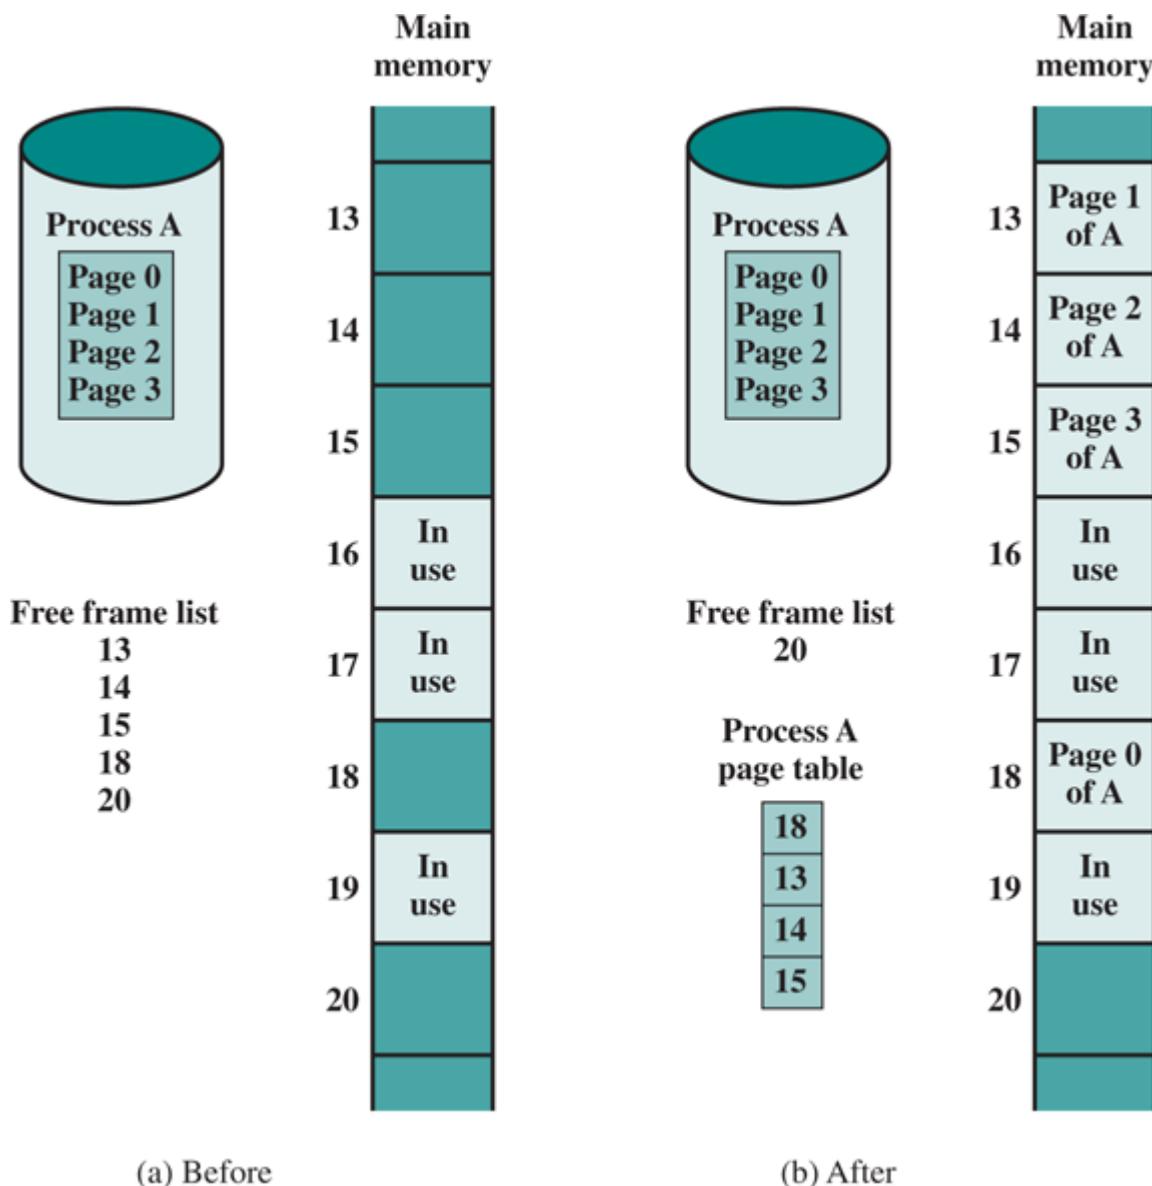

Figure 9.15 Allocation of Free Frames

Now suppose, as in this example, that there are not sufficient unused contiguous frames to hold the process. Does this prevent the OS from loading A? The answer is no, because we can once again use the concept of logical address. A simple base address will no longer suffice. Rather, the OS maintains a **page table** for each process. The page table shows the frame location for each page of the process. Within the program, each logical address consists of a page number and a relative address within the page. Recall that in the case of simple partitioning, a logical address is the location of a word relative to the beginning of the program; the processor translates that into a physical address. With paging, the logical-to-physical address translation is still done by processor hardware.

The processor must know how to access the page table of the current process. Presented with a logical address (page number, relative address), the processor uses the page table to produce a physical address (frame number, relative address). An example is shown in [Figure 9.16](#).

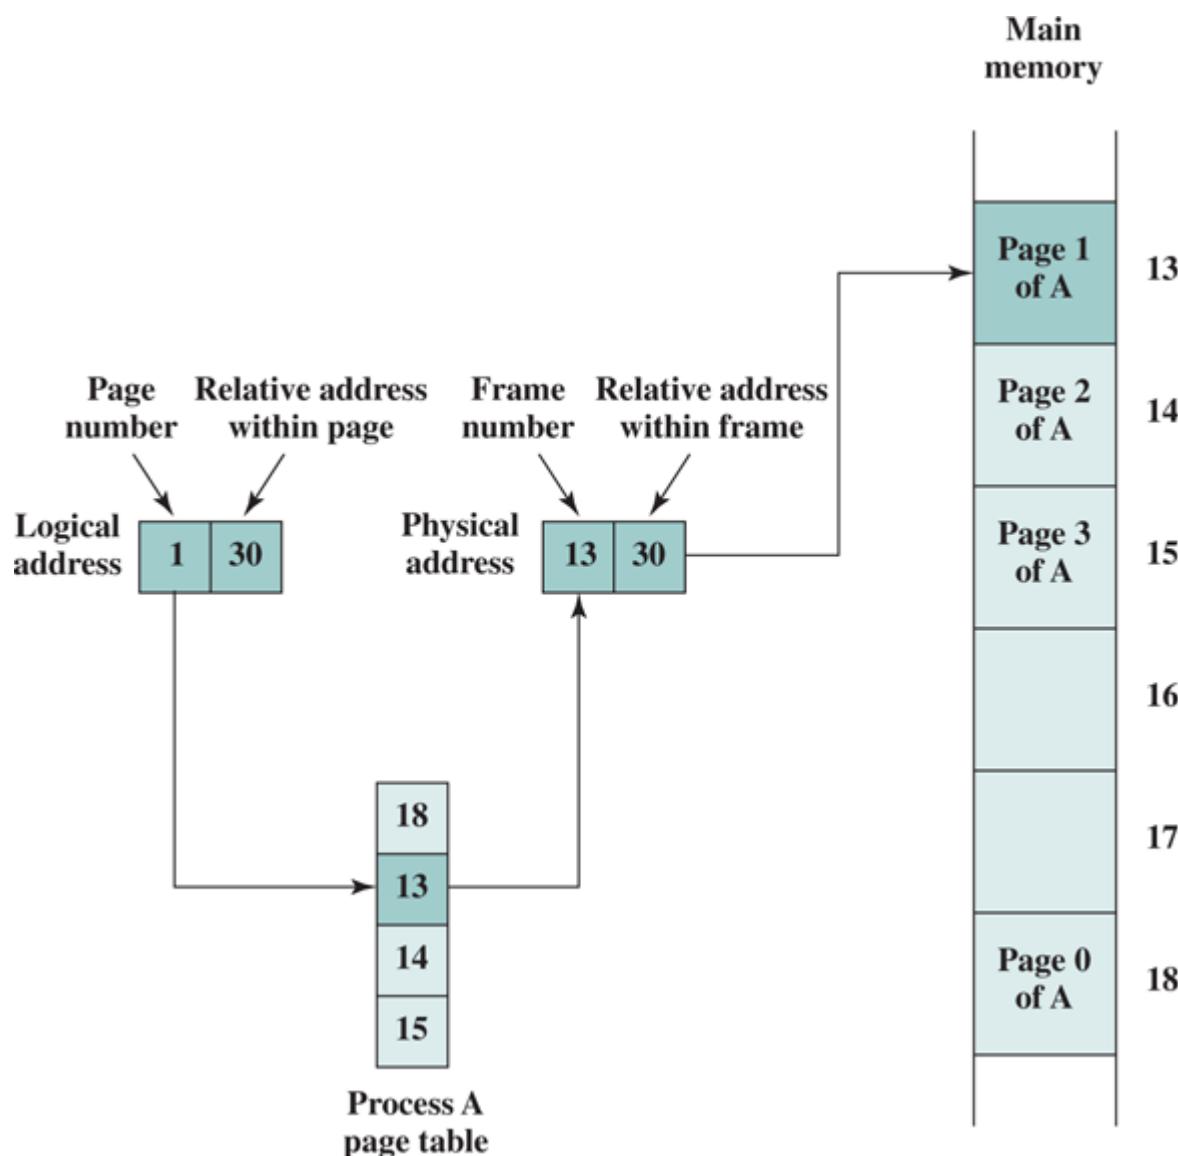

Figure 9.16 Logical and Physical Addresses

This approach solves the problems raised earlier. Main memory is divided into many small equal-size frames. Each process is divided into frame-size pages: smaller processes require fewer pages, larger processes require more. When a process is brought in, its pages are loaded into available frames, and a page table is set up.

Virtual Memory

DEMAND PAGING

With the use of paging, truly effective multiprogramming systems came into being. Furthermore, the simple tactic of breaking a process up into pages led to the development of another important concept: virtual memory.

To understand virtual memory, we must add a refinement to the paging scheme just discussed. That refinement is **demand paging**, which simply means that each page of a process is brought in only when it is needed, that is, on demand.

Consider a large process, consisting of a long program plus a number of arrays of data. Over any short period of time, execution may be confined to a small section of the program (e.g., a subroutine), and perhaps only one or two arrays of data are being used. This is the principle of locality, which we introduced in [Chapter 4](#). It would clearly be wasteful to load in dozens of pages for that process when only a few pages will be used before the program is suspended. We can make better use of memory by loading in just a few pages. Then, if the program branches to an instruction on a page not in main memory, or if the program references data on a page not in memory, a **page fault** is triggered. This tells the OS to bring in the desired page.

Thus, at any one time, only a few pages of any given process are in memory, and therefore more processes can be maintained in memory. Furthermore, time is saved because unused pages are not swapped in and out of memory. However, the OS must be clever about how it manages this scheme. When it brings one page in, it must throw another page out; this is known as **page replacement**. If it throws out a page just before it is about to be used, then it will just have to go get that page again almost immediately. Too much of this leads to a condition known as **thrashing**: the processor spends most of its time swapping pages rather than executing instructions. The avoidance of thrashing was a major research area in the 1970s and led to a variety of complex but effective algorithms. In essence, the OS tries to guess, based on recent history, which pages are least likely to be used in the near future.

Aleksandr Lukin/123RF

Page Replacement Algorithm Simulators

A discussion of page replacement algorithms is beyond the scope of this chapter. A potentially effective technique is least recently used (LRU), the same algorithm discussed in [Chapter 4](#) for cache replacement. In practice, LRU is difficult to implement for a virtual memory paging scheme. Several alternative approaches that seek to approximate the performance of LRU are in use.

With demand paging, it is not necessary to load an entire process into main memory. This fact has a remarkable consequence: *It is possible for a process to be larger than all of main memory*. One of the most fundamental restrictions in programming has been lifted. Without demand paging, a programmer must be acutely aware of how much memory is available. If the program being written is too large, the programmer must devise ways to structure the program into pieces that can be loaded one at a time. With demand paging, that job is left to the OS and the hardware. As far as the programmer is concerned, he or she is dealing with a huge memory, the size associated with disk storage.

Because a process executes only in main memory, that memory is referred to as **real memory**. But a programmer or user perceives a much larger memory—that which is allocated on the disk. This latter is therefore referred to as **virtual memory**. Virtual memory allows for very effective multiprogramming and relieves the user of the unnecessarily tight constraints of main memory.

PAGE TABLE STRUCTURE

The basic mechanism for reading a word from memory involves the translation of a virtual, or logical, address, consisting of page number and offset, into a physical address, consisting of frame number and offset, using a page table. Because the page table is of variable length, depending on the size of

the process, we cannot expect to hold it in registers. Instead, it must be in main memory to be accessed. **Figure 9.16** suggests a hardware implementation of this scheme. When a particular process is running, a register holds the starting address of the page table for that process. The page number of a virtual address is used to index that table and look up the corresponding frame number. This is combined with the offset portion of the virtual address to produce the desired real address.

In most systems, there is one page table per process. But each process can occupy huge amounts of virtual memory. For example, in the VAX architecture, each process can have up to $2^{31} = 2$ Gbytes of virtual memory. Using $2^9 = 512$ – byte pages, that means that as many as 2^{22} page table entries are required *per process*. Clearly, the amount of memory devoted to page tables alone could be unacceptably high. To overcome this problem, most virtual memory schemes store page tables in virtual memory rather than real memory. This means that page tables are subject to paging just as other pages are. When a process is running, at least a part of its page table must be in main memory, including the page table entry of the currently executing page. Some processors make use of a two-level scheme to organize large page tables. In this scheme, there is a page directory, in which each entry points to a page table. Thus, if the length of the page directory is X , and if the maximum length of a page table is Y , then a process can consist of up to $X \times Y$ pages. Typically, the maximum length of a page table is restricted to be equal to one page. We will see an example of this two-level approach when we consider the Intel x86 later in this chapter.

An alternative approach to the use of one- or two-level page tables is the use of an inverted page table structure (**Figure 9.17**). Variations on this approach are used on the PowerPC, UltraSPARC, and the IA-64 architecture. An implementation of the Mach OS on the RT-PC also uses this technique.

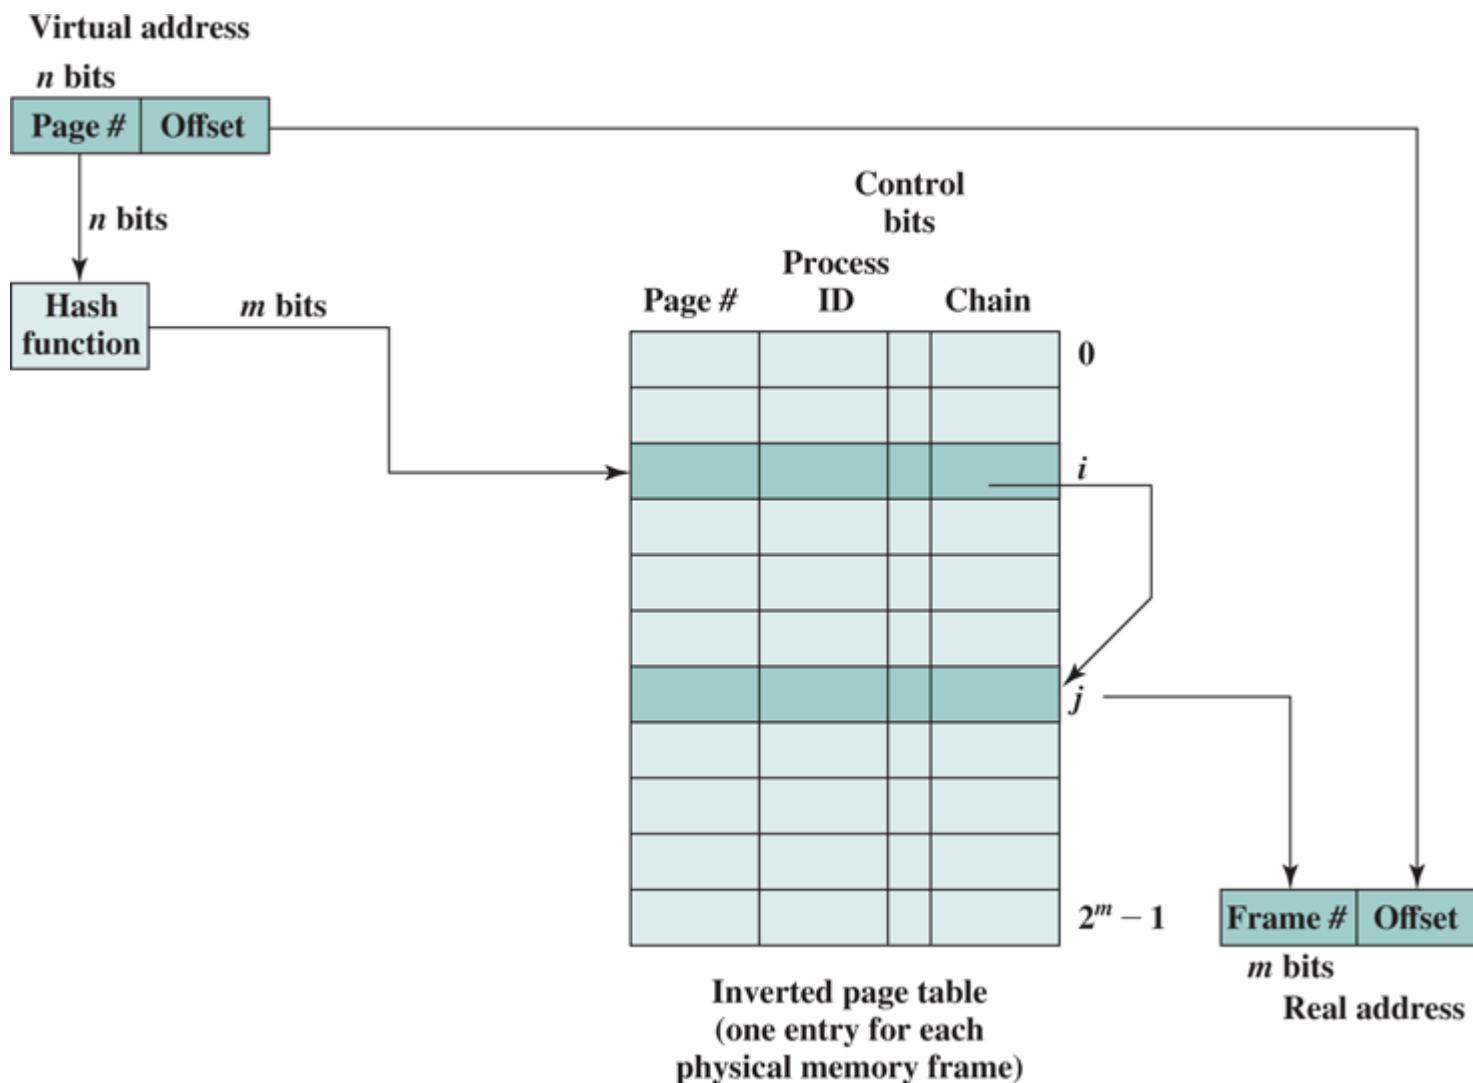

Figure 9.17 Inverted Page Table Structure

In this approach, the page number portion of a virtual address is mapped into a hash value using a simple hashing function.² The hash value is a pointer to the inverted page table, which contains the page table entries. There is one entry in the inverted page table for each real memory page frame, rather than one per virtual page. Thus a fixed proportion of real memory is required for the tables regardless of the number of processes or virtual pages supported. Because more than one virtual address may map into the same hash table entry, a chaining technique is used for managing the overflow. The hashing technique results in chains that are typically short—between one and two entries. The page table's structure is called *inverted* because it indexes page table entries by frame number rather than by virtual page number.

² A hash function maps numbers in the range 0 through M into numbers in the range 0 through N , where $M > N$. The output of the hash function is used as an index into the hash table. Since more than one input maps into the same output, it is possible for an input item to map to a hash table entry that is already occupied. In that case, the new item must *overflow* into another hash table location. Typically, the new item is placed in the first succeeding empty space, and a pointer from the original location is provided to chain the entries together.

Translation Lookaside Buffer

In principle, then, every virtual memory reference can cause two physical memory accesses: one to fetch the appropriate page table entry, and one to fetch the desired data. Thus, a straightforward virtual memory scheme would have the effect of doubling the memory access time. To overcome this problem, most virtual memory schemes make use of a special cache for page table entries, usually called a **translation lookaside buffer (TLB)**. This cache functions in the same way as a memory cache and contains those page table entries that have been most recently used. **Figure 9.18** is a flowchart that shows the use of the TLB. By the principle of locality, most virtual memory references will be to locations in recently used pages. Therefore, most references will involve page table entries in the cache. Numerous studies have shown that this scheme can significantly improve performance [MITT17b].

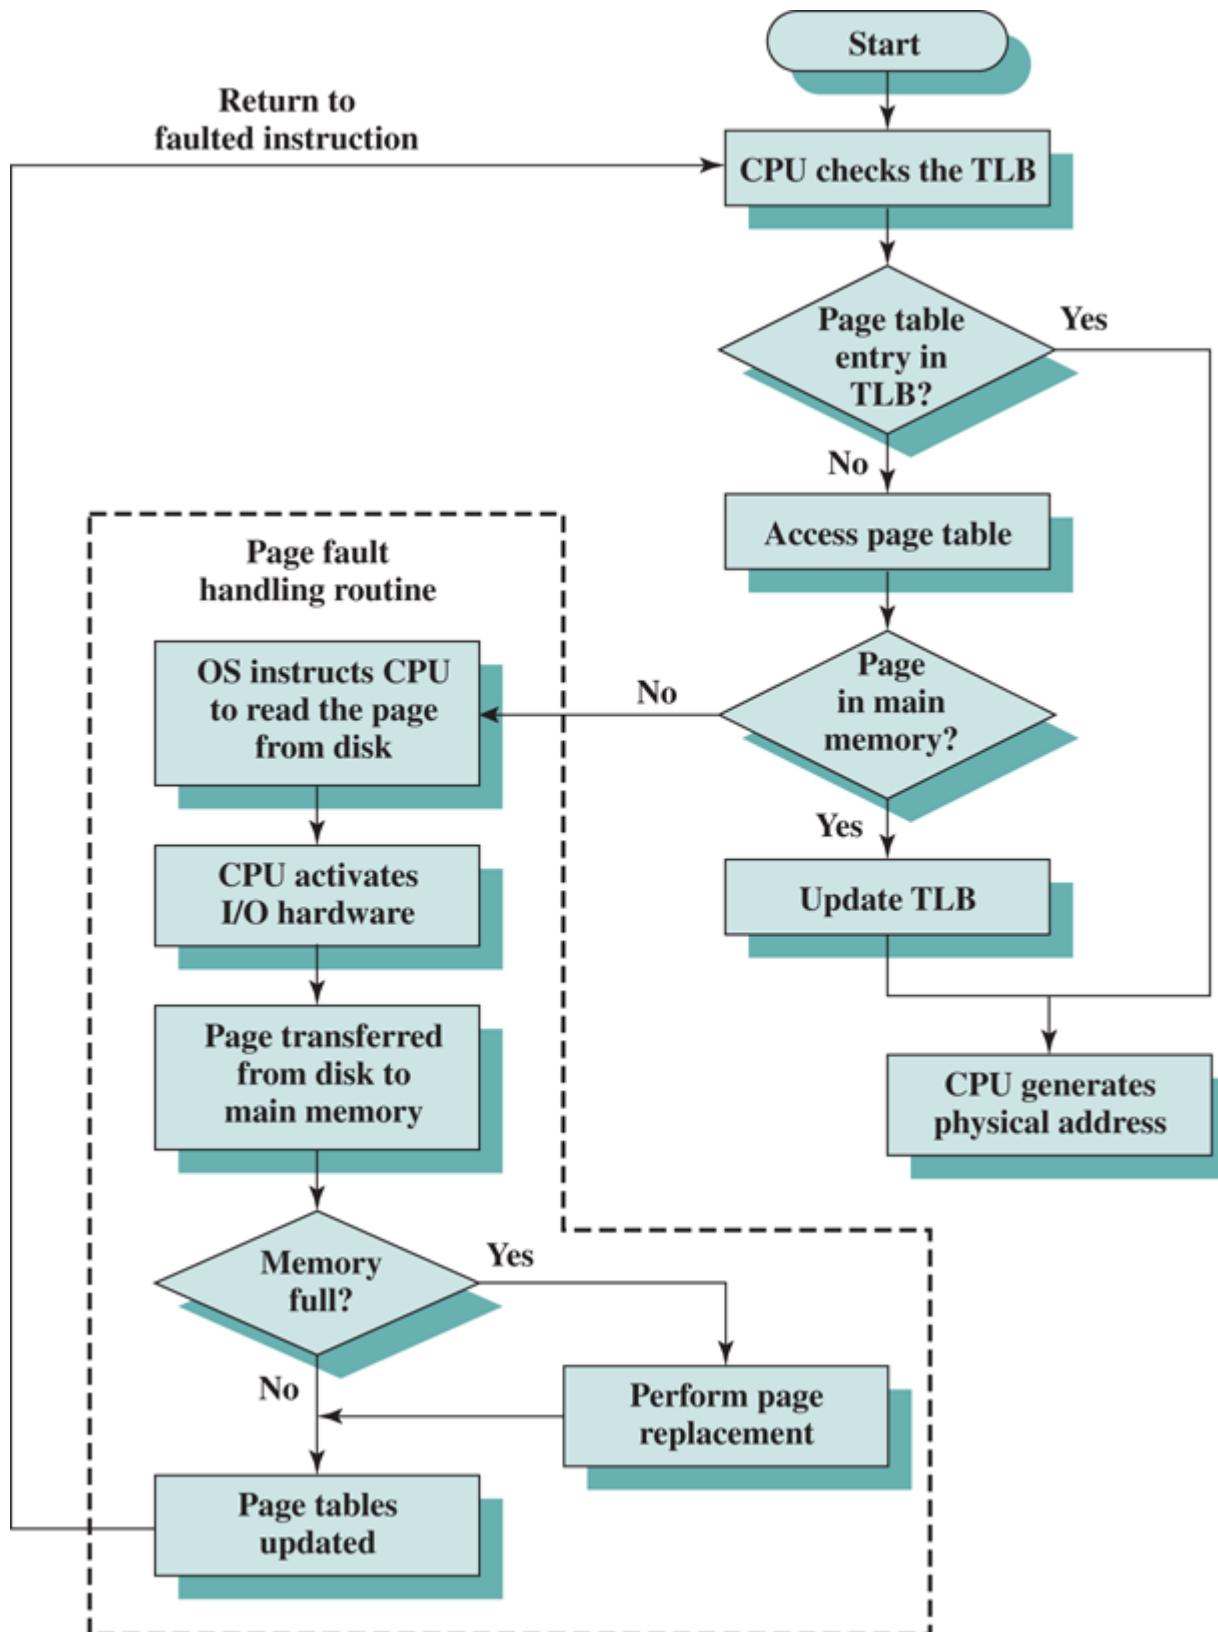

Figure 9.18 Operation of Paging and Translation Lookaside Buffer (TLB)

Note that the virtual memory mechanism must interact with the cache system (not the TLB cache, but the main memory cache). This is illustrated in [Figure 9.19](#). A virtual address will generally be in the form of a page number, offset. First, the memory system consults the TLB to see if the matching page table entry is present. If it is, the real (physical) address is generated by combining the frame number with the offset. If not, the entry is accessed from a page table. Once the real address is generated, which is in the form of a tag and a remainder, the cache is consulted to see if the block containing that word is present (see [Figure 5.3](#)). If so, it is returned to the processor. If not, the word is retrieved from main memory. The TLB is sometimes implemented as content-addressable memory (CAM). The CAM

search key is the virtual address and the search result is a physical address. If the requested address is present in the TLB, the CAM search yields a match quickly and the retrieved physical address can be used to access memory.

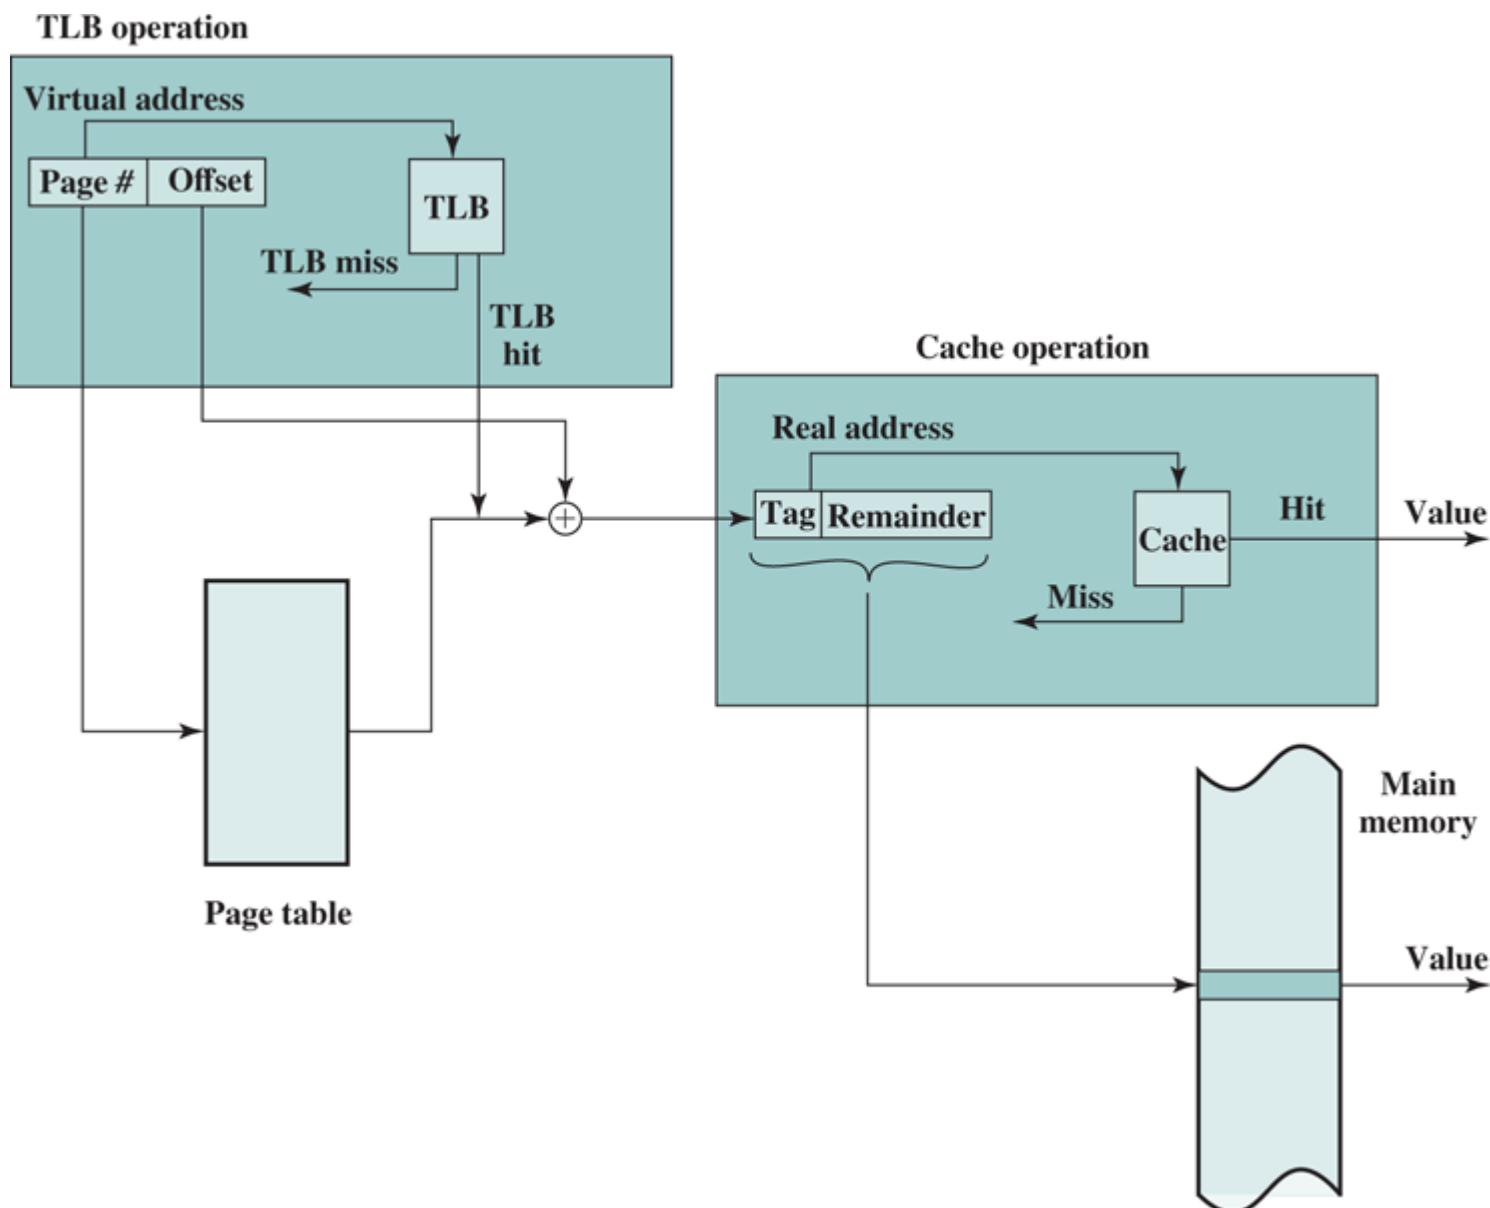

Figure 9.19 Translation Lookaside Buffer and Cache Operation

The reader should be able to appreciate the complexity of the processor hardware involved in a single memory reference. The virtual address is translated into a real address. This involves reference to a page table, which may be in the TLB, in main memory, or on disk. The referenced word may be in cache, in main memory, or on disk. In the latter case, the page containing the word must be loaded into main memory and its block loaded into the cache. In addition, the page table entry for that page must be updated.

Segmentation

There is another way in which addressable memory can be subdivided, known as *segmentation*. Whereas paging is invisible to the programmer and serves the purpose of providing the programmer with a larger address space, segmentation is usually visible to the programmer and is provided as a convenience for organizing programs and data, and as a means for associating privilege and protection attributes with instructions and data.

Segmentation allows the programmer to view memory as consisting of multiple address spaces or segments. Segments are of variable, indeed dynamic, size. Typically, the programmer or the OS will assign programs and data to different segments. There may be a number of program segments for various types of programs, as well as a number of data segments. Each segment may be assigned access and usage rights. Memory references consist of a (segment number, offset) form of address.

This organization has a number of advantages to the programmer over a non-segmented address space:

1. It simplifies the handling of growing data structures. If the programmer does not know ahead of time how large a particular data structure will become, it is not necessary to guess. The data structure can be assigned its own segment, and the OS will expand or shrink the segment as needed.
2. It allows programs to be altered and recompiled independently without requiring that an entire set of programs be relinked and reloaded. Again, this is accomplished using multiple segments.
3. It lends itself to sharing among processes. A programmer can place a utility program or a useful table of data in a segment that can be addressed by other processes.
4. It lends itself to protection. Because a segment can be constructed to contain a well-defined set of programs or data, the programmer or a system administrator can assign access privileges in a convenient fashion.

These advantages are not available with paging, which is invisible to the programmer. On the other hand, we have seen that paging provides for an efficient form of memory management. To combine the advantages of both, some systems are equipped with the hardware and OS software to provide both.

9.4 Intel x86 Memory Management

Since the introduction of the 32-bit architecture, microprocessors have evolved sophisticated memory management schemes that build on the lessons learned with medium- and large-scale systems. In many cases, the microprocessor versions are superior to their larger-system antecedents. Because the schemes were developed by the microprocessor hardware vendor and may be employed with a variety of operating systems, they tend to be quite general purpose. A representative example is the scheme used on the Intel x86 architecture.

Address Spaces

The x86 includes hardware for both segmentation and paging. Both mechanisms can be disabled, allowing the user to choose from four distinct views of memory:

- **Unsegmented unpaged memory:** In this case, the virtual address is the same as the physical address. This is useful, for example, in low-complexity, high-performance controller applications.
- **Unsegmented paged memory:** Here memory is viewed as a paged linear address space. Protection and management of memory is done via paging. This is favored by some operating systems (e.g., Berkeley UNIX).
- **Segmented unpaged memory:** Here memory is viewed as a collection of logical address spaces. The advantage of this view over a paged approach is that it affords protection down to the level of a single byte, if necessary. Furthermore, unlike paging, it guarantees that the translation table needed (the segment table) is on-chip when the segment is in memory. Hence, segmented unpaged memory results in predictable access times.
- **Segmented paged memory:** Segmentation is used to define logical memory partitions subject to access control, and paging is used to manage the allocation of memory within the partitions. Operating systems such as UNIX System V favor this view.

Segmentation

When segmentation is used, each virtual address (called a logical address in the x86 documentation) consists of a 16-bit segment reference and a 32-bit offset. Two bits of the segment reference deal with the protection mechanism, leaving 14 bits for specifying a particular segment. Thus, with unsegmented memory, the user's virtual memory is $2^{32} = 4\text{Gbytes}$. With segmented memory, the total virtual memory space as seen by a user is $2^{46} = 64\text{terabytes (Tbytes)}$. The physical address space employs a 32-bit address for a maximum of 4 Gbytes.

The amount of virtual memory can actually be larger than the 64 Tbytes. This is because the processor's interpretation of a virtual address depends on which process is currently active. Virtual address space is divided into two parts. One-half of the virtual address space (8K segments \times 4Gbytes) is global, shared by all processes; the remainder is local and is distinct for each process.

Associated with each segment are two forms of protection: privilege level and access attribute. There are four privilege levels, from most protected (level 0) to least protected (level 3). The privilege level associated with a data segment is its "classification"; the privilege level associated with a program segment is its "clearance." An executing program may only access data segments for which its clearance level is lower than (more privileged) or equal to (same privilege) the privilege level of the data segment.

The hardware does not dictate how these privilege levels are to be used; this depends on the OS

design and implementation. It was intended that privilege level 1 would be used for most of the OS, and level 0 would be used for that small portion of the OS devoted to memory management, protection, and access control. This leaves two levels for applications. In many systems, applications will reside at level 3, with level 2 being unused. Specialized application subsystems that must be protected because they implement their own security mechanisms are good candidates for level 2. Some examples are database management systems, office automation systems, and software engineering environments.

In addition to regulating access to data segments, the privilege mechanism limits the use of certain instructions. Some instructions, such as those dealing with memory-management registers, can only be executed in level 0. I/O instructions can only be executed up to a certain level that is designated by the OS; typically, this will be level 1.

The access attribute of a data segment specifies whether read/write or read-only accesses are permitted. For program segments, the access attribute specifies read/execute or read-only access.

The address translation mechanism for segmentation involves mapping a virtual address into what is referred to as a linear address ([Figure 9.20b](#)). A virtual address consists of the 32-bit offset and a 16-bit segment selector ([Figure 9.20a](#)). An instruction fetching or storing an operand specifies the offset and a register containing the segment selector. The segment selector consists of the following fields:

15	3 2 1 0
Index	T I RPL

TI = Table indicator

RPL = Requestor privilege level

(a) Segment selector

31	22 21	12 11	0
Directory	Table	Offset	

(b) Linear address

31	24 23 22	20 19	16 15 14 13 12 11	8 7	0
Base 31...24	G B	D / L A V L	Segment limit 19...16	P DPL S Type	Base 23...16
Base 15...0			Segment limit 15...0		

AVL = Available for use by system software

L = 64-bit code segment

Base = Segment base address

(64-bit mode only)

D/B = Default operation size

P = Segment present

DPL = Descriptor privilege size

Type = Segment type

G = Granularity

S = Descriptor type

(c) Segment descriptor (segment table entry)

31	12 11 9	7 6 5	4 3 2 1 0	
Page frame address 31...12		AVL	P S 0 A D T	P P U R W P

AVL = Available for systems programmer use

PWT = Write through

 = Reserved

P = Page size

US = User/supervisor

A = Accessed

RW = Read-write

PCD = Cache disable

P = Present

(d) Page directory entry

31	12 11 9	7 6 5	4 3 2 1 0	
Page frame address 31...12		AVL	D A D T	P P U R W P

D = Dirty

(e) Page table entry

Figure 9.20 Intel x86 Memory Management Formats

- **Table Indicator (TI):** Indicates whether the global segment table or a local segment table should be used for translation.

- Segment Number:** The number of the segment. This serves as an index into the segment table.
 - **Requested Privilege Level (RPL):** The privilege level requested for this access.
- Each entry in a segment table consists of 64 bits, as shown in [Figure 9.20c](#). The fields are defined in [Table 9.5](#).

Table 9.5 x86 Memory Management Parameters

Segment Descriptor (Segment Table Entry)	
Base	Defines the starting address of the segment within the 4-Gbyte linear address space.
D/B bit	In a code segment, this is the D bit and indicates whether operands and addressing modes are 16 or 32 bits.
Descriptor Privilege Level (DPL)	Specifies the privilege level of the segment referred to by this segment descriptor.
Granularity bit (G)	Indicates whether the Limit field is to be interpreted in units by one byte or 4 Kbytes.
Limit	Defines the size of the segment. The processor interprets the limit field in one of two ways, depending on the granularity bit: in units of one byte, up to a segment size limit of 1 Mbyte, or in units of 4 Kbytes, up to a segment size limit of 4 Gbytes.
S bit	Determines whether a given segment is a system segment or a code or data segment.
Segment Present bit (P)	Used for nonpaged systems. It indicates whether the segment is present in main memory. For paged systems, this bit is always set to 1.
Type	Distinguishes between various kinds of segments and indicates the access attributes.
Page Directory Entry and Page Table Entry	

Accessed bit (A)

This bit is set to 1 by the processor in both levels of page tables when a read or write operation to the corresponding page occurs.

Dirty bit (D)

This bit is set to 1 by the processor when a write operation to the corresponding page occurs.

Page Frame Address

Provides the physical address of the page in memory if the present bit is set. Since page frames are aligned on 4K boundaries, the bottom 12 bits are 0, and only the top 20 bits are included in the entry. In a page directory, the address is that of a page table.

Page Cache Disable bit (PCD)

Indicates whether data from page may be cached.

Page Size bit (PS)

Indicates whether page size is 4 Kbyte or 4 Mbyte.

Page Write Through bit (PWT)

Indicates whether write-through or write-back caching policy will be used for data in the corresponding page.

Present bit (P)

Indicates whether the page table or page is in main memory.

Read/Write bit (RW)

For user-level pages, indicates whether the page is read-only access or read/write access for user-level programs.

User/Supervisor bit (US)

Indicates whether the page is available only to the operating system (supervisor level) or is available to both operating system and applications (user level).

Paging

Segmentation is an optional feature and may be disabled. When segmentation is in use, addresses

used in programs are virtual addresses and are converted into linear addresses, as just described. When segmentation is not in use, linear addresses are used in programs. In either case, the following step is to convert that linear address into a real 32-bit address.

To understand the structure of the linear address, you need to know that the x86 paging mechanism is actually a two-level table lookup operation. The first level is a page directory, which contains up to 1024 entries. This splits the 4-Gbyte linear memory space into 1024 page groups, each with its own page table, and each 4 Mbytes in length. Each page table contains up to 1024 entries; each entry corresponds to a single 4-Kbyte page. Memory management has the option of using one page directory for all processes, one page directory for each process, or some combination of the two. The page directory for the current task is always in main memory. Page tables may be in virtual memory.

Figure 9.20 shows the formats of entries in page directories and page tables, and the fields are defined in **Table 9.5**. Note that access control mechanisms can be provided on a page or page group basis.

The x86 also makes use of a translation lookaside buffer. The buffer can hold 32 page table entries. Each time that the page directory is changed, the buffer is cleared.

Figure 9.21 illustrates the combination of segmentation and paging mechanisms. For clarity, the translation lookaside buffer and memory cache mechanisms are not shown.

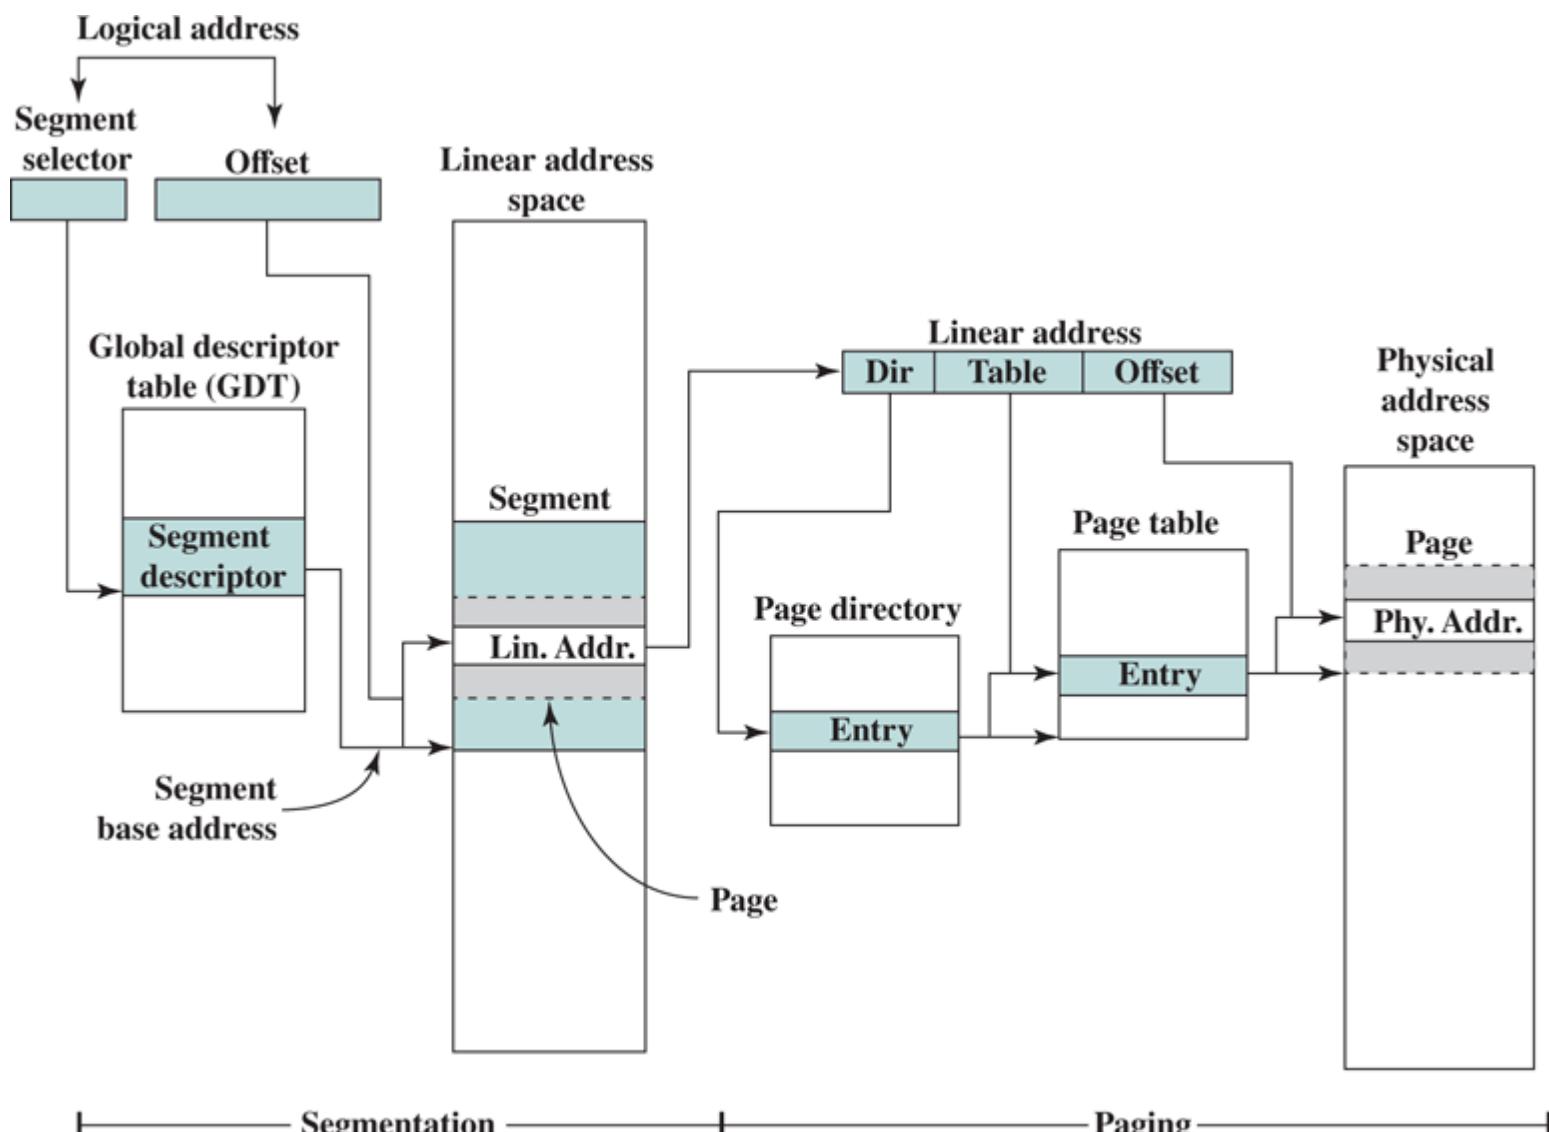

Figure 9.21 Intel x86 Memory Address Translation Mechanisms

Finally, the x86 includes a new extension not found on the earlier 80386 or 80486, the provision for two page sizes. If the PSE (page size extension) bit in control register 4 is set to 1, then the paging unit permits the OS programmer to define a page as either 4 Kbyte or 4 Mbyte in size.

When 4-Mbyte pages are used, there is only one level of table lookup for pages. When the hardware accesses the page directory, the page directory entry (**Figure 9.20d**) has the PS bit set to 1. In this case, bits 9 through 21 are ignored and bits 22 through 31 define the base address for a 4-Mbyte page in memory. Thus, there is a single page table.

The use of 4-Mbyte pages reduces the memory-management storage requirements for large main memories. With 4-Kbyte pages, a full 4-Gbyte main memory requires about 4 Mbytes of memory just for the page tables. With 4-Mbyte pages, a single table, 4 Kbytes in length, is sufficient for page memory management.

9.5 ARM Memory Management

ARM provides a versatile virtual memory system architecture that can be tailored to the needs of the embedded system designer.

Memory System Organization

Figure 9.22 provides an overview of the memory management hardware in the ARM for virtual memory. The virtual memory translation hardware uses one or two levels of tables for translation from virtual to physical addresses, as explained subsequently. The translation lookaside buffer (TLB) is a cache of recent page table entries. If an entry is available in the TLB, then the TLB directly sends a physical address to main memory for a read or write operation. As explained in [Chapter 5](#), data is exchanged between the processor and main memory via the cache. If a logical cache organization is used (**Figure 5.5a**), then the ARM supplies that address directly to the cache as well as supplying it to the TLB when a cache miss occurs. If a physical cache organization is used (**Figure 5.5b**), then the TLB must supply the physical address to the cache.

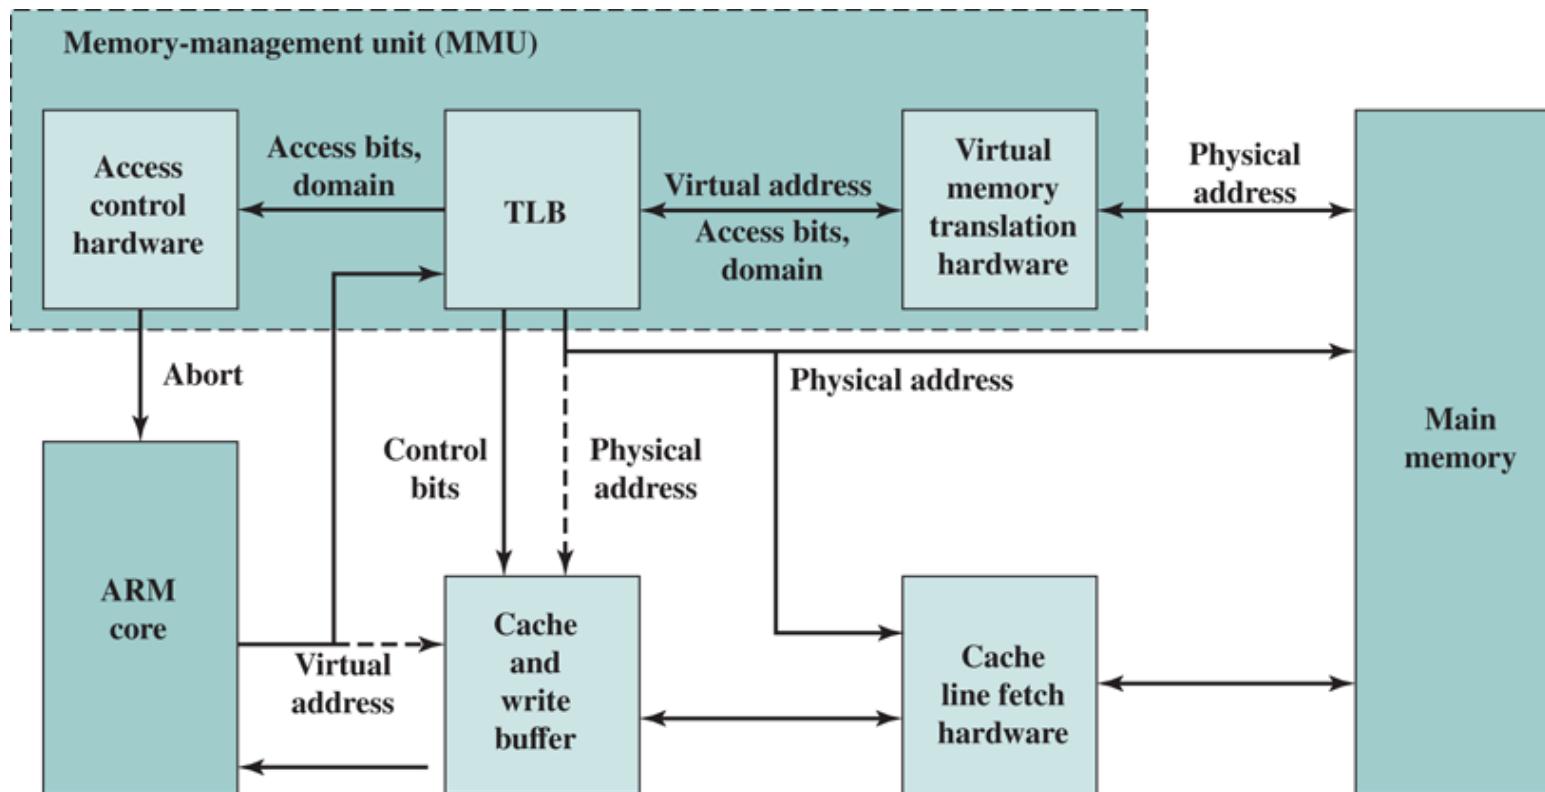

Figure 9.22 ARM Memory System Overview

Entries in the translation tables also include access control bits, which determine whether a given process may access a given portion of memory. If access is denied, access control hardware supplies an abort signal to the ARM processor.

Virtual Memory Address Translation

The ARM supports memory access based on either sections or pages:

- **Supersections (optional):** Consist of 16-MB blocks of main memory.
- **Sections:** Consist of 1-MB blocks of main memory.

- **Large pages:** Consist of 64-kB blocks of main memory.
- **Small pages:** Consist of 4-kB blocks of main memory.

Sections and supersections are supported to allow mapping of a large region of memory while using only a single entry in the TLB. Additional access control mechanisms are extended within small pages to 1kB subpages, and within large pages to 16kB subpages. The translation table held in main memory has two levels:

- **Level 1 table:** Holds level 1 descriptors that contain the base address and translation properties for a Section and Supersection; and translation properties and pointers to a level 2 table for a large page or a small page.
- **Level 2 table:** Holds level 2 descriptors that contain the base address and translation properties for a Small page or a Large page. A level 2 table requires 1 kB of memory.

The memory-management unit (MMU) translates virtual addresses generated by the processor into physical addresses to access main memory, and also derives and checks the access permission. Translations occur as the result of a TLB miss, and start with a first-level fetch. A section-mapped access only requires a first-level fetch, whereas a page-mapped access also requires a second-level fetch.

Figure 9.23 shows the two-level address translation process for small pages. There is a single level 1 (L1) page table with 4K 32-bit entries. Each L1 entry points to a level 2 (L2) page table with 256 32-bit entries. Each of the L2 entry points to a 4-kB page in main memory. The 32-bit virtual address is interpreted as follows: The most significant 12 bits are an index into the L1 page table. The next 8 bits are an index into the relevant L2 page table. The least significant 12 bits index a byte in the relevant page in main memory.

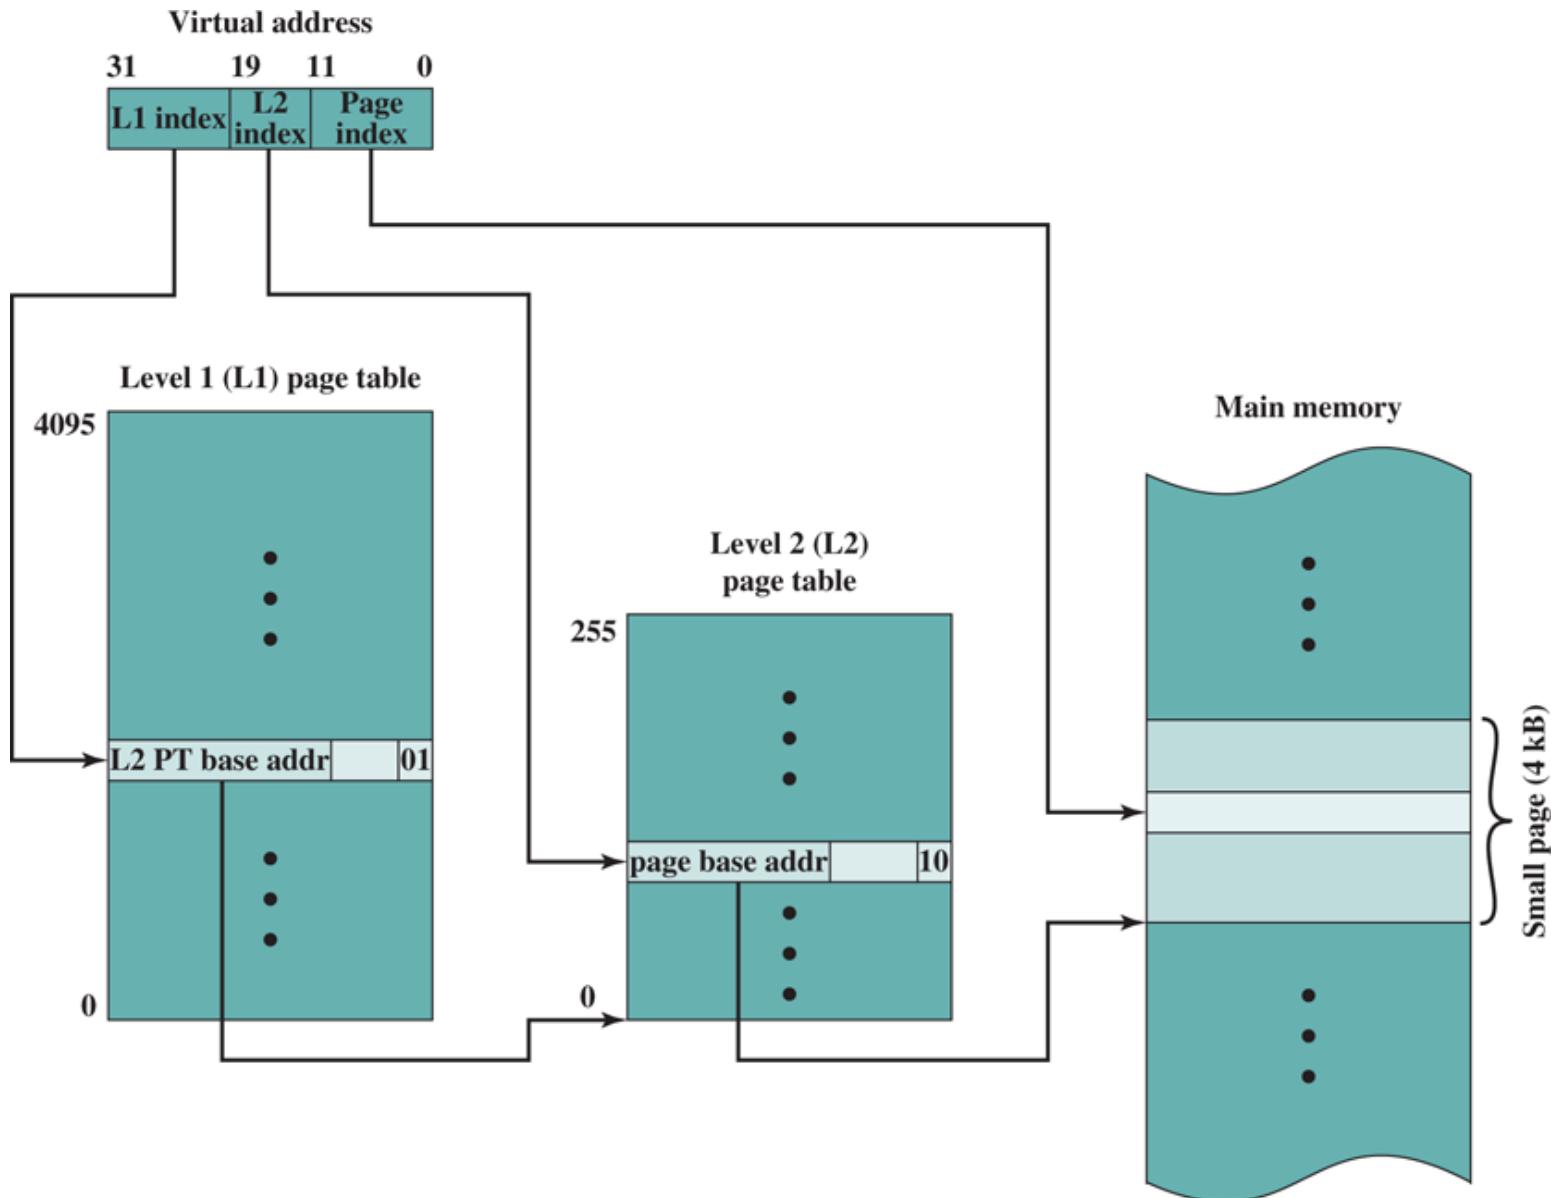

Figure 9.23 ARM Virtual Memory Address Translation for Small Pages

A similar two-page lookup procedure is used for large pages. For sections and supersections, only the L1 page table lookup is required.

Memory-Management Formats

To get a better understanding of the ARM memory management scheme, we consider the key formats, as shown in [Figure 9.24](#). The control bits shown in this figure are defined in [Table 9.6](#).

	31	24 23	20 19	14	12 11 10 9 8	5 4 3 2 1 0			
Fault			IGN		0 0				
Page table	Coarse page table base address		P	Domain	SBZ	0 1			
Section	Section base address		S B Z	0 n G	S AP X	TEX	AP P	Domain	X N C B 1 0
Supersection	Supersection base address	Base address [35:32]	S B Z	1 n G	S AP X	TEX	AP P	Base address [39:36]	X N C B 1 0

(a) Alternative first-level descriptor formats

	31	16 15 14	12 11 10 9 8 7 6 5 4 3 2 1 0					
Fault			IGN		0 0			
Small page	Small page base address		n G	S AP X	TEX	AP	C B 1 X N	
Large page	Large page base address		X N	TEX	n G S AP X	SBZ	AP	C B 0 1

(b) Alternative second-level descriptor formats

	31	24 23	20 19	0
Supersection	Level 1 table index	Supersection index		
Section	Level 1 table index	Section index		
Small page	Level 1 table index	Level 2 table index	Page index	
Large page	Level 1 table index	Level 2 table index	Page index	

(c) Virtual memory address formats

Figure 9.24 ARM Memory-Management Formats

Table 9.6 ARM Memory-Management Parameters

Access Permission (AP), Access Permission Extension (APX)

These bits control access to the corresponding memory region. If an access is made to an area of memory without the required permissions, a Permission Fault is raised.

Bufferable (B) bit

Determines, with the TEX bits, how the write buffer is used for cacheable memory.

Cacheable (C) bit

Determines whether this memory region can be mapped through the cache.

Domain

Collection of memory regions. Access control can be applied on the basis of domain.

not Global (nG)

Determines whether the translation should be marked as global (0), or process specific (1).

Shared (S)

Determines whether the translation is for not-shared (0), or shared (1) memory.

SBZ

Should be zero.

Type Extension (TEX)

These bits, together with the B and C bits, control accesses to the caches, how the write buffer is used, and if the memory region is shareable and therefore must be kept coherent.

Execute Never (XN)

Determines whether the region is executable (0) or not executable (1).

For the L1 table, each entry is a descriptor of how its associated 1-MB virtual address range is mapped. Each entry has one of four alternative formats:

- **Bits [1 : 0] = 00:** The associated virtual addresses are unmapped, and attempts to access them generate a translation fault.
- **Bits [1 : 0] = 01:** The entry gives the physical address of an L2 page table, which specifies how the associated virtual address range is mapped.
- **Bits [1 : 0] = 01: and bit19 = 0:** The entry is a section descriptor for its associated virtual addresses.
- **Bits [1 : 0] = 01: and bit19 = 1:** The entry is a supersection descriptor for its associated virtual addresses.

Entries with bits [1 : 0] = 11 are reserved.

For memory structured into pages, a two-level page table access is required. Bits [31:10] of the L1 page entry contain a pointer to a L2 page table. For small pages, the L2 entry contains a 20-bit pointer to the base address of a 4-kB page in main memory.

For large pages, the structure is more complex. As with virtual addresses for small pages, a virtual address for a large page structure includes a 12-bit index into the level one table and an 8-bit index into the L2 table. For the 64-kB large pages, the page index portion of the virtual address must be 16 bits. To accommodate all of these bits in a 32-bit format, there is a 4-bit overlap between the page index field and the L2 table index field. ARM accommodates this overlap by requiring that each page table entry in a L2 page table that supports large pages be replicated 16 times. In effect, the size of the L2 page table is reduced from 256 entries to 16 entries, if all of the entries refer to large pages. However, a given L2 page can service a mixture of large and small pages, hence the need for the replication of large page entries.

For memory structured into sections or supersections, a one-level page table access is required. For sections, bits [31:20] of the L1 entry contain a 12-bit pointer to the base of the 1-MB section in main memory.

For supersections, bits [31:24] of the L1 entry contain an 8-bit pointer to the base of the 16-MB section in main memory. As with large pages, a page table entry replication is required. In the case of supersections, the L1 table index portion of the virtual address overlaps by 4 bits with the supersection index portion of the virtual address. Therefore, 16 identical L1 page table entries are required.

The range of physical address space can be expanded by up to eight additional address bits (bits [23:20] and [8:5]). The number of additional bits is implementation dependent. These additional bits can be interpreted as extending the size of physical memory by as much as a factor of $2^8 = 256$. Thus, physical memory may in fact be as much as 256 times as large as the memory space available to each individual process.

Access Control

The AP access control bits in each table entry control access to a region of memory by a given process. A region of memory can be designated as no access, read only, or read-write. Further, the region can be designated as privileged access only, reserved for use by the OS and not by applications.

ARM also employs the concept of a domain, which is a collection of sections and/or pages that have particular access permissions. The ARM architecture supports 16 domains. The domain feature allows multiple processes to use the same translation tables while maintaining some protection from each other.

Each page table entry and TLB entry contains a field that specifies which domain the entry is in. A 2-bit field in the Domain Access Control Register controls access to each domain. Each field allows the access to an entire domain to be enabled and disabled very quickly, so that whole memory areas can be swapped in and out of virtual memory very efficiently. Two kinds of domain access are supported:

- **Clients:** Users of domains (execute programs and access data) that must observe the access permissions of the individual sections and/or pages that make up that domain.
- **Managers:** Control the behavior of the domain (the current sections and pages in the domain, and the domain access), and bypass the access permissions for table entries in that domain.

One program can be a client of some domains, and a manager of some other domains, and have no access to the remaining domains. This allows very flexible memory protection for programs that

access different memory resources.

- 9.6 If a process may be dynamically assigned to different locations in main memory, what is the implication for the addressing mechanism?
- 9.7 Is it necessary for all of the pages of a process to be in main memory while the process is executing?
- 9.8 Must the pages of a process in main memory be contiguous?
- 9.9 Is it necessary for the pages of a process in main memory to be in sequential order?
- 9.10 What is the purpose of a translation lookaside buffer?

Problems

9.1 Suppose that we have a multiprogrammed computer in which each job has identical characteristics. In one computation period, T , for a job, half the time is spent in I/O and the other half in processor activity. Each job runs for a total of N periods. Assume that a simple round-robin priority is used, and that I/O operations can overlap with processor operation. Define the following quantities:

- Turnaround time = actual to complete a job..
- Throughput = average number of jobs completed per time period T .
- Processor utilization = percentage of time that the processor is active (not waiting).

Compute these quantities for one, two, and four simultaneous jobs, assuming that the period T is distributed in each of the following ways:

- a. I/O first half, processor second half;
- b. I/O first and fourth quarters, processor second and third quarters.

9.2 An I/O-bound program is one that, if run alone, would spend more time waiting for I/O than using the processor. A processor-bound program is the opposite. Suppose a short-term scheduling algorithm favors those programs that have used little processor time in the recent past. Explain why this algorithm favors I/O-bound programs and yet does not permanently deny processor time to processor-bound programs.

9.3 A program computes the row sums

$$C_i = \sum_{j=1} a_{ij}$$

of an array A that is 100 by 100. Assume that the computer uses demand paging with a page size of 1000 words, and that the amount of main memory allotted for data is five page frames. Is there any difference in the page fault rate if A were stored in virtual memory by rows or columns? Explain.

9.4 Consider a fixed partitioning scheme with equal-size partitions of 2²⁴ bytes and a total main memory size of 2²⁴ bytes. A process table is maintained that includes a pointer to a partition for each resident process. How many bits are required for the pointer?

9.5 Consider a dynamic partitioning scheme. Show that, on average, the memory contains half as many holes as segments.

9.6 Suppose the page table for the process currently executing on the processor looks like the following. All numbers are decimal, everything is numbered starting from zero, and all addresses are memory byte addresses. The page size is 1024 bytes.

Virtual page number	Valid bit	Reference bit	Modify bit	Page frame number
0	1	1	0	4
1	1	1	1	7
2	0	0	0	—
3	1	0	0	2
4	0	0	0	—
5	1	0	1	0

- a. Describe exactly how, in general, a virtual address generated by the CPU is translated into a physical main memory address.
- b. What physical address, if any, would each of the following virtual addresses correspond to? (Do not try to handle any page faults, if any.)
 - i. 1052
 - ii. 2221
 - iii. 5499

9.7 Give reasons that the page size in a virtual memory system should be neither very small nor very large.

9.8 A process references five pages, A, B, C, D, and E, in the following order:

A; B; C; D; A; B; E; A; B; C; D; E

Assume that the replacement algorithm is first-in-first-out and find the number of page transfers during this sequence of references starting with an empty main memory with three page frames. Repeat for four page frames.

9.9 The following sequence of virtual page numbers is encountered in the course of execution on a computer with virtual memory:

3 4 2 6 4 7 1 3 2 6 3 5 1 2 3

Assume that a least recently used page replacement policy is adopted. Plot a graph of page hit ratio (fraction of page references in which the page is in main memory) as a function of main-memory page capacity n for $1 \leq n \leq 8$. Assume that main memory is initially empty.

9.10 In the VAX computer, user page tables are located at virtual addresses in the system space. What is the advantage of having user page tables in virtual rather than main memory?

What is the disadvantage?

9.11 Suppose the program statement

```
for (i = 1 ; i6 = n ; i++)
a[i]=b[i]+c[i];
```

is executed in a memory with page size of 1000 words. Let $n = 1000$. Using a machine that has a full range of register-to-register instructions and employs index registers, write a hypothetical program to implement the foregoing statement. Then show the sequence of page references during execution.

9.12 The IBM System/370 architecture uses a two-level memory structure and refers to the two levels as segments and pages, although the segmentation approach lacks many of the features described earlier in this chapter. For the basic 370 architecture, the page size may be either 2 Kbytes or 4 Kbytes, and the segment size is fixed at either 64 Kbytes or 1 Mbyte. For the 370/XA and 370/ESA architectures, the page size is 4 Kbytes and the segment size is 1 Mbyte. Which advantages of segmentation does this scheme lack? What is the benefit of segmentation for the 370?

9.13 Consider a computer system with both segmentation and paging. When a segment is in memory, some words are wasted on the last page. In addition, for a segment size s and a page size p , there are s/p page table entries. The smaller the page size, the less waste in the last page of the segment, but the larger the page table. What page size minimizes the total overhead?

9.14 A computer has a cache, main memory, and a disk used for virtual memory. If a referenced word is in the cache, 20 ns are required to access it. If it is in main memory but not in the cache, 60 ns are needed to load it into the cache, and then the reference is started again. If the word is not in main memory, 12 ms are required to fetch the word from disk, followed by 60 ns to copy it to the cache, and then the reference is started again. The cache hit ratio is 0.9 and the main-memory hit ratio is 0.6. What is the average time in ns required to access a referenced word on this system?

9.15 Assume a task is divided into four equal-sized segments and that the system builds an eight-entry page descriptor table for each segment. Thus, the system has a combination of segmentation and paging. Assume also that the page size is 2 Kbytes.

- What is the maximum size of each segment?
- What is the maximum logical address space for the task?
- Assume that an element in physical location 00021ABC is accessed by this task. What is the format of the logical address that the task generates for it? What is the maximum physical address space for the system?

9.16 Assume a microprocessor capable of accessing up to 2^{32} bytes of physical main memory. It implements one segmented logical address space of maximum size 2^{31} bytes. Each instruction contains the whole two-part address. External memory management units (MMUs) are used, whose management scheme assigns contiguous blocks of physical memory of fixed size 2^{22} bytes to segments. The starting physical address of a segment is always divisible by 1024. Show the detailed interconnection of the external mapping mechanism that converts logical addresses to physical addresses using the appropriate number of MMUs, and show the detailed internal structure of an MMU (assuming that each MMU contains a 128-entry directly mapped segment descriptor cache) and how each MMU is selected.

9.17 Consider a paged logical address space (composed of 32 pages of 2 Kbytes each) mapped into a 1-Mbyte physical memory space.

- What is the format of the processor's logical address?
- What is the length and width of the page table (disregarding the "access rights" bits)?
- What is the effect on the page table if the physical memory space is reduced by half?

9.18 In IBM's mainframe operating system, OS/390, one of the major modules in the kernel is the System Resource Manager (SRM). This module is responsible for the allocation of resources among address spaces (processes). The SRM gives OS/390 a degree of

sophistication unique among operating systems. No other mainframe OS, and certainly no other type of OS, can match the functions performed by SRM. The concept of resource includes processor, real memory, and I/O channels. SRM accumulates statistics pertaining to utilization of processor, channel, and various key data structures. Its purpose is to provide optimum performance based on performance monitoring and analysis. The installation sets forth various performance objectives, and these serve as guidance to the SRM, which dynamically modifies installation and job performance characteristics based on system utilization. In turn, the SRM provides reports that enable the trained operator to refine the configuration and parameter settings to improve user service.

This problem concerns one example of SRM activity. Real memory is divided into equal-sized blocks called frames, of which there may be many thousands. Each frame can hold a block of virtual memory referred to as a page. SRM receives control approximately 20 times per second and inspects each and every page frame. If the page has not been referenced or changed, a counter is incremented by 1. Over time, SRM averages these numbers to determine the average number of seconds that a page frame in the system goes untouched. What might be the purpose of this and what action might SRM take?

9.19 For each of the ARM virtual address formats shown in [Figure 9.24](#), show the physical address format.

9.20 Draw a figure similar to [Figure 9.23](#) for ARM virtual memory translation when main memory is divided into sections.

Integers**

Fractions

10.5 Hexadecimal Notation

10.6 Key Terms and Problems

Learning Objectives

After studying this chapter, you should be able to:

- Understand the basic concepts and terminology of **positional number systems**.
- Explain the techniques for converting between **decimal** and **binary** for both integers and fractions.
- Explain the rationale for using **hexadecimal notation**.

10.1 The Decimal System

In everyday life we use a system based on decimal digits (0, 1, 2, 3, 4, 5, 6, 7, 8, 9) to represent numbers, and refer to the system as the decimal system. Consider what the number 83 means. It means eight tens plus three:

$$83 = (8 \times 10) + 3$$

The number 4728 means four thousands, seven hundreds, two tens, plus eight:

$$4728 = (4 \times 1000) + (7 \times 100) + (2 \times 10) + 8$$

The decimal system is said to have a **base**, or **radix**, of 10. This means that each digit in the number is multiplied by 10 raised to a power corresponding to that digit's position:

$$\begin{aligned} 83 &= (8 \times 10^1) + (3 \times 10^0) \\ 4728 &= (4 \times 10^3) + (7 \times 10^2) + (2 \times 10^1) + (8 \times 10^0) \end{aligned}$$

The same principle holds for decimal fractions, but negative powers of 10 are used. Thus, the decimal fraction 0.256 stands for 2 tenths plus 5 hundredths plus 6 thousandths:

$$0.256 = (2 \times 10^{-1}) + (5 \times 10^{-2}) + (6 \times 10^{-3})$$

A number with both an integer and fractional part has digits raised to both positive and negative powers of 10:

$$\begin{aligned} 442.256 &= (4 \times 10^2) + (4 \times 10^1) + (2 \times 10^0) + (2 \times 10^{-1}) + (5 \times 10^{-2}) \\ &\quad + (6 \times 10^{-3}) \end{aligned}$$

In any number, the leftmost digit is referred to as the **most significant digit**, because it carries the highest value. The rightmost digit is called the **least significant digit**. In the preceding decimal number, the 4 on the left is the most significant digit and the 6 on the right is the least significant digit.

Table 10.1 shows the relationship between each digit position and the value assigned to that position. Each position is weighted 10 times the value of the position to the right and one-tenth the value of the position to the left. Thus, positions represent successive powers of 10. If we number the positions as indicated in **Table 10.1**, then position i is weighted by the value 10^i .

Table 10.1 Positional Interpretation of a Decimal Number

4	7	2	2	5	6
100s	10s	1s	tenths	hundredths	thousandths
10^2	10^1	10^0	10^{-1}	10^{-2}	10^{-3}
position 2	position 1	position 0	position -1	position -2	position -3

In general, for the decimal representation of $X = \{ \dots d_2 d_1 d_0 . d_{-1} d_{-2} d_{-3} \dots \}$, the value of X is

$$X = \sum_i (d_i \times 10^i) \quad (10.1)$$

One other observation is worth making. Consider the number 509 and ask how many tens are in the number. Because there is a 0 in the tens position, you might be tempted to say there are no tens. But there are in fact 50 tens. What the 0 in the tens position means is that there are no tens left over that cannot be lumped into the hundreds, or thousands, and so on. Therefore, because each position holds only the leftover numbers that cannot be lumped into higher positions, each digit position needs to have a value of no greater than nine. Nine is the maximum value that a position can hold before it flips over into the next higher position.

10.2 Positional Number Systems

In a positional number system, each number is represented by a string of digits in which each digit position i has an associated weight r^i , where r is the radix, or base, of the number system. The general form of a number in such a system with radix r is

$$(\dots a_3 a_2 a_1 a_0 \cdot a_{-1} a_{-2} a_{-3} \dots)_r$$

where the value of any digit a_i is an integer in the range $0 \leq a_i < r$. The dot between a_0 and a_{-1} is called the **radix point**. The number is defined to have the value

$$\begin{aligned} \dots + a_3 r^3 + a_2 r^2 + a_1 r^1 + a_0 r^0 + a_{-1} r^{-1} + a_{-2} r^{-2} + a_{-3} r^{-3} + \dots \\ = \sum_i (a_i \times r^i) \end{aligned} \quad (10.2)$$

The decimal system, then, is a special case of a positional number system with radix 10 and with digits in the range 0 through 9.

As an example of another positional system, consider the system with base 7. **Table 10.2** shows the weighting value for positions –1 through 4. In each position, the digit value ranges from 0 through 6.

Table 10.2 Positional Interpretation of a Number in Base 7

Position	4	3	2	1	0	-1
Value in Exponential Form	7^4	7^3	7^2	7^1	7^0	7^{-1}
Decimal Value	2401	343	49	7	1	1/7

10.3 The Binary System

In the decimal system, 10 different digits are used to represent numbers with a base of 10. In the binary system, we have only two digits, 1 and 0. Thus, numbers in the binary system are represented to base 2.

To avoid confusion, we will sometimes put a subscript on a number to indicate its base. For example, 83_{10} and 4728_{10} are numbers represented in decimal notation or, more briefly, decimal numbers. The digits 1 and 0 in binary notation have the same meaning as in decimal notation:

$$\begin{aligned}0_2 &= 0_{10} \\1_2 &= 1_{10}\end{aligned}$$

To represent larger numbers, as with decimal notation, each digit in a binary number has a value depending on its position:

$$\begin{aligned}10_2 &= (1 \times 2^1) + (0 \times 2^0) = 2_{10} \\11_2 &= (1 \times 2^1) + (1 \times 2^0) = 3_{10} \\100_2 &= (1 \times 2^2) + (0 \times 2^1) + (0 \times 2^0) = 4_{10}\end{aligned}$$

and so on. Again, fractional values are represented with negative powers of the radix:

$$1001.101 = 2^3 + 2^0 + 2^{-1} + 2^{-3} = 9.625_{10}$$

In general, for the binary representation of $Y = \{ \dots b_2 b_1 b_0 . b_{-1} b_{-2} b_{-3} \dots \}$, the value of Y is

$$Y = \sum_i (b_i \times 2^i) \tag{10.3}$$

10.4 Converting Between Binary and Decimal

It is a simple matter to convert a number from binary notation to decimal notation. In fact, we showed several examples in the previous subsection. All that is required is to multiply each binary digit by the appropriate power of 2 and add the results.

To convert from decimal to binary, the integer and fractional parts are handled separately.

Integers

For the integer part, recall that in binary notation, an integer represented by

$$b_{m-1}b_{m-2}\dots b_2b_1b_0 \quad b_i = 0 \text{ or } 1$$

has the value

$$(b_{m-1} \times 2^{m-1}) + (b_{m-2} \times 2^{m-2}) + \dots + (b_1 \times 2^1) + b_0$$

Suppose it is required to convert a decimal integer N into binary form. If we divide N by 2, in the decimal system, and obtain a quotient N_1 and a remainder R_0 , we may write

$$N = 2 \times N_1 + R_0 \quad R_0 = 0 \text{ or } 1$$

Next, we divide the quotient N_1 by 2. Assume that the new quotient is N_2 and the new remainder R_1 .

Then

$$N_1 = 2 \times N_2 + R_1 \quad R_1 = 0 \text{ or } 1$$

so that

$$N = 2(2N_2 + R_1) + R_0 = (N_2 \times 2^2) + (R_1 \times 2^1) + R_0$$

If next

$$N_2 = 2N_3 + R_2$$

we have

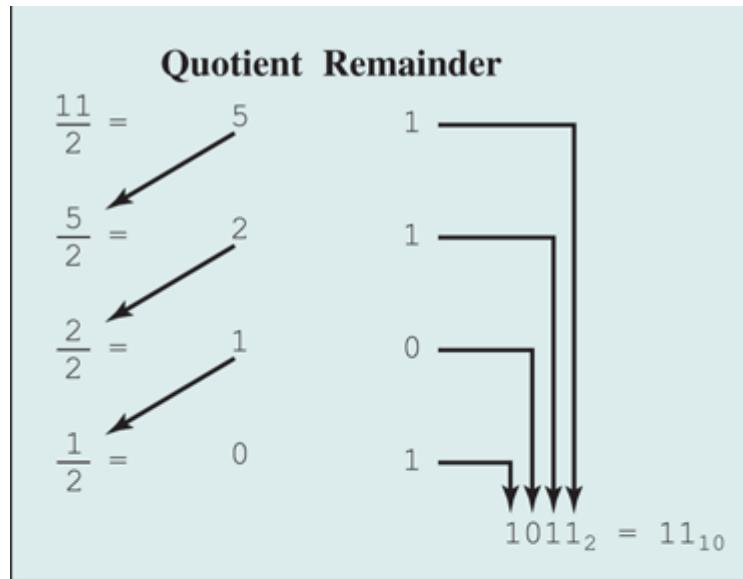

$$N = (N_3 \times 2^3) + (R_2 \times 2^2) + (R_1 \times 2^1) + R_0$$

Because $N > N_1 > N_2 \dots$, continuing this sequence will eventually produce a quotient $N_{m-1} = 1$ (except for the decimal integers 0 and 1, whose binary equivalents are 0 and 1, respectively) and a remainder R_{m-2} , which is 0 or 1. Then

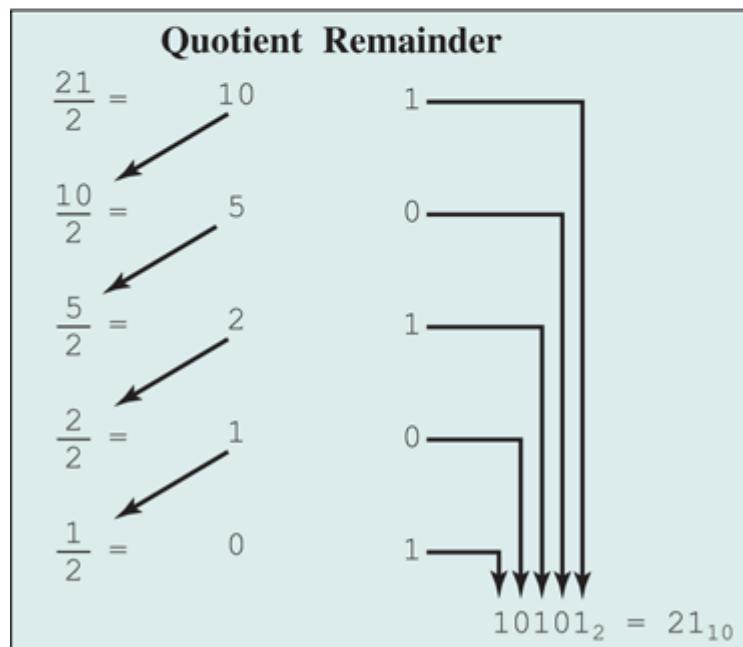

$$N = (1 \times 2^{m-1}) + (R_{m-2} \times 2^{m-2}) + \dots + (R_2 \times 2^2) + (R_1 \times 2^1) + R_0$$

which is the binary form of N . Hence, we convert from base 10 to base 2 by repeated divisions by 2. The remainders and the final quotient, 1, give us, in order of increasing significance, the binary digits

of N . **Figure 10.1** shows two examples.

(a) 11_{10}

(b) 21_{10}

Figure 10.1 Examples of Converting from Decimal Notation to Binary Notation for Integers

Fractions

For the fractional part, recall that in binary notation, a number with a value between 0 and 1 is represented by

$$0.b_{-1}b_{-2}b_{-3}\dots b_i = 0 \text{ or } 1$$

and has the value

$$(b_{-1} \times 2^{-1}) + (b_{-2} \times 2^{-2}) + (b_{-3} \times 2^{-3}) \dots$$

This can be rewritten as

$$2^{-1} \times (b_{-1} + 2^{-1} \times (b_{-2} + 2^{-1} \times (b_{-3} + \dots) \dots))$$

This expression suggests a technique for conversion. Suppose we want to convert the number F ($0 < F < 1$) from decimal to binary notation. We know that F can be expressed in the form

$$F = 2^{-1} \times (b_{-1} + 2^{-1} \times (b_{-2} + 2^{-1} \times (b_{-3} + \dots) \dots))$$

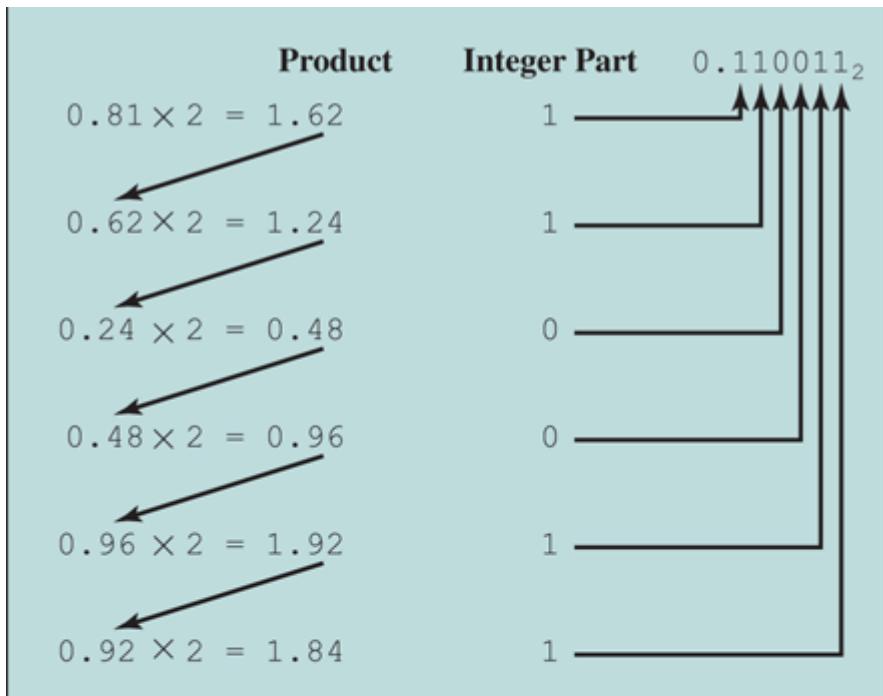

If we multiply F by 2, we obtain,

$$2 \times F = b_{-1} + 2^{-1} \times (b_{-2} + 2^{-1} \times (b_{-3} + \dots) \dots)$$

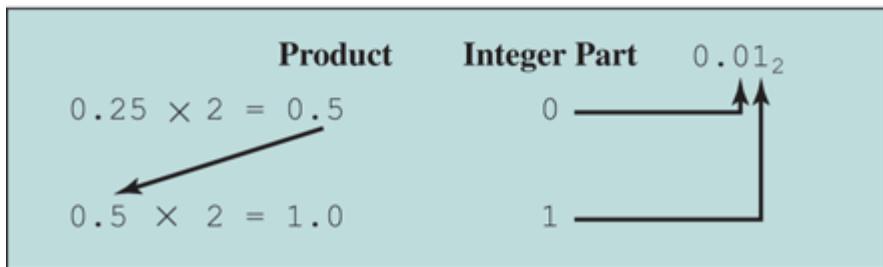

From this equation, we see that the integer part of $(2 \times F)$, which must be either 0 or 1 because $0 < F < 1$, is simply b_{-1} . So we can say $(2 \times F) = b_{-1} + F_1$, where $0 < F_1 < 1$ and where

$$F_1 = 2^{-1} \times (b_{-2} + 2^{-1} \times (b_{-3} + 2^{-1} \times (b_{-4} + \dots) \dots))$$

To find b_{-2} , we repeat the process. Therefore, the conversion algorithm involves repeated multiplication by 2. At each step, the fractional part of the number from the previous step is multiplied by 2. The digit to the left of the decimal point in the product will be 0 or 1 and contributes to the binary representation, starting with the most significant digit. The fractional part of the product is used as the multiplicand in the next step. **Figure 10.2** shows two examples.

(a) $0.81_{10} = 0.110011_2$ (approximately)

(b) $0.25_{10} = 0.01_2$ (exactly)

Figure 10.2 Examples of Converting from Decimal Notation to Binary Notation for Fractions

This process is not necessarily exact; that is, a decimal fraction with a finite number of digits may require a binary fraction with an infinite number of digits. In such cases, the conversion algorithm is usually halted after a prespecified number of steps, depending on the desired accuracy.

10.5 Hexadecimal Notation

Because of the inherent binary nature of digital computer components, all forms of data within computers are represented by various binary codes. However, no matter how convenient the binary system is for computers, it is exceedingly cumbersome for human beings. Consequently, most computer professionals who must spend time working with the actual raw data in the computer prefer a more compact notation.

What notation to use? One possibility is the decimal notation. This is certainly more compact than binary notation, but it is awkward because of the tediousness of converting between base 2 and base 10.

Instead, a notation known as hexadecimal has been adopted. Binary digits are grouped into sets of four bits, called a **nibble**. Each possible combination of four binary digits is given a symbol, as follows:

0000 = 0	0100 = 4	1000 = 8	1100 = C
0001 = 1	0101 = 5	1001 = 9	1101 = D
0010 = 2	0110 = 6	1010 = A	1110 = E
0011 = 3	0111 = 7	1011 = B	1111 = F

Because 16 symbols are used, the notation is called **hexadecimal**, and the 16 symbols are the **hexadecimal digits**.

A sequence of hexadecimal digits can be thought of as representing an integer in base 16 ([Table 10.3](#)). Thus,

Table 10.3 Decimal, Binary, and Hexadecimal

Decimal (base 10)	Binary (base 2)	Hexadecimal (base 16)
0	0000	0
1	0001	1
2	0010	2
3	0011	3
4	0100	4
5	0101	5
6	0110	6
7	0111	7
8	1000	8

9	1001	9
10	1010	A
11	1011	B
12	1100	C
13	1101	D
14	1110	E
15	1111	F
16	0001 0000	10
17	0001 0001	11
18	0001 0010	12
31	0001 1111	1F
100	0110 0100	64
255	1111 1111	FF
256	0001 0000 0000	100

$$\begin{aligned}
 2C_{16} &= (2_{16} \times 16^1) + (C_{16} \times 16^0) \\
 &= (2_{10} \times 16^1) + (12_{10} \times 16^0) = 44
 \end{aligned}$$

Thus, viewing hexadecimal numbers as numbers in the positional number system with base 16, we have

$$Z = \sum_i (h_i \times 16^i) \quad (10.4)$$

where 16 is the base and each hexadecimal digit h_i is in the decimal range $0 \leq h_i < 15$, equivalent to the hexadecimal range $0 \leq h_i \leq F$.

Hexadecimal notation is not only used for representing integers but also used as a concise notation for representing any sequence of binary digits, whether they represent text, numbers, or some other type of data. The reasons for using hexadecimal notation are as follows:

1. It is more compact than binary notation.
2. In most computers, binary data occupy some multiple of 4 bits, and hence some multiple of a single hexadecimal digit.

3. It is extremely easy to convert between binary and hexadecimal notation.

As an example of the last point, consider the binary string 110111100001. This is equivalent to

$$\begin{array}{r} 1101 \ 1110 \ 0001 = \text{DE1}_{16} \\ \text{D} \quad \text{E} \quad \quad \quad 1 \end{array}$$

This process is performed so naturally that an experienced programmer can mentally convert visual representations of binary data to their hexadecimal equivalent without written effort.

10.6 Key Terms and Problems

Key Terms

base
binary
decimal
fraction
hexadecimal
integer
least significant digit
most significant digit
nibble
positional number system
radix
radix point

Problems

10.1 Count from 1 to 20_{10} in the following bases:

- a. 8
- b. 6
- c. 5
- d. 3

10.2 Order the numbers $(1.1)_2$, $(1.4)_{10}$, and $(1.5)_{16}$ from smallest to largest.

10.3 Perform the indicated base conversions:

- a. 54_8 to base 5
- b. 312_4 to base 7
- c. 520_6 to base 7
- d. 12212_3 to base 9

10.4 What generalizations can you draw about converting a number from one base to a power of that base; e.g., from base 3 to base 9 (3^2) or from base 2 to base 4 (2^2) or base 8 (2^3)?

10.5 Convert the following binary numbers to their decimal equivalents:

- a. 001100
- b. 000011
- c. 011100
- d. 111100
- e. 101010

10.6 Convert the following binary numbers to their decimal equivalents:

- a. 11100.011
- b. 110011.10011
- c. 1010101010.1

10.7 Convert the following decimal numbers to their binary equivalents:

- a. 64
- b. 100
- c. 111
- d. 145
- e. 255

10.8 Convert the following decimal numbers to their binary equivalents:

- a. 34.75
- b. 25.25
- c. 27.1875

10.9 Prove that every real number with a terminating binary representation (finite number of digits to the right of the binary point) also has a terminating decimal representation (finite number of digits to the right of the decimal point).

10.10 Express the following octal numbers (number with radix 8) in hexadecimal notation:

- a. 12
- b. 5655
- c. 2550276
- d. 76545336
- e. 3726755

10.11 Convert the following hexadecimal numbers to their decimal equivalents:

- a. C
- b. 9F
- c. D52
- d. 67E
- e. ABCD

10.12 Convert the following hexadecimal numbers to their decimal equivalents:

- a. F.4
- b. D3.E
- c. 1111.1
- d. 888.8
- e. EBA.C

10.13 Convert the following decimal numbers to their hexadecimal equivalents:

- a. 16
- b. 80
- c. 2560
- d. 3000
- e. 62,500

10.14 Convert the following decimal numbers to their hexadecimal equivalents:

- a. 204.125
- b. 255.875

- c. 631.25
- d. 10000.00390625

10.15 Convert the following hexadecimal numbers to their binary equivalents:

- a. E
- b. 1C
- c. A64
- d. 1F.C
- e. 239.4

10.16 Convert the following binary numbers to their hexadecimal equivalents:

- a. 1001.1111
- b. 110101.011001
- c. 10100111.111011

Learning Objectives

After studying this chapter, you should be able to:

- Understand the distinction between the way in which numbers are represented (the binary format) and the algorithms used for the basic arithmetic operations.
- Explain **twos complement representation**.
- Present an overview of the techniques for doing basic arithmetic operations in twos complement notation.
- Understand the use of significand, base, and exponent in the representation of **floating-point numbers**.
- Present an overview of the IEEE 754 standard for floating-point representation.
- Understand some of the key concepts related to floating-point arithmetic, including guard bits, rounding, subnormal numbers, underflow and overflow.

We begin our examination of the processor with an overview of the arithmetic and

logic unit (ALU). The chapter then focuses on the most complex aspect of the ALU, computer arithmetic. The implementation of simple logic and arithmetic functions in digital logic are described in [Chapter 12](#), and logic functions that are part of the ALU are described in [Chapter 13](#).

Computer arithmetic is commonly performed on two very different types of numbers: integer and floating point. In both cases, the representation chosen is a crucial design issue and is treated first, followed by a discussion of arithmetic operations.

This chapter includes a number of examples, each of which is highlighted in a shaded box.

11.1 The Arithmetic and Logic Unit

The ALU is that part of the computer that actually performs arithmetic and logical operations on data. All of the other elements of the computer system—control unit, registers, memory, I/O—are there mainly to bring data into the ALU for it to process and then to take the results back out. We have, in a sense, reached the core or essence of a computer when we consider the ALU.

An ALU and indeed, all electronic components in the computer, are based on the use of simple digital logic devices that can store binary digits and perform simple Boolean logic operations.

Figure 11.1 indicates, in general terms, how the ALU is interconnected with the rest of the processor. Operands for arithmetic and logic operations are presented to the ALU in registers, and the results of an operation are stored in registers. These registers are temporary storage locations within the processor that are connected by signal paths to the ALU (e.g., see **Figure 1.6**). The ALU may also set flags as the result of an operation. For example, an overflow flag is set to 1 if the result of a computation exceeds the length of the register into which it is to be stored.

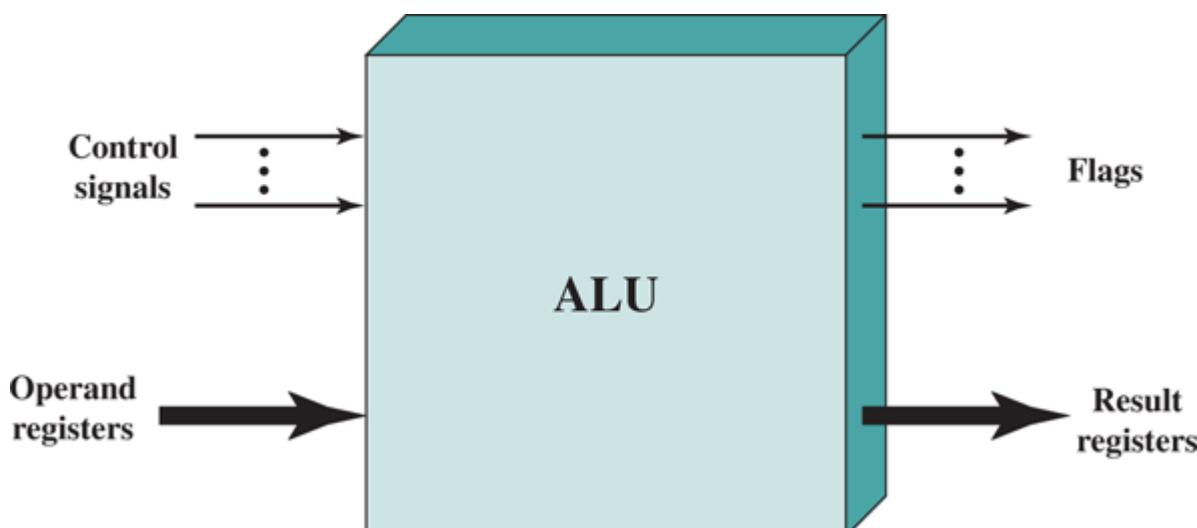

Figure 11.1 ALU Inputs and Outputs

The flag values are also stored in registers within the processor. The processor provides signals that control the operation of the ALU and the movement of the data into and out of the ALU.

11.2 Integer Representation

In the binary number system,¹ arbitrary numbers can be represented with just the digits zero and one, the minus sign (for negative numbers), and the period, or **radix point** (for numbers with a fractional component).

¹ See Chapter 10 for a basic refresher on number systems (decimal, binary, hexadecimal).

$$-1101.0101_2 = -13.3125_{10}$$

For purposes of computer storage and processing, however, we do not have the benefit of special symbols for the minus sign and radix point. Only binary digits (0 and 1) may be used to represent numbers. If we are limited to nonnegative integers, the representation is straightforward.

An 8-bit word can represent the numbers from 0 to 255, such as

00000000	=	0
00000001	=	1
00101001	=	41
10000000	=	128
11111111	=	255

In general, if an n -bit sequence of binary digits $a_{n-1}a_{n-2}\dots a_1a_0$ is interpreted as an unsigned integer A, its value is

$$A = \sum_{i=0}^{n-1} 2^i a_i$$

Sign-Magnitude Representation

There are several alternative conventions used to represent negative as well as positive integers, all of which involve treating the most significant (leftmost) bit in the word as a **sign bit**. If the sign bit is 0, the number is positive; if the sign bit is 1, the number is negative.

The simplest form of representation that employs a sign bit is the sign-magnitude representation. In an n -bit word, the rightmost $n-1$ bits hold the magnitude of the integer.

$$\begin{aligned} +18 &= 00010010 \\ -18 &= 10010010 \text{ (sign magnitude)} \end{aligned}$$

The general case can be expressed as follows:

Sign Magnitude

$$A = \begin{cases} \sum_{i=0}^{n-1} 2^i a_i & \text{if } a_{n-1} = 0 \\ -\sum_{i=0}^{n-1} 2^i a_i & \text{if } a_{n-1} = 1 \end{cases} \quad (11.1)$$

There are several drawbacks to sign-magnitude representation. One is that addition and subtraction require a consideration of both the signs of the numbers and their relative magnitudes to carry out the required operation. This should become clear in the discussion in [Section 11.3](#). Another drawback is that there are two representations of 0:

$$\begin{aligned} +0_{10} &= 00000000 \\ -0_{10} &= 10000000 \text{ (sign magnitude)} \end{aligned}$$

This is inconvenient because it is slightly more difficult to test for 0 (an operation performed frequently on computers) than if there were a single representation.

Because of these drawbacks, sign-magnitude representation is rarely used in implementing the integer portion of the ALU. Instead, the most common scheme is twos complement representation.²

² In the literature, the terms *two's complement* or *2's complement* are often used. Here we follow the practice used in standards documents and omit the apostrophe (e.g., IEEE Std 100-1992, *The New IEEE Standard Dictionary of Electrical and Electronics Terms*).

Twos Complement Representation

Like sign magnitude, twos complement representation uses the most significant bit as a sign bit, making it easy to test whether an integer is positive or negative. It differs from the use of the sign-magnitude representation in the way that the other bits are interpreted. [Table 11.1](#) highlights key characteristics of twos complement representation and arithmetic, which are elaborated in this section and the next.

Table 11.1 Characteristics of Twos Complement Representation and Arithmetic

Range	-2^{n-1} through $2^{n-1} - 1$
Number of Representations of Zero	One
Negation	Take the Boolean complement of each bit of the corresponding positive number, then add 1 to the resulting bit pattern viewed as an unsigned integer.
Expansion of Bit Length	Add additional bit positions to the left and fill in with the value of the original sign bit.
Overflow Rule	If two numbers with the same sign (both positive or both negative) are added, then overflow occurs if and only if the result has the opposite sign.
Subtraction Rule	To subtract B from A , take the twos complement of B and add it to A .

Most treatments of twos complement representation focus on the rules for producing negative numbers, with no formal proof that the scheme is valid. Instead, our presentation of twos complement integers in this section and in [Section 11.3](#) is based on [DATT93], which suggests that twos complement representation is best understood by defining it in terms of a weighted sum of bits, as we did previously for unsigned and sign-magnitude representations. The advantage of this treatment is that it does not leave any lingering doubt that the rules for arithmetic operations in twos complement notation may not work for some special cases.

Consider an n -bit integer, A , in twos complement representation. If A is positive, then the sign bit, a_{n-1} , is zero. The remaining bits represent the magnitude of the number in the same fashion as for sign magnitude:

$$A = \sum_{i=0}^{n-1} 2^i a_i \text{ for } A \geq 0$$

The number zero is identified as positive and therefore has a 0 sign bit and a magnitude of all 0s. We can see that the range of positive integers that may be represented is from 0 (all of the magnitude bits are 0) through $2^{n-1} - 1$ (all of the magnitude bits are 1). Any larger number would require more bits.

Now, for a negative number A ($A < 0$), the sign bit, a_{n-1} , is one. The remaining $n-1$ bits can take on any one of 2^{n-1} values. Therefore, the range of negative integers that can be represented is from -1 to -2^{n-1} . We would like to assign the bit values to negative integers in such a way that arithmetic can be handled in a straightforward fashion, similar to unsigned integer arithmetic. In unsigned integer representation, to compute the value of an integer from the bit representation, the weight of the most significant bit is $+2^{n-1}$. For a representation with a sign bit, it turns out that the desired arithmetic properties are achieved, as we will see in [Section 11.3](#), if the weight of the most significant bit is -2^{n-1} . This is the convention used in twos complement representation, yielding the following expression for negative numbers:

Twos Complement

$$A = -2^{n-1} a_{n-1} + \sum_{i=0}^{n-1} 2^i a_i \quad (11.2)$$

[Equation \(11.2\)](#) defines the twos complement representation for both positive and negative numbers. For $a_{n-1} = 0$, the term $-2^{n-1} a_{n-1} = 0$ and the equation defines a nonnegative integer. When $a_{n-1} = 1$, the term 2^{n-1} is subtracted from the summation term, yielding a negative integer.

[Table 11.2](#) compares the sign-magnitude and twos complement representations for 4-bit integers. Although twos complement is an awkward representation from the human point of view, we will see that it facilitates the most important arithmetic operations, addition and subtraction. For this reason, it is almost universally used as the processor representation for integers.

Table 11.2 Alternative Representations for 4-Bit Integers

Decimal Representation	Sign-Magnitude Representation	Twos Complement Representation	Biased Representation
+8	—	—	1111

+7	0111	0111	1110
+6	0110	0110	1101
+5	0101	0101	1100
+4	0100	0100	1011
+3	0011	0011	1010
+2	0010	0010	1001
+1	0001	0001	1000
+0	0000	0000	0111
-0	1000	—	—
-1	1001	1111	0110
-2	1010	1110	0101
-3	1011	1101	0100
-4	1100	1100	0011
-5	1101	1011	0010
-6	1110	1010	0001
-7	1111	1001	0000
-8	—	1000	—

A useful illustration of the nature of twos complement representation is a value box, in which the value on the far right in the box is $1 (2^0)$ and each succeeding position to the left is double in value, until the leftmost position, which is negated. As you can see in [Figure 11.2a](#), the most negative twos complement number that can be represented is -2^{n-1} ; if any of the bits other than the sign bit is one, it adds a positive amount to the number. Also, it is clear that a negative number must have a 1 at its leftmost position and a positive number must have a 0 in that position. Thus, the largest positive number is a 0 followed by all 1s, which equals $2^{n-1} - 1$.

The rest of [Figure 11.2](#) illustrates the use of the value box to convert from twos complement to decimal and from decimal to twos complement.

-128	64	32	16	8	4	2	1

(a) An eight-position twos complement value box

-128	64	32	16	8	4	2	1
1	0	0	0	0	0	1	1

$$-128 + 2 + 1 = -125$$

(b) Convert binary 10000011 to decimal

-128	64	32	16	8	4	2	1
1	0	0	0	1	0	0	0

$$-120 = -128 + 8$$

(c) Convert decimal -120 to binary

Figure 11.2 Use of a Value Box for Conversion between Twos Complement Binary and Decimal

Range Extension

It is sometimes desirable to take an n -bit integer and store it in m bits, where $m > n$. This expansion of bit length is referred to as **range extension**, because the range of numbers that can be expressed is extended by increasing the bit length.

In sign-magnitude notation, this is easily accomplished: simply move the sign bit to the new leftmost position and fill in with zeros.

+18 = 00010010 (sign magnitude, 8 bits)
+18 = 000000000010010 (sign magnitude, 16 bits)
-18 = 10010010 (sign magnitude, 8 bits)
-18 = 100000000010010 (sign magnitude, 16 bits)

This procedure will not work for twos complement negative integers. Using the same example,

+18 = 00010010 (twos complement, 8 bits)
+18 = 000000000010010 (twos complement, 16 bits)
-18 = 11101110 (twos complement, 8 bits)
-32,658 = 100000001101110 (twos complement, 16 bits)

The next to last line is easily seen using the value box of [Figure 11.2](#). The last line can be verified using [Equation \(11.2\)](#) or a 16-bit value box.

Instead, the rule for twos complement integers is to move the sign bit to the new leftmost position and fill in with copies of the sign bit. For positive numbers, fill in with zeros, and for negative numbers, fill in with ones. This is called sign extension.

-18 = 11101110 (twos complement, 8 bits)
-18 = 111111111101110 (twos complement, 16 bits)

To see why this rule works, let us again consider an n -bit sequence of binary digits $a_{n-1}a_{n-2}\dots a_1a_0$ interpreted as a twos complement integer A , so that its value is

$$A = -2^{n-1}a_{n-1} + \sum_{i=0}^{n-1} 2^i a_i$$

If A is a positive number, the rule clearly works. Now, if A is negative we want to construct an m -bit representation, with $m > n$. Then

$$A = -2^{m-1}a_{m-1} + \sum_{i=0}^{m-1} 2^i a_i$$

The two values must be equal:

$$\begin{aligned} -2^{m-1} + \sum_{i=0}^{m-1} 2^i a_i &= -2^{n-1} + \sum_{i=0}^{n-1} 2^i a_i \\ -2^{m-1} + \sum_{i=n-1}^{m-2} 2^i a_i &= -2^{n-1} \\ -2^{n-1} + \sum_{i=n-1}^{m-2} 2^i a_i &= 2^{m-1} \\ 1 + \sum_{i=0}^{n-1} 2^i + \sum_{i=n-1}^{m-2} 2^i a_i &= 1 + \sum_{i=0}^{m-1} 2^i \\ \sum_{i=n-1}^{m-2} 2^i a_i &= \sum_{i=n-1}^{m-1} 2^i \\ \Rightarrow a_{m-2} = \dots &= a_{n-2} = a_{n-2} = 1 \end{aligned}$$

In going from the first to the second equation, we require that the least significant $n-1$ bits do not change between the two representations. Then we get to the next to last equation, which is only true if all of the bits in positions $n-1$ through $m-2$ are 1. Therefore, the sign-extension rule works. The reader may find the rule easier to grasp after studying the discussion on twos complement negation at the beginning of [Section 11.3](#).

Fixed-Point Representation

Finally, we mention that the representations discussed in this section are sometimes referred to as fixed point. This is because the radix point (binary point) is fixed and assumed to be to the right of the rightmost digit. The programmer can use the same representation for binary fractions by scaling the numbers so that the binary point is implicitly positioned at some other location.

11.3 Integer Arithmetic

This section examines common arithmetic functions on numbers in twos complement representation.

Negation

In sign-magnitude representation, the rule for forming the negation of an integer is simple: invert the sign bit. In twos complement notation, the negation of an integer can be formed with the following rules:

1. Take the Boolean complement of each bit of the integer (including the sign bit). That is, set each 1 to 0 and each 0 to 1.
2. Treating the result as an unsigned binary integer, add 1.

This two-step process is referred to as the **twos complement operation**, or the taking of the twos complement of an integer.

$$\begin{array}{rcl} +18 & = & 00010010 \text{ (twos complement)} \\ \text{bitwise complement} & = & 11101101 \\ & +1 & \\ & - & \\ & 11101110 & = -18 \end{array}$$

As expected, the negative of the negative of that number is itself:

$$\begin{array}{rcl} -18 & = & 11101110 \text{ (twos complement)} \\ \text{bitwise complement} & = & 00010001 \\ & +1 & \\ & - & \\ & 00010010 & = +18 \end{array}$$

We can demonstrate the validity of the operation just described using the definition of the twos complement representation in [Equation \(11.2\)](#). Again, interpret an n -bit sequence of binary digits $a_{n-1}a_{n-2}\dots a_1a_0$ as a twos complement integer A , so that its value is

$$A = -2^{n-1}a_{n-1} + \sum_{i=0}^{n-2} 2^i a_i$$

Now form the bitwise complement, $\bar{a}_{n-1}\bar{a}_{n-2}\dots\bar{a}_0$, and, treating this as an unsigned integer, add 1.

Finally, interpret the resulting n -bit sequence of binary digits as a twos complement integer B , so that its value is

$$B = -2^{n-1}\bar{a}_{n-1} + 1 + \sum_{i=0}^{n-2} 2^i \bar{a}_i$$

Now, we want $A = -B$, which means $A + B = 0$. This is easily shown to be true:

$$\begin{aligned} A + B &= \\ &- (a_{n-1} + \bar{a}_{n-1}) 2^{n-1} + 1 + \sum_{i=0}^{n-2} 2^i (a_i + \bar{a}_i) \\ &= \end{aligned}$$

$$\begin{aligned}
 & -2^{n-1} + 1 + \sum_{i=0}^n 2^i \\
 = & -2^{n-1} + 1 + (2^{n-1} - 1) \\
 = & -2^{n-1} + 2^{n-1} = 0
 \end{aligned}$$

The preceding derivation assumes that we can first treat the bitwise complement of A as an unsigned integer for the purpose of adding 1, and then treat the result as a twos complement integer. There are two special cases to consider. First, consider $A = 0$. In that case, for an 8-bit representation:

0	=	00000000 (twos complement)	
bitwise complement	=	11111111	
	+1		
	-	100000000	=0

There is a *carry* out of the most significant bit position, which is ignored. The result is that the negation of 0 is 0, as it should be.

The second special case is more of a problem. If we take the negation of the bit pattern of 1 followed by $n - 1$ zeros, we get back the same number. For example, for 8-bit words,

+128	=	10000000 (twos complement)	
bitwise complement	=	01111111	
	+1		
	-	10000000	= -128

Some such anomaly is unavoidable. The number of different bit patterns in an n -bit word is 2^n , which is an even number. We wish to represent positive and negative integers and 0. If an equal number of positive and negative integers are represented (sign magnitude), then there are two representations for 0. If there is only one representation of 0 (twos complement), then there must be an unequal number of negative and positive numbers represented. In the case of twos complement, for an n -bit length, there is a representation for -2^{n-1} but not for $+2^{n-1}$.

Addition and Subtraction

Addition in twos complement is illustrated in [Figure 11.3](#). Addition proceeds as if the two numbers were unsigned integers. The first four examples illustrate successful operations. If the result of the operation is positive, we get a positive number in twos complement form, which is the same as in unsigned-integer form. If the result of the operation is negative, we get a negative number in twos complement form. Note that, in some instances, there is a carry bit beyond the end of the word (indicated by shading), which is ignored.

$ \begin{array}{rcl} 1001 & = & -7 \\ +\underline{0101} & = & 5 \\ 1110 & = & -2 \\ \hline \text{(a)} & (-7) + (+5) & \end{array} $	$ \begin{array}{rcl} 1100 & = & -4 \\ +\underline{0100} & = & 4 \\ \hline \text{(b)} & (-4) + (+4) & 0 \end{array} $
$ \begin{array}{rcl} 0011 & = & 3 \\ +\underline{0100} & = & 4 \\ 0111 & = & 7 \\ \hline \text{(c)} & (+3) + (+4) & \end{array} $	$ \begin{array}{rcl} 1100 & = & -4 \\ +\underline{1111} & = & -1 \\ \hline \text{(d)} & (-4) + (-1) & -5 \end{array} $
$ \begin{array}{rcl} 0101 & = & 5 \\ +\underline{0100} & = & 4 \\ 1001 & = & \text{Overflow} \\ \hline \text{(e)} & (+5) + (+4) & \end{array} $	$ \begin{array}{rcl} 1001 & = & -7 \\ +\underline{1010} & = & -6 \\ \hline \text{(f)} & (-7) + (-6) & \text{Overflow} \end{array} $

Figure 11.3 Addition of Numbers in Twos Complement Representation

On any addition, the result may be larger than can be held in the word size being used. This condition is called **overflow**. When overflow occurs, the ALU must signal this fact so that no attempt is made to use the result. To detect overflow, the following rule is observed:

OVERFLOW RULE:

If two numbers are added, and they are both positive or both negative, then overflow occurs if and only if the result has the opposite sign.

Figures 11.3e and f show examples of overflow. Note that overflow can occur whether or not there is a carry.

Subtraction is easily handled with the following rule:

SUBTRACTION RULE:

To subtract one number (**subtrahend**) from another (**minuend**), take the twos complement (negation) of the subtrahend and add it to the minuend.

Thus, subtraction is achieved using addition, as illustrated in **Figure 11.4**. The last two examples demonstrate that the overflow rule still applies.

$ \begin{array}{r} 0010 = 2 \\ +1001 = -7 \\ \hline 1011 = -5 \end{array} $	$ \begin{array}{r} 0101 = 5 \\ +1110 = -2 \\ \hline 10011 = 3 \end{array} $
(a) $M = 2 = 0010$ $S = 7 = 0111$ $-S = 1001$	(b) $M = 5 = 0101$ $S = 2 = 0010$ $-S = 1110$
$ \begin{array}{r} 1011 = -5 \\ +1110 = -2 \\ \hline 11001 = -7 \end{array} $	$ \begin{array}{r} 0101 = 5 \\ +0010 = 2 \\ \hline 0111 = 7 \end{array} $
(c) $M = -5 = 1011$ $S = 2 = 0010$ $-S = 1110$	(d) $M = 5 = 0101$ $S = -2 = 1110$ $-S = 0010$
$ \begin{array}{r} 0111 = 7 \\ +0111 = 7 \\ \hline 1110 = \text{Overflow} \end{array} $	$ \begin{array}{r} 1010 = -6 \\ +1100 = -4 \\ \hline 10110 = \text{Overflow} \end{array} $
(e) $M = 7 = 0111$ $S = -7 = 1001$ $-S = 0111$	(f) $M = -6 = 1010$ $S = 4 = 0100$ $-S = 1100$

Figure 11.4 Subtraction of Numbers in Twos Complement Representation ($M - S$)

Some insight into twos complement addition and subtraction can be gained by looking at a geometric depiction [BENH92], as shown in [Figure 11.5](#). The circle in the upper half of each part of the figure is formed by selecting the appropriate segment of the number line and joining the endpoints. Note that when the numbers are laid out on a circle, the twos complement of any number is horizontally opposite that number (indicated by dashed horizontal lines). Starting at any number on the circle, we can add positive k (or subtract negative k) to that number by moving k positions clockwise, and we can subtract positive k (or add negative k) from that number by moving k positions counterclockwise. If an arithmetic operation results in traversal of the point where the endpoints are joined, an incorrect answer is given (overflow).

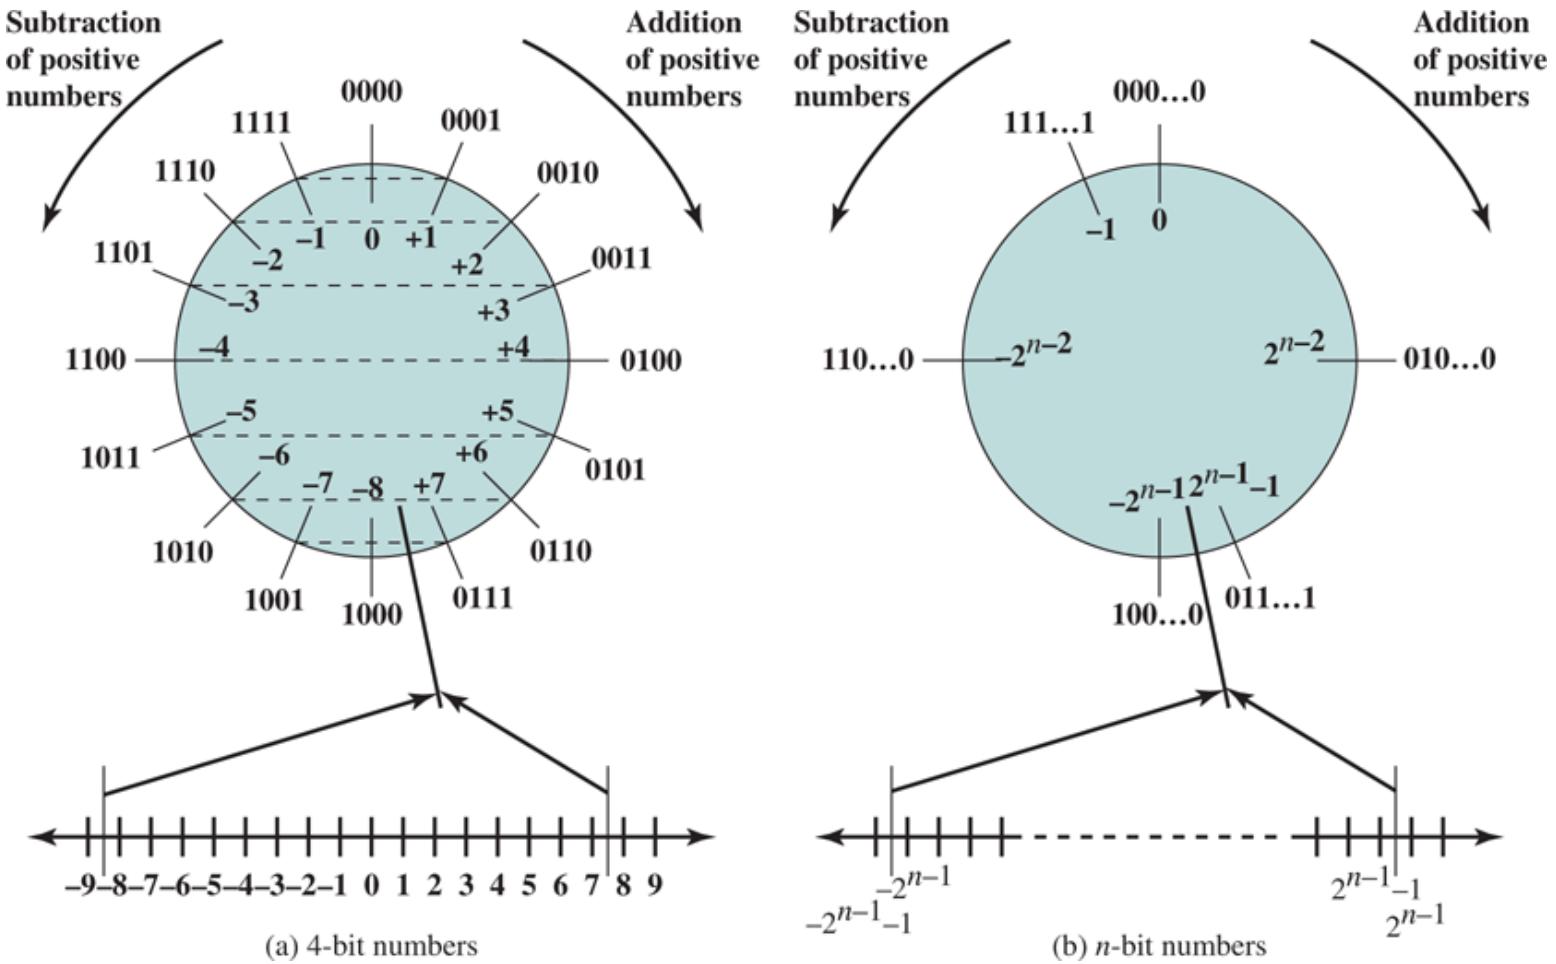

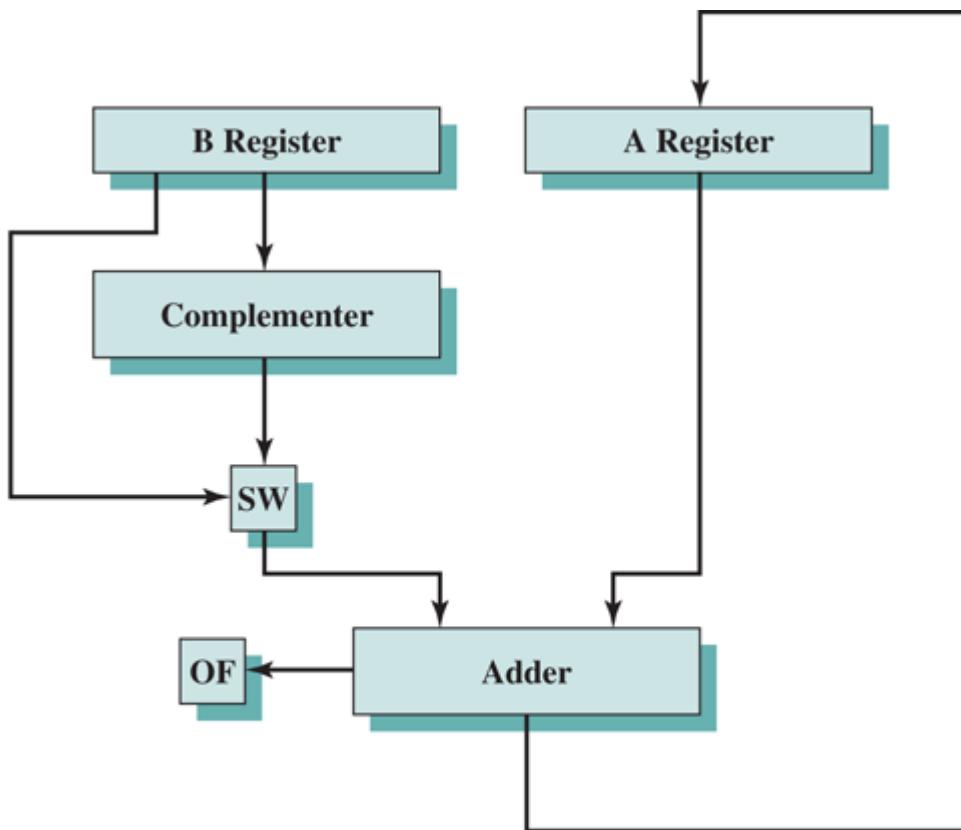

Figure 11.5 Geometric Depiction of Twos Complement Integers

ALL OF the examples of [Figures 11.3](#) and [11.4](#) are easily traced in the circle of [Figure 11.5](#).

[Figure 11.6](#) suggests the data paths and hardware elements needed to accomplish addition and subtraction. The central element is a binary adder, which is presented two numbers for addition and produces a sum and an overflow indication. The binary adder treats the two numbers as unsigned integers. (A logic implementation of an adder is given in Chapter 12.) For addition, the two numbers are presented to the adder from two registers, designated in this case as A and B registers. The result may be stored in one of these registers or in a third. The overflow indication is stored in a 1-bit overflow flag (0 = no overflow ; 1 = overflow). For subtraction, the subtrahend (B register) is passed through a twos completer so that its twos complement is presented to the adder. Note that [Figure 11.6](#) only shows the data paths. Control signals are needed to control whether or not the completer is used, depending on whether the operation is addition or subtraction.

Multiplication

Compared with addition and subtraction, multiplication is a complex operation, whether performed in hardware or software. A wide variety of algorithms have been used in various computers. The purpose of this subsection is to give the reader some feel for the type of approach typically taken. We begin with the simpler problem of multiplying two unsigned (nonnegative) integers, and then we look at one of the most common techniques for multiplication of numbers in two's complement representation.

UNSIGNED INTEGERS

Figure 11.7 illustrates the multiplication of unsigned binary integers, as might be carried out using paper and pencil. Several important observations can be made:

$ \begin{array}{r} 1011 \\ \times 1101 \\ \hline 1011 \\ 0000 \\ 1011 \\ 1011 \\ \hline 10001111 \end{array} $	Multiplicand (11) Multiplier (13) Partial products Product (143)
--	---

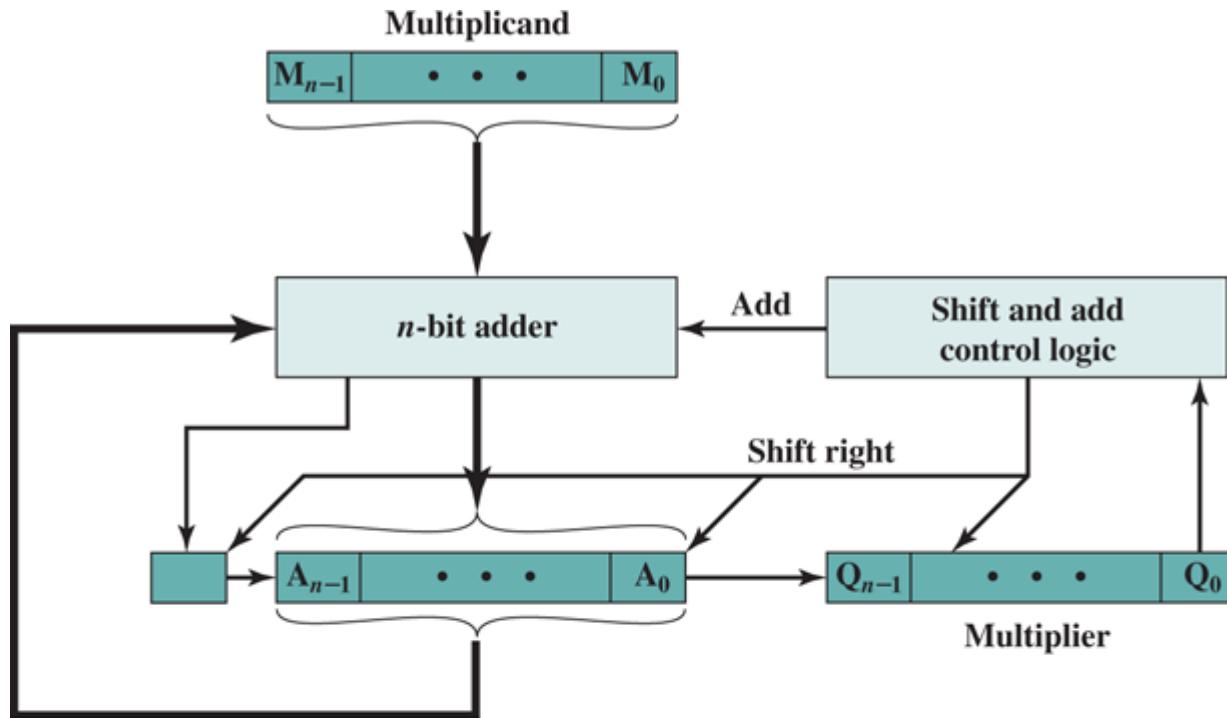

Figure 11.7 Multiplication of Unsigned Binary Integers

1. Multiplication involves the generation of **partial products**, one for each digit in the **multiplier**.

- These partial products are then summed to produce the final product.
2. The partial products are easily defined. When the multiplier bit is 0, the partial product is 0. When the multiplier is 1, the partial product is the **multiplicand**.
 3. The total product is produced by summing the partial products. For this operation, each successive partial product is shifted one position to the left relative to the preceding partial product.
 4. The multiplication of two n -bit binary integers results in a **product** of up to $2n$ bits in length (e.g., $11 \times 11 = 1001$).

Compared with the pencil-and-paper approach, there are several things we can do to make computerized multiplication more efficient. First, we can perform a running addition on the partial products rather than waiting until the end. This eliminates the need for storage of all the partial products; fewer registers are needed. Second, we can save some time on the generation of partial products. For each 1 on the multiplier, an add and a shift operation are required; but for each 0, only a shift is required.

Figure 11.8a shows a possible implementation employing these measures. The multiplier and multiplicand are loaded into two registers (Q and M). A third register, the A register, is also needed and is initially set to 0. There is also a 1-bit C register, initialized to 0, which holds a potential carry bit resulting from addition.

(a) Block diagram

C	A	Q	M		Initial values	
0	0000	1101	1011		Add {	
0	1011	1101	1011	Add	First cycle	
0	0101	1110	1011	Shift	{	Shift }
0	0010	1111	1011	Shift		Second cycle
0	1101	1111	1011	Add	{	Third cycle
0	0110	1111	1011	Shift		Shift }
1	0001	1111	1011	Add	{	Fourth cycle
0	1000	1111	1011	Shift		Shift }

(b) Example from Figure 10.7 (product in A, Q)

Figure 11.8 Hardware Implementation of Unsigned Binary Multiplication

The operation of the multiplier is as follows. Control logic reads the bits of the multiplier one at a time. If Q_0 is 1, then the multiplicand is added to the A register and the result is stored in the A register, with the C bit used for overflow. Then all of the bits of the C, A, and Q registers are shifted to the right one bit, so that the C bit goes into A_{n-1} , A_0 goes into Q_{n-1} , and Q_0 is lost. If Q_0 is 0, then no addition is performed, just the shift. This process is repeated for each bit of the original multiplier. The resulting $2n$ -bit product is contained in the A and Q registers. A flowchart of the operation is shown in [Figure 11.9](#), and an example is given in [Figure 11.8b](#). Note that on the second cycle, when the multiplier bit is 0, there is no add operation.

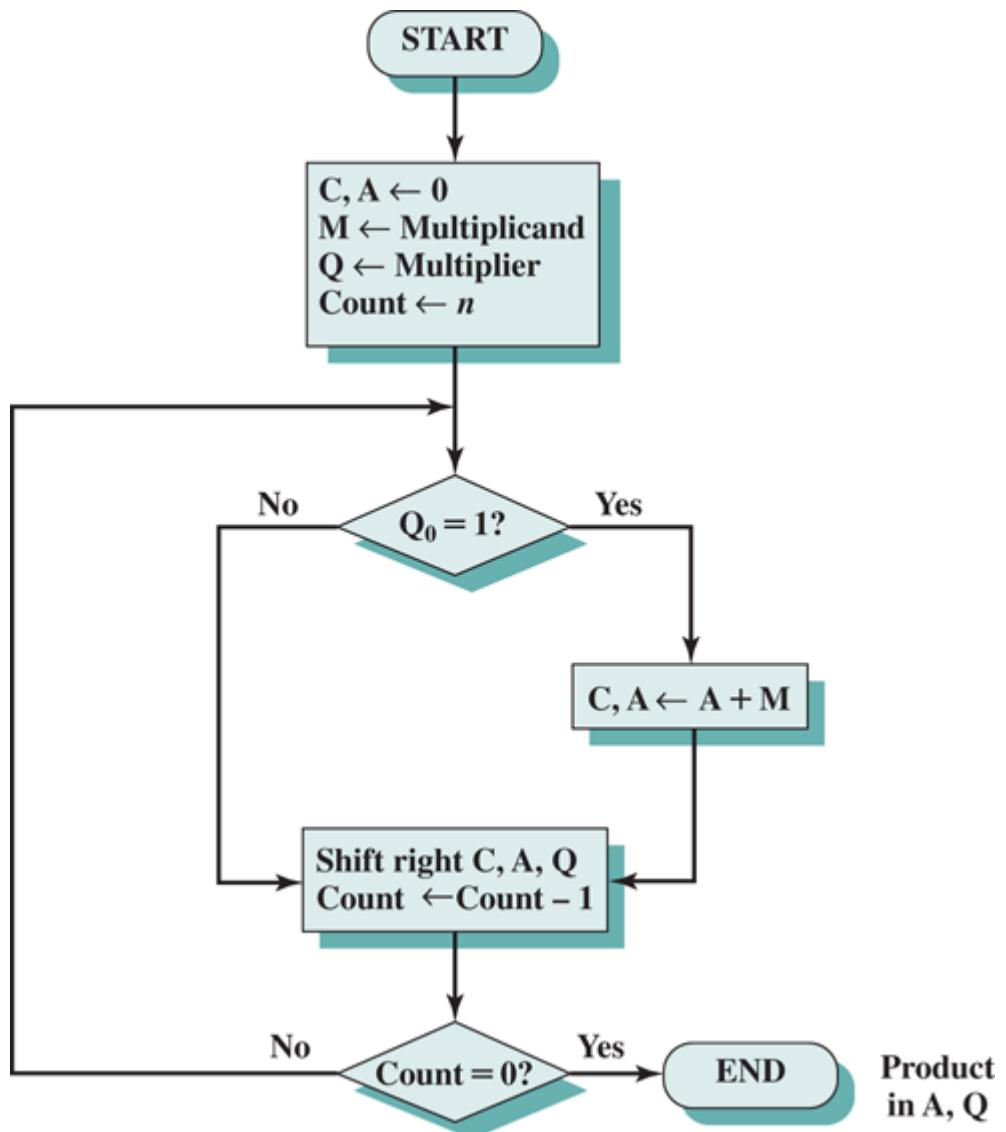

Figure 11.9 Flowchart for Unsigned Binary Multiplication

TWOS COMPLEMENT MULTIPLICATION

We have seen that addition and subtraction can be performed on numbers in twos complement notation by treating them as unsigned integers. Consider

$$\begin{array}{r}
 1001 \\
 +0011 \\
 \hline
 1100
 \end{array}$$

If these numbers are considered to be unsigned integers, then we are adding 9 (1001) plus 3 (0011) to get 12 (1100). As twos complement integers, we are adding $-7(1001)$ to 3 (0011) to get $-4(1100)$.

Unfortunately, this simple scheme will not work for multiplication. To see this, consider again [Figure 11.7](#). We multiplied 11 (1011) by 13 (1101) to get 143 (10001111). If we interpret these as twos complement numbers, we have $-5(1011)$ times $-3(1101)$ equals $-13(10001111)$. This example demonstrates that straightforward multiplication will not work if both the multiplicand and multiplier are negative. In fact, it will not work if either the multiplicand or the multiplier is negative. To justify this statement, we need to go back to [Figure 11.7](#) and explain what is being done in terms of operations with powers of 2. Recall that any unsigned binary number can be expressed as a sum of powers of 2. Thus,

$$1101 = 1 \times 2^3 + 1 \times 2^2 + 0 \times 2^1 + 1 \times 2^0 = 2^3 + 2^2 + 2^0$$

Further, the multiplication of a binary number by 2^n is accomplished by shifting that number to the left n bits. With this in mind, [Figure 11.10](#) recasts [Figure 11.7](#) to make the generation of partial products by multiplication explicit. The only difference in [Figure 11.10](#) is that it recognizes that the partial products should be viewed as $2n$ -bit numbers generated from the n -bit multiplicand.

1011	
$\times 1101$	
<hr/>	
00001011	$1011 \times 1 \times 2^0$
00000000	$1011 \times 0 \times 2^1$
00101100	$1011 \times 1 \times 2^2$
01011000	$1011 \times 1 \times 2^3$
<hr/>	
10001111	

Figure 11.10 Multiplication of Two Unsigned 4-Bit Integers Yielding an 8-Bit Result

Thus, as an unsigned integer, the 4-bit multiplicand 1011 is stored in an 8-bit word as 00001011. Each partial product (other than that for 2^0) consists of this number shifted to the left, with the unoccupied positions on the right filled with zeros (e.g., a shift to the left of two places yields 00101100).

Now we can demonstrate that straightforward multiplication will not work if the multiplicand is negative. The problem is that each contribution of the negative multiplicand as a partial product must be a negative number on a $2n$ -bit field; the sign bits of the partial products must line up. This is demonstrated in [Figure 11.11](#), which shows that multiplication of 1001 by 0011. If these are treated as unsigned integers, the multiplication of $9 \times 3 = 27$ proceeds simply. However, if 1001 is interpreted as the twos complement value -7 , then each partial product must be a negative twos complement number of $2n$ (8) bits, as shown in [Figure 11.11b](#). Note that this is accomplished by padding out each partial product to the left with binary 1s.

$\begin{array}{r} 1001 \quad (9) \\ \times 0011 \quad (3) \\ \hline 00001001 \quad 1001 \times 2^0 \\ 00010010 \quad 1001 \times 2^1 \\ \hline 00011011 \quad (27) \end{array}$	$\begin{array}{r} 1001 \quad (-7) \\ \times 0011 \quad (3) \\ \hline 11111001 \quad (-7) \times 2^0 = (-7) \\ 11110010 \quad (-7) \times 2^1 = (-14) \\ \hline 11101011 \quad (-21) \end{array}$
---	--

(a) Unsigned integers

(b) Twos complement integers

Figure 11.11 Comparison of Multiplication of Unsigned and Twos Complement Integers

If the multiplier is negative, straightforward multiplication also will not work. The reason is that the bits of the multiplier no longer correspond to the shifts or multiplications that must take place. For example, the 4-bit decimal number -3 is written 1101 in twos complement. If we simply took partial products based on each bit position, we would have the following correspondence:

$$1101 \leftrightarrow - (1 \times 2^3 + 1 \times 2^2 + 0 \times 2^1 + 1 \times 2^0) = - (2^3 + 2^2 + 2^0)$$

In fact, what is desired is – (2 + 2). So this multiplier cannot be used directly in the manner we have been describing.

There are a number of ways out of this dilemma. One would be to convert both multiplier and multiplicand to positive numbers, perform the multiplication, and then take the two's complement of the result if and only if the sign of the two original numbers differed. Implementers have preferred to use techniques that do not require this final transformation step. One of the most common of these is Booth's algorithm [BOOT51]. This algorithm also has the benefit of speeding up the multiplication process, relative to a more straightforward approach.

Booth's algorithm is depicted in **Figure 11.12** and can be described as follows. As before, the multiplier and multiplicand are placed in the Q and M registers, respectively. There is also a 1-bit register placed logically to the right of the least significant bit (Q_0) of the Q register and designated Q_{-1} ; its use is explained shortly. The results of the multiplication will appear in the A and Q registers. A and Q_{-1} are initialized to 0. As before, control logic scans the bits of the multiplier one at a time. Now, as each bit is examined, the bit to its right is also examined. If the two bits are the same (1–1 or 0–0), then all of the bits of the A, Q, and Q_{-1} registers are shifted to the right 1 bit. If the two bits differ, then the multiplicand is added to or subtracted from the A register, depending on whether the two bits are 0–1 or 1–0. Following the addition or subtraction, the right shift occurs. In either case, the right shift is such that the leftmost bit of A, namely A_{n-1} , not only is shifted into A_{n-2} , but also remains in A_{n-1} . This is required to preserve the sign of the number in A and Q. It is known as an **arithmetic shift**, because it preserves the sign bit.

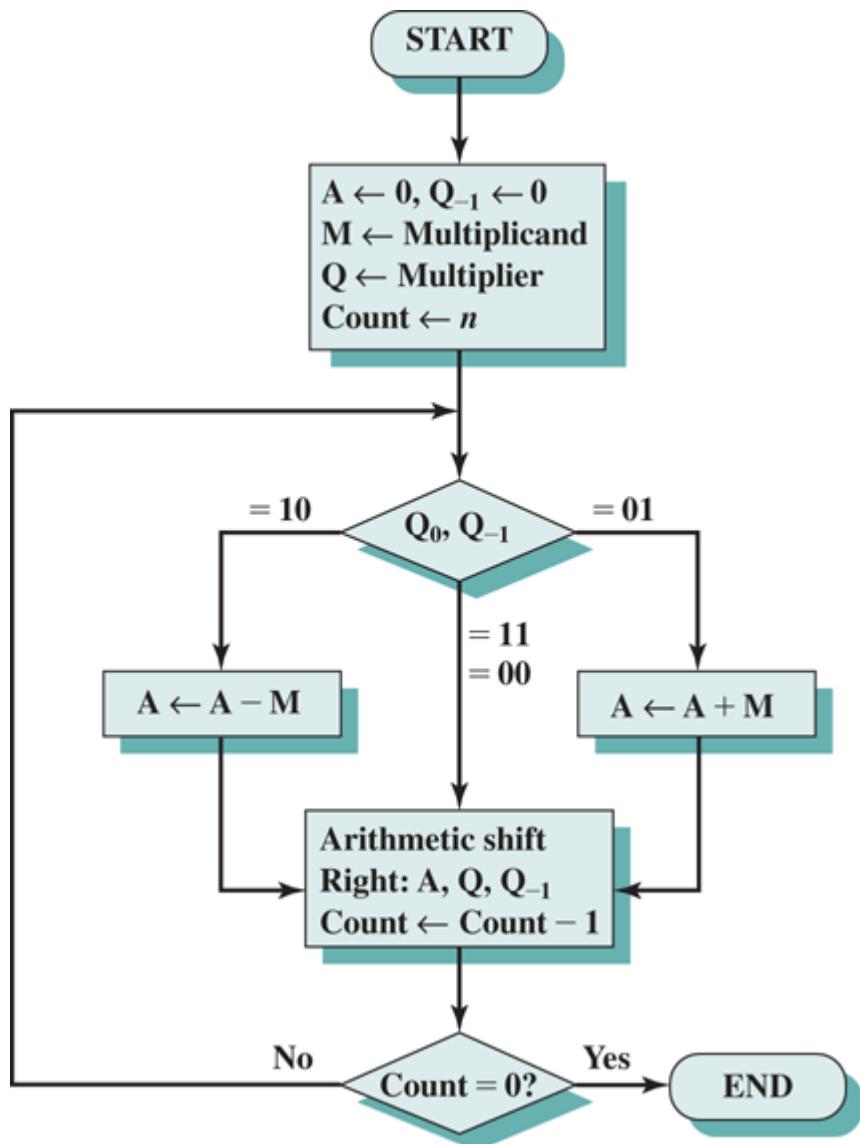

Figure 11.12 Booth's Algorithm for Twos Complement Multiplication

Figure 11.13 shows the sequence of events in Booth's algorithm for the multiplication of 7 by 3. More compactly, the same operation is depicted in Figure 11.14a. The rest of Figure 11.14 gives other examples of the algorithm. As can be seen, it works with any combination of positive and negative numbers. Note also the efficiency of the algorithm. Blocks of 1s or 0s are skipped over, with an average of only one addition or subtraction per block.

A	Q	Q ₋₁	M	Initial values	
0000	0011	0	0111		
1001	0011	0	0111	A ← A - M	First cycle
1100	1001	1	0111	Shift	
1110	0100	1	0111	Shift	Second cycle
0101	0100	1	0111	A ← A + M	
0010	1010	0	0111	Shift	Third cycle
0001	0101	0	0111	Shift

$$(c) (-7) \times (3) = (-21)$$

$$(d) (-7) \times (-3) = (21)$$

Figure 11.14 Examples Using Booth's Algorithm

Why does Booth's algorithm work? Consider first the case of a positive multiplier. In particular, consider a positive multiplier consisting of one block of 1s surrounded by 0s (e.g., 00011110). As we know, multiplication can be achieved by adding appropriately shifted copies of the multiplicand:

$$\begin{aligned}
 M \times (00011110) &= M \times (2^4 + 2^3 + 2^2 + 2^1) \\
 &= M \times (16 + 8 + 4 + 2) \\
 &= M \times 30
 \end{aligned}$$

The number of such operations can be reduced to two if we observe that

$$2^n + 2^{n-1} + \dots + 2^{n-K} = 2^{n+1} - 2^{n-K} \quad (11.3)$$

$$\begin{aligned}
 M \times (00011110) &= M \times (2^5 - 2^1) \\
 &= M \times (32 - 2) \\
 &= M \times 30
 \end{aligned}$$

So the product can be generated by one addition and one subtraction of the multiplicand. This scheme extends to any number of blocks of 1s in a multiplier, including the case in which a single 1 is treated as a block.

$$\begin{aligned}
 M \times (01111010) &= M \times (2^6 + 2^5 + 2^4 + 2^3 + 2^1) \\
 &= M \times (2^7 - 2^3 + 2^2 - 2^1)
 \end{aligned}$$

Booth's algorithm conforms to this scheme by performing a subtraction when the first 1 of the block is encountered (1–0) and an addition when the end of the block is encountered (0–1).

To show that the same scheme works for a negative multiplier, we need to observe the following. Let X be a negative number in two's complement notation:

$$\text{Representation of } X = \{ 1x_{n-2}x_{n-1}\dots x_1x_0 \}$$

Then the value of X can be expressed as follows:

$$X = -2^{n-1} + (x_{n-2} \times 2^{n-2}) + (x_{n-3} \times 2^{n-3}) + \dots + (x_1 \times 2^1) + (x_0 \times 2^0) \quad (11.4)$$

The reader can verify this by applying the algorithm to the numbers in **Table 11.2**.

The leftmost bit of X is 1, because X is negative. Assume that the leftmost 0 is in the k th position. Thus, X is of the form

$$\text{Representation of } X = \{ 111\dots 10x_{k-1}x_{k-2}\dots x_1x_0 \} \quad (11.5)$$

Then the value of X is

$$X = -2^{n-1} + 2^{n-2} + \dots + 2^{k+1} + (x_{k-1} \times 2^{k-1}) + \dots + (x_0 \times 2^0) \quad (11.6)$$

From **Equation (11.3)**, we can say that

$$2^{n-2} + 2^{n-3} + \dots + 2^{k-1} = 2^{n-1} - 2^{k-1}$$

Rearranging

$$-2^{n-1} + 2^{n-2} + 2^{n-3} + \dots + 2^{k+1} = -2^{k+1} \quad (11.7)$$

Substituting **Equation (11.7)** into **Equation (11.6)**, we have

$$X = -2^{k+1} + (x_{k-1} \times 2^{k-1}) + \dots + (x_0 \times 2^0) \quad (11.8)$$

At last we can return to Booth's algorithm. Remembering the representation of X [**Equation (11.5)**], it is clear that all of the bits from x_0 up to the leftmost 0 are handled properly because they produce all of the terms in **Equation (11.8)** but (-2^{k+1}) , and thus are in the proper form. As the algorithm scans over the leftmost 0 and encounters the next 1 (2^{k+1}), a 1–0 transition occurs and a subtraction takes place (-2^{k+1}) . This is the remaining term in **Equation (11.8)**.

As an example, consider the multiplication of some multiplicand by (-6) . In two's complement representation, using an 8-bit word, (-6) is represented as 11111010. By **Equation (11.4)**, we know that

$$-6 = -2^7 + 2^6 + 2^5 + 2^4 + 2^3 + 2^1$$

which the reader can easily verify. Thus,

$$M \times (11111010) = M \times (-2^7 + 2^6 + 2^5 + 2^4 + 2^3 + 2^1)$$

Using Equation (11.7),

$$M \times (11111010) = M \times (-2^3 + 2^1)$$

which the reader can verify is still $M \times (-6)$. Finally, following our earlier line of reasoning,

$$M \times (11111010) = M \times (-2^3 + 2^2 - 2^1)$$

We can see that Booth's algorithm conforms to this scheme. It performs a subtraction when the first 1 is encountered (10), an addition when (01) is encountered, and finally another subtraction when the first 1 of the next block of 1s is encountered. Thus, Booth's algorithm performs fewer additions and subtractions than a more straightforward algorithm.

Division

Division is somewhat more complex than multiplication, but is based on the same general principles. As before, the basis for the algorithm is the paper-and-pencil approach, and the operation involves repetitive shifting and addition or subtraction.

Figure 11.15 shows an example of the long division of unsigned binary integers. It is instructive to describe the process in detail. First, the bits of the **dividend** are examined from left to right, until the set of bits examined represents a number greater than or equal to the **divisor**; this is referred to as the divisor being able to divide the number. Until this event occurs, 0s are placed in the **quotient** from left to right. When the event occurs, a 1 is placed in the quotient and the divisor is subtracted from the partial dividend. The result is referred to as a *partial remainder*.

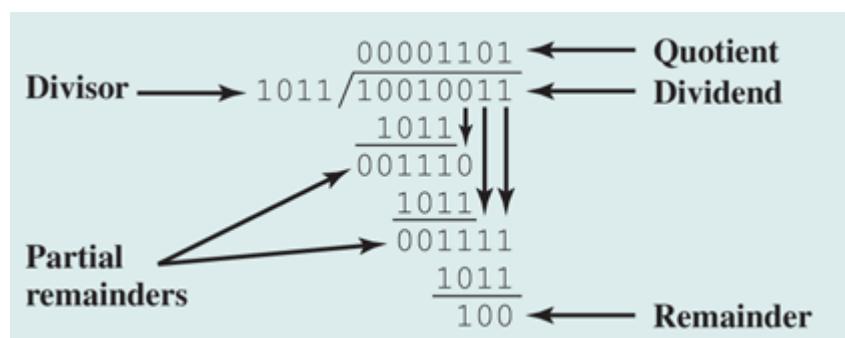

Figure 11.15 Example of Division of Unsigned Binary Integers

From this point on, the division follows a cyclic pattern. At each cycle, additional bits from the dividend are appended to the partial remainder until the result is greater than or equal to the divisor. As before, the divisor is subtracted from this number to produce a new partial remainder. The process continues until all the bits of the dividend are exhausted.

Figure 11.16 shows a machine algorithm that corresponds to the long division process. The divisor is placed in the M register, the dividend in the Q register. At each step, the A and Q registers together are shifted to the left 1 bit. M is subtracted from A to determine whether A divides the partial remainder.³ If it does, then Q_0 gets a 1 bit. Otherwise, Q_0 gets a 0 bit and M must be added back to A to restore the previous value. The count is then decremented, and the process continues for n steps. At the end, the quotient is in the Q register and the **remainder** is in the A register.

³ This is subtraction of unsigned integers. A result that requires a borrow out of the most significant bit is a negative result.

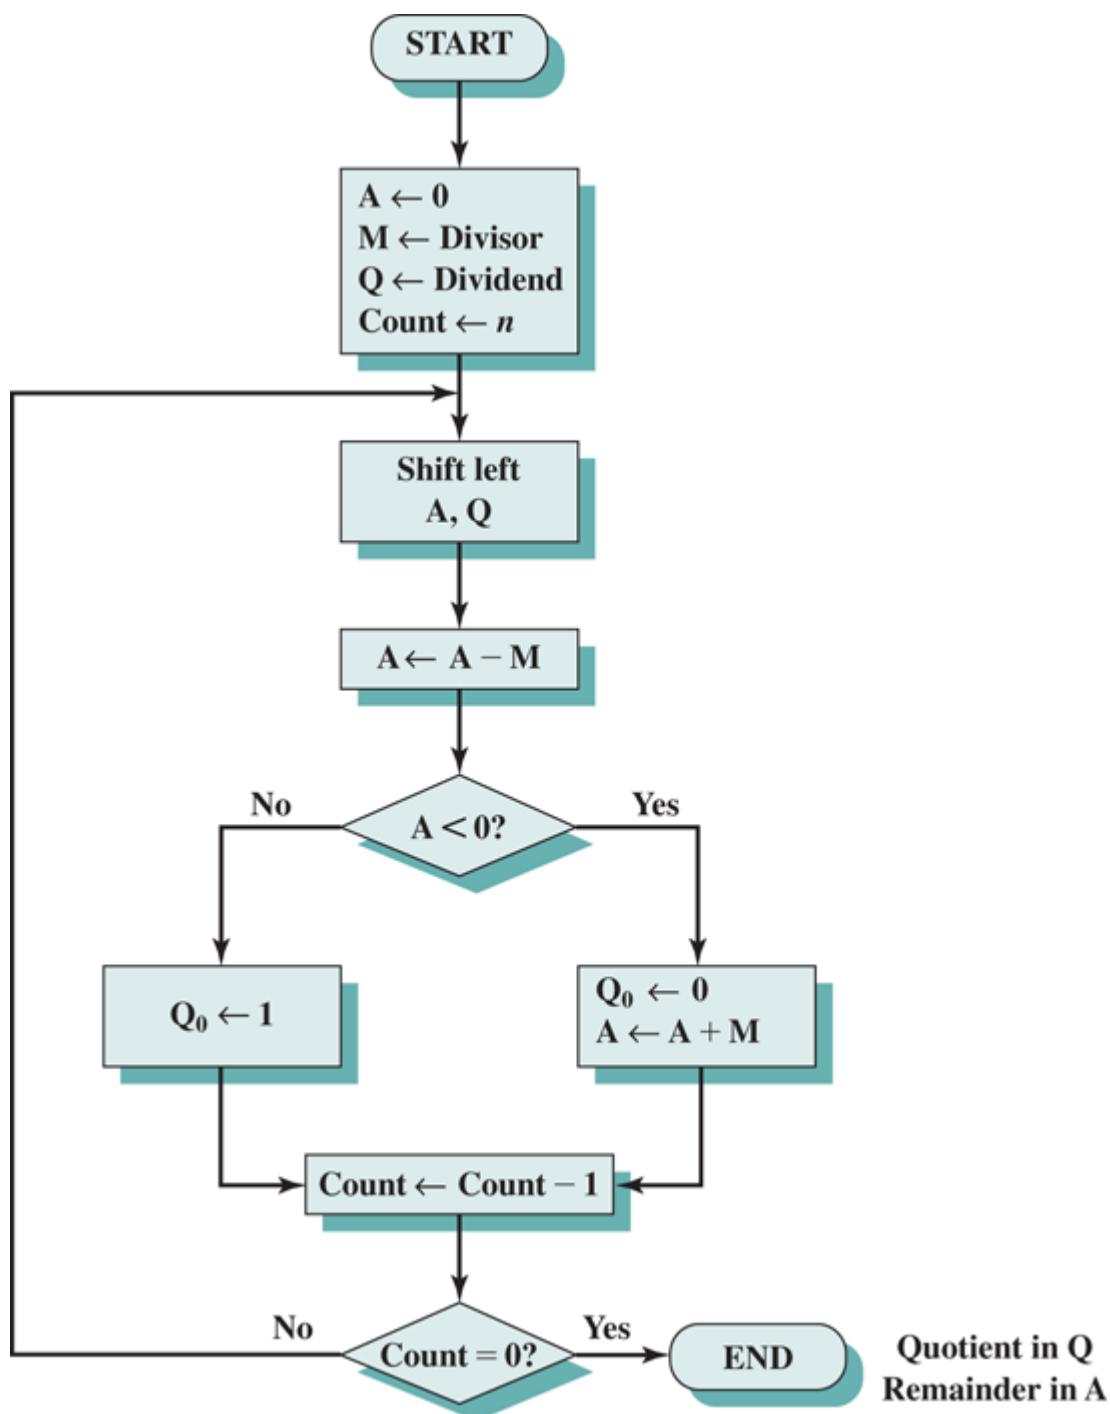

Figure 11.16 Flowchart for Unsigned Binary Division

This process can, with some difficulty, be extended to negative numbers. We give here one approach for two's complement numbers. An example of this approach is shown in [Figure 11.17](#).

A	Q	
0000	0111	Initial value
0000	1110	Shift
1101		Use twos complement of 0011 for subtraction
1101		Subtract
0000	1110	Restore, set $Q_0 = 0$
0001	1100	Shift
1101		Subtract
1110	1100	Restore, set $Q_0 = 0$
0011	1000	Shift
1101		Subtract, set $Q_0 = 1$
0000	1001	
0001	0010	Shift
1101		Subtract
1110	0010	Restore, set $Q_0 = 0$
0001		

Figure 11.17 Example of Restoring Twos Complement Division (7/3)

The algorithm assumes that the divisor V and the dividend D are positive and that $|V| < |D|$. If $|V| = |D|$, then the quotient $Q = 1$ and the remainder $R = 0$. If $|V| > |D|$, then $Q = 0$ and $R = D$. The algorithm can be summarized as follows:

1. Load the twos complement of the divisor into the M register; that is, the M register contains the negative of the divisor. Load the dividend into the A, Q registers. The dividend must be expressed as a $2n$ -bit positive number. Thus, for example, the 4-bit 0111 becomes 00000111.
2. Shift A, Q left 1 bit position.
3. Perform $A \leftarrow A - M$. This operation subtracts the divisor from the contents of A.
4.
 - a. If the result is nonnegative (most significant bit of A = 0), then set $Q_0 \leftarrow 1$.
 - b. If the result is negative (most significant bit of A = 1), then set $Q_0 \leftarrow 0$. and restore the previous value of A.
5. Repeat steps 2 through 4 as many times as there are bit positions in Q.
6. The remainder is in A and the quotient is in Q.

To deal with negative numbers, we recognize that the remainder is defined by

$$D = Q \times V + R$$

That is, the remainder is the value of R needed for the preceding equation to be valid. Consider the following examples of integer division with all possible combinations of signs of D and V :

$$\begin{aligned} D = 7 \quad V = 3 &\Rightarrow Q = 2 \quad R = 1 \\ D = 7 \quad V = -3 &\Rightarrow Q = -2 \quad R = 1 \\ D = -7 \quad V = 3 &\Rightarrow Q = -2 \quad R = -1 \\ D = -7 \quad V = -3 &\Rightarrow Q = 2 \quad R = -1 \end{aligned}$$

The reader will note from [Figure 11.17](#) that $(-7) / (3)$ and $(7) / (-3)$ produce different remainders. We see that the magnitudes of Q and R are unaffected by the input signs and that the signs of Q and R are easily derivable from the signs of D and V . Specifically, $\text{sign}(R) = \text{sign}(D)$ and $\text{sign}(Q) = \text{sign}(D) \times \text{sign}(V)$. Hence, one way to do twos complement division is to convert the operands into unsigned values and, at the end, to account for the signs by complementation where needed. This is the method of choice for the restoring division algorithm [PARH10].

11.4 Floating-Point Representation

Principles

With a fixed-point notation (e.g., twos complement) it is possible to represent a range of positive and negative integers centered on or near 0. By assuming a fixed binary or radix point, this format allows the representation of numbers with a fractional component as well.

This approach has limitations. Very large numbers cannot be represented, nor can very small fractions. Furthermore, the fractional part of the quotient in a division of two large numbers could be lost.

For decimal numbers, we get around this limitation by using scientific notation. Thus, 976,000,000,000,000 can be represented as 9.76×10^{14} , and 0.0000000000000976 can be represented as 9.76×10^{-14} . What we have done, in effect, is dynamically to slide the decimal point to a convenient location and use the exponent of 10 to keep track of that decimal point. This allows a range of very large and very small numbers to be represented with only a few digits.

This same approach can be taken with binary numbers. We can represent a number in the form

$$\pm S \times B^{\pm E}$$

This number can be stored in a binary word with three fields:

- Sign: plus or minus
- Significand S
- Exponent E

The **base** B is implicit and need not be stored because it is the same for all numbers. Typically, it is assumed that the radix point is to the right of the leftmost, or most significant, bit of the significand. That is, there is one bit to the left of the radix point.

The principles used in representing binary floating-point numbers are best explained with an example. **Figure 11.18a** shows a typical 32-bit floating-point format. The leftmost bit stores the **sign** of the number (0 = positive, 1 = negative). The **exponent** value is stored in the next 8 bits. The representation used is known as a **biased representation**. A fixed value, called the bias, is subtracted from the field to get the true exponent value. Typically, the bias equals $(2^{k-1} - 1)$, where k is the number of bits in the binary exponent. In this case, the 8-bit field yields the numbers 0 through 255. With a bias of 127 ($2^7 - 1$), the true exponent values are in the range –127 to +128. In this example, the base is assumed to be 2.

(a) Format

$$\begin{array}{lll}
 1.1010001 \times 2^{10100} & = 0 \ 10010011 \ 10100010000000000000000000 = 1.6328125 \times 2^{20} \\
 -1.1010001 \times 2^{10100} & = 1 \ 10010011 \ 10100010000000000000000000 = -1.6328125 \times 2^{20} \\
 1.1010001 \times 2^{-10100} & = 0 \ 01101011 \ 10100010000000000000000000 = 1.6328125 \times 2^{-20} \\
 -1.1010001 \times 2^{-10100} & = 1 \ 01101011 \ 10100010000000000000000000 = -1.6328125 \times 2^{-20}
 \end{array}$$

(b) Examples

Figure 11.18 Typical 32-Bit Floating-Point Format

Table 11.2 shows the biased representation for 4-bit integers. Note that when the bits of a biased representation are treated as unsigned integers, the relative magnitudes of the numbers do not change. For example, in both biased and unsigned representations, the largest number is 1111 and the smallest number is 0000. This is not true of sign-magnitude or twos complement representation. An advantage of biased representation is that nonnegative floating-point numbers can be treated as integers for comparison purposes.

The final portion of the word (23 bits in this case) is the **significand**.⁴

⁴ The term **mantissa**, sometimes used instead of *significand*, is considered obsolete. *Mantissa* also means “the fractional part of a logarithm,” so is best avoided in this context.

Any floating-point number can be expressed in many ways.

The following are equivalent, where the significand is expressed in binary form:

$$\begin{aligned}
 & 0.110 \times 2^5 \\
 & 110 \times 2^2 \\
 & 0.0110 \times 2^6
 \end{aligned}$$

To simplify operations on floating-point numbers, it is typically required that they be normalized. A **normal number** is one in which the most significant digit of the significand is nonzero. For base 2 representation, a normal number is therefore one in which the most significant bit of the significand is one. As was mentioned, the typical convention is that there is one bit to the left of the radix point. Thus, a normal nonzero number is one in the form

$$\pm 1.bbb \dots b \times 2^{\pm E}$$

where b is either binary digit (0 or 1). Because the most significant bit is always one, it is unnecessary to store this bit; rather, it is implicit. Thus, the 23-bit field is used to store a 24-bit significand with a value in the half open interval [1, 2). Given a number that is not normal, the number may be normalized by shifting the radix point to the right of the leftmost 1 bit and adjusting the exponent

accordingly.

Figure 11.18b gives some examples of numbers stored in this format. For each example, on the left is the binary number; in the center is the corresponding bit pattern; on the right is the decimal value. Note the following features:

- The sign is stored in the first bit of the word.
- The first bit of the true significand is always 1 and need not be stored in the significand field.
- The value 127 is added to the true exponent to be stored in the exponent field.
- The base is 2.

For comparison, **Figure 11.19** indicates the range of numbers that can be represented in a 32-bit word. Using two's complement integer representation, all of the integers from -2^{31} to $2^{31} - 1$ can be represented, for a total of 2^{32} different numbers. With the example floating-point format of **Figure 11.18**, the following ranges of numbers are possible:

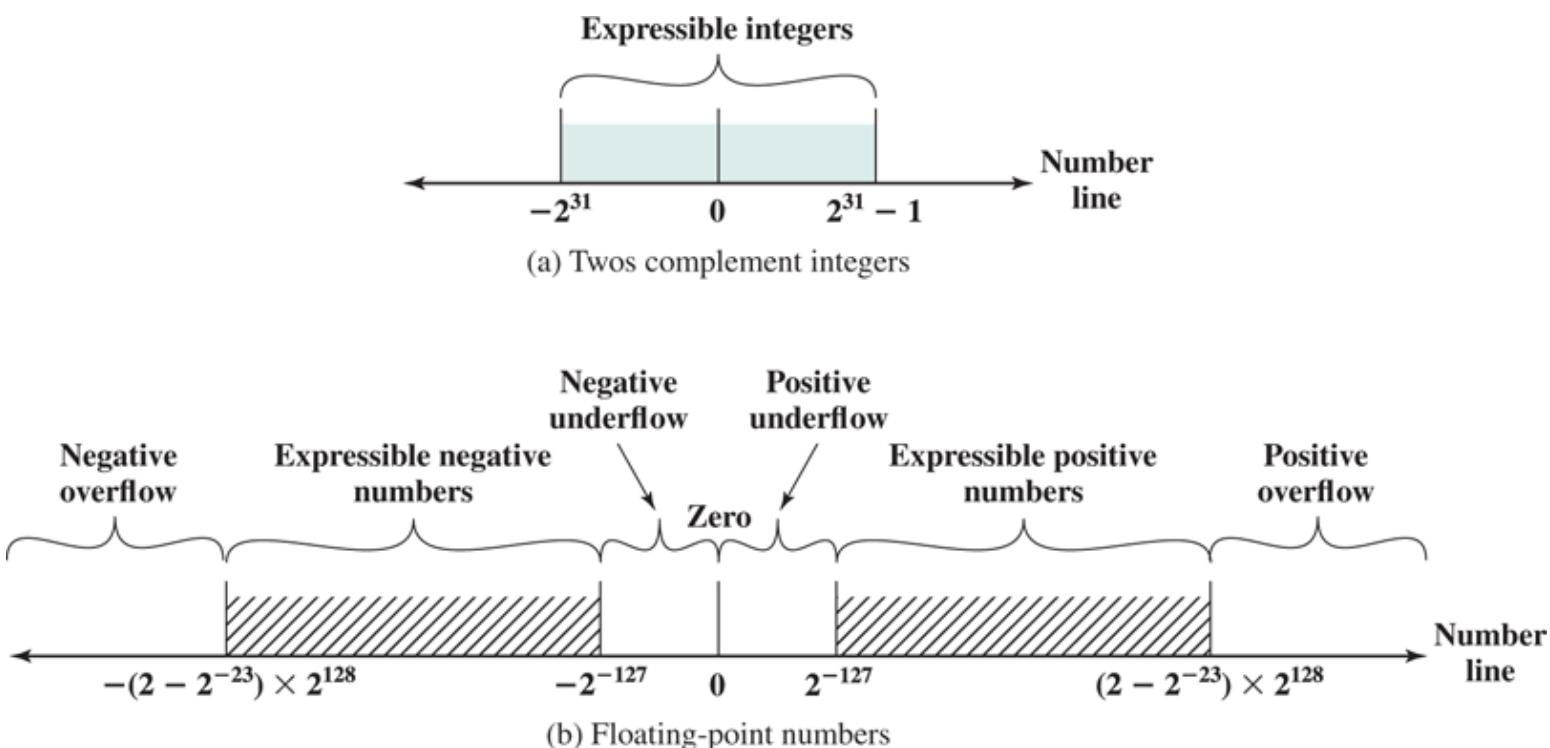

Figure 11.19 Expressible Numbers in Typical 32-Bit Formats

- Negative numbers between $-2 - 2^{-23} \times 2^{128}$ and -2^{-127}
- Positive numbers between 2^{-127} and $2 - 2^{-23} \times 2^{128}$

Five regions on the number line are not included in these ranges:

- Negative numbers less than $-(2 - 2^{-23}) \times 2^{128}$, called **negative overflow**
- Negative numbers greater than 2^{-127} , called **negative underflow**
- Zero
- Positive numbers less than 2^{-127} , called **positive underflow**
- Positive numbers greater than $(2 - 2^{-23}) \times 2^{128}$, called **positive overflow**

The representation as presented will not accommodate a value of 0. However, as we shall see, actual floating-point representations include a special bit pattern to designate zero. Overflow occurs when an arithmetic operation results in an absolute value greater than can be expressed with an exponent of 128 (e.g., $2^{120} \times 2^{100} = 2^{220}$). Underflow occurs when the fractional magnitude is too small (e.g., $-120 - 100 - 220$).

$2^{-n} \times 2^{32} = 2^{-n}$). Underflow is a less serious problem because the result can generally be satisfactorily approximated by 0.

It is important to note that we are not representing more individual values with floating-point notation. The maximum number of different values that can be represented with 32 bits is still 2^{32} . What we have done is to spread those numbers out in two ranges, one positive and one negative. In practice, most floating-point numbers that one would wish to represent are represented only approximately. However, for moderate sized integers, the representation is exact.

Also, note that the numbers represented in floating-point notation are not spaced evenly along the number line, as are fixed-point numbers. The possible values get closer together near the origin and farther apart as you move away, as shown in [Figure 11.20](#). This is one of the trade-offs of floating-point math: Many calculations produce results that are not exact and have to be rounded to the nearest value that the notation can represent.

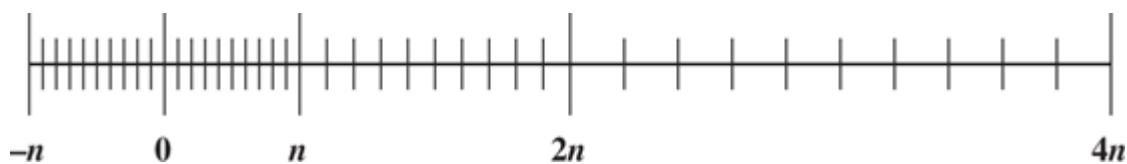

Figure 11.20 Density of Floating-Point Numbers

In the type of format depicted in [Figure 11.18](#), there is a trade-off between range and precision. The example shows 8 bits devoted to the exponent and 23 to the significand. If we increase the number of bits in the exponent, we expand the range of expressible numbers. But because only a fixed number of different values can be expressed, we have reduced the density of those numbers and therefore the precision. The only way to increase both range and precision is to use more bits. Thus, most computers offer, at least, single-precision numbers and double-precision numbers. For example, a processor could support a single-precision format of 64 bits, and a double-precision format of 128 bits.

So there is a trade-off between the number of bits in the exponent and the number of bits in the significand. But it is even more complicated than that. The implied base of the exponent need not be 2. The IBM S/390 architecture, for example, uses a base of 16 [ANDE67b]. The format consists of a 7-bit exponent and a 24-bit significand.

In the IBM base-16 format,

$$0.11010001 \times 2^{10100} = 0.11010001 \times 16^{101}$$

and the exponent is stored to represent 5 rather than 20.

The advantage of using a larger exponent is that a greater range can be achieved for the same number of exponent bits. But remember, we have not increased the number of different values that can be represented. Thus, for a fixed format, a larger exponent base gives a greater range at the expense of less precision.

IEEE Standard for Binary Floating-Point Representation

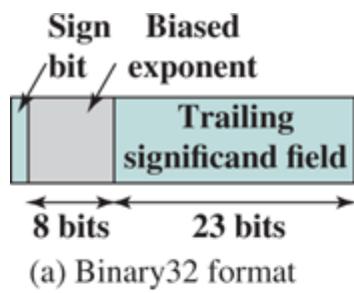

The most important floating-point representation is defined in IEEE Standard 754, adopted in 1985 and revised in 2008. This standard was developed to facilitate the portability of programs from one processor to another and to encourage the development of sophisticated, numerically oriented programs. The standard has been widely adopted and is used on virtually all contemporary

processors and arithmetic coprocessors. IEEE 754-2008 covers both binary and decimal floating-point representations. In this chapter, we deal only with binary representations.

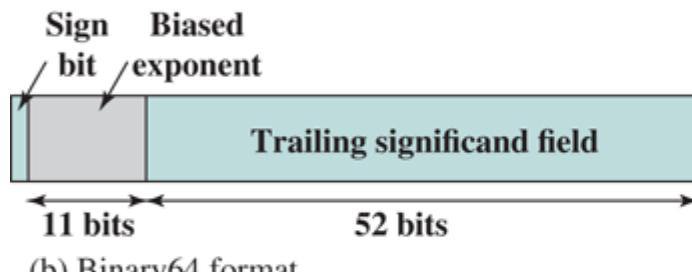

IEEE 754-2008 defines the following different types of floating-point formats:

- **Arithmetic format:** All the mandatory operations defined by the standard are supported by the format. The format may be used to represent floating-point operands or results for the operations described in the standard.
- **Basic format:** This format covers five floating-point representations, three binary and two decimal, whose encodings are specified by the standard, and which can be used for arithmetic. At least one of the basic formats is implemented in any conforming implementation.
- **Interchange format:** A fully specified, fixed-length binary encoding that allows data interchange between different platforms and that can be used for storage.

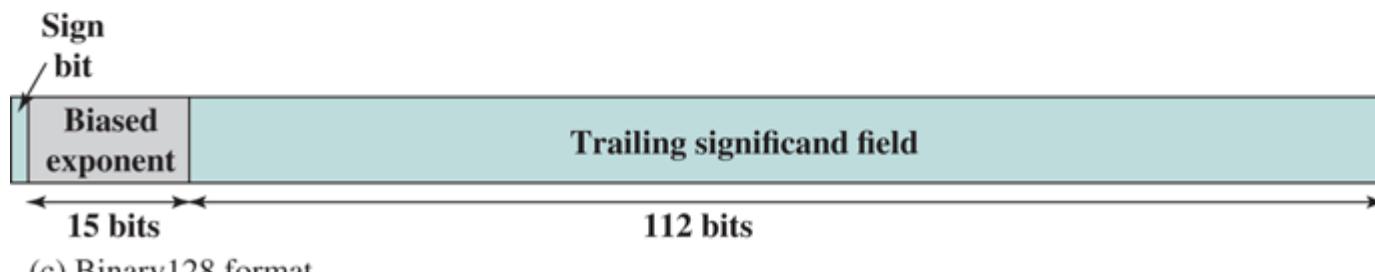

The three basic binary formats have bit lengths of 32, 64, and 128 bits, with exponents of 8, 11, and 15 bits, respectively (Figure 11.21). Table 11.3 summarizes the characteristics of the three formats. The two basic decimal formats have bit lengths of 64 and 128 bits. All of the basic formats are also arithmetic format types (can be used for arithmetic operations) and interchange format types (platform independent).

(a) Binary32 format

(b) Binary64 format

(c) Binary128 format

Figure 11.21 IEEE 754 Formats

Table 11.3 IEEE 754 Format Parameters

Parameter	Format		
	Binary32	Binary64	Binary128

Storage width (bits)	32	64	128
Exponent width (bits)	8	11	15
Exponent bias	127	1023	16383
Maximum exponent	127	1023	16383
Minimum exponent	-126	-1022	-16382
Approx normal number range (base 10)	$10^{-38}, 10^{+38}$	$10^{-308}, 10^{+308}$	$10^{-4932}, 10^{+4932}$
Trailing significand width (bits)*	23	52	112
Number of exponents	254	2046	32766
Number of fractions	2^{23}	2^{52}	2^{112}
Number of values	1.98×2^{31}	1.99×2^{63}	1.99×2^{128}
Smallest positive normal number	2^{-126}	2^{-1022}	2^{-16362}
Largest positive normal number	$2^{128} - 2^{104}$	$2^{1024} - 2^{971}$	$2^{16384} - 2^{16271}$
Smallest subnormal magnitude	2^{-149}	2^{-1074}	2^{-16494}

Note: * Not including implied bit and not including sign bit.

Several other formats are specified in the standard. The binary16 format is only an interchange format and is intended for storage of values when higher precision is not required. The binary $\{k\}$ format and the decimal $\{k\}$ format are interchange formats with total length k bits and with defined lengths for the significand and exponent. The format must be a multiple of 32 bits; thus formats are defined for $k = 160, 192$, and so on. These two families of formats are also arithmetic formats.

In addition, the standard defines **extended precision formats**, which extend a supported basic format by providing additional bits in the exponent (extended range) and in the significand (extended precision). The exact format is implementation dependent, but the standard places certain constraints on the length of the exponent and significand. These formats are arithmetic format types but not interchange format types. The extended formats are to be used for intermediate calculations. With their greater precision, the extended formats lessen the chance of a final result that has been contaminated by excessive roundoff error; with their greater range, they also lessen the chance of an intermediate overflow aborting a computation whose final result would have been representable in a basic format. An additional motivation for the extended format is that it affords some of the benefits of a larger basic format without incurring the time penalty usually associated with higher precision.

Finally, IEEE 754-2008 defines an **extendable precision format** as a format with a precision and range that are defined under user control. Again, these formats may be used for intermediate calculations, but the standard places no constraint on format or length.

Table 11.4 shows the relationship between defined formats and format types.

Table 11.4 IEEE Formats

Format	Format Type		
	Arithmetic Format	Basic Format	Interchange Format
binary16			X
binary32	X	X	X
binary64	X	X	X
binary128	X	X	X
binary{k} ($k = n \times 32$ for $n > 4$)	X		X
decimal64	X	X	X
decimal128	X	X	X
decimal{k} ($k = n \times 32$ for $n > 4$)	X		X
extended precision	X		
extendable precision	X		

Not all bit patterns in the IEEE formats are interpreted in the usual way; instead, some bit patterns are used to represent special values. **Table 11.5** indicates the values assigned to various bit patterns. The exponent values of all zeros (0 bits) and all ones (1 bits) define special values. The following classes of numbers are represented:

Table 11.5 Interpretation of IEEE 754 Floating-Point Numbers

(a) binary32 format				
	Sign	Biased Exponent	Fraction	Value
positive zero	0	0	0	0
negative zero	1	0	0	-0
plus infinity	0	all 1s	0	∞
minus infinity	1	all 1s	0	$-\infty$

quiet NaN	0 or 1	all 1s	$\neq 0 ; \text{firstbit} = 1$	qNaN
signaling NaN	0 or 1	all 1s	$\neq 0 ; \text{firstbit} = 0$	sNaN
positive normal nonzero	0	$0 < e < 225$	f	$2^{e - 127} (1.f)$
negative normal nonzero	1	$0 < e < 225$	f	$-2^{e - 127} (1.f)$
positive subnormal	0	0	$f \neq 0$	$2^{e - 126} (0.f)$
negative subnormal	1	0	$f \neq 0$	$-2^{e - 126} (0.f)$

(b) binary64 format

	Sign	Biased Exponent	Fraction	Value
positive zero	0	0	0	0
negative zero	1	0	0	-0
plus infinity	0	all 1s	0	∞
minus infinity	1	all 1s	0	$-\infty$
quiet NaN	0 or 1	all 1s	$\neq 0 ; \text{firstbit} = 1$	qNaN
signaling NaN	0 or 1	all 1s	$\neq 0 ; \text{firstbit} = 0$	sNaN
positive normal nonzero	0	$0 < e < 2047$	f	$2^{e - 1023} (1.f)$
negative normal nonzero	1	$0 < e < 2047$	f	$-2^{e - 1023} (1.f)$
positive subnormal	0	0	$f \neq 0$	$2^{e - 1022} (0.f)$
negative subnormal	1	0	$f \neq 0$	$-2^{e - 1022} (0.f)$

(c) binary128 format

	Sign	Biased Exponent	Fraction	Value
positive zero	0	0	0	0
negative zero	1	0	0	-0
				∞

plus infinity	0	all 1s	0	
minus infinity	1	all 1s	0	$-\infty$
quiet NaN	0 or 1	all 1s	$\neq 0 ; \text{firstbit} = 1$	qNaN
signaling NaN	0 or 1	all 1s	$\neq 0 ; \text{firstbit} = 0$	sNaN
positive normal nonzero	0	all 1s	f	$2^{e - 16383} (1.f)$
negative normal nonzero	1	all 1s	f	$-2^{e - 16383} (1.f)$
positive subnormal	0	0	$f \neq 0$	$2^{e - 16383} (0.f)$
negative subnormal	1	0	$f \neq 0$	$-2^{e - 16383} (0.f)$

- For exponent values in the range of 1 through 254 for 32-bit format, 1 through 2046 for 64-bit format, and 1 through 16382, normal nonzero floating-point numbers are represented. The exponent is biased, so that the range of exponents is –126 through +127 for 32-bit format, and so on. A normal number requires a 1 bit to the left of the binary point; this bit is implied, giving an effective 24-bit, 53-bit, or 113-bit significand. Because one of the bits is implied, the corresponding field in the binary format is referred to as the **trailing significand field**.
- An exponent of zero together with a fraction of zero represents positive or negative zero, depending on the sign bit. As was mentioned, it is useful to have an exact value of 0 represented.
- An exponent of all ones together with a fraction of zero represents positive or negative infinity, depending on the sign bit. It is also useful to have a representation of infinity. This leaves it up to the user to decide whether to treat overflow as an error condition or to carry the value ∞ and proceed with whatever program is being executed.
- An exponent of zero together with a nonzero fraction represents a subnormal number. In this case, the bit to the left of the binary point is zero and the true exponent is –126 or –1022. The number is positive or negative depending on the sign bit.
- An exponent of all ones together with a nonzero fraction is given the value NaN, which means *Not a Number*, and is used to signal various exception conditions.

The significance of subnormal numbers and NaNs is discussed in [Section 11.5](#).

11.5 Floating-Point Arithmetic

Table 11.6 summarizes the basic operations for floating-point arithmetic. For addition and subtraction, it is necessary to ensure that both operands have the same exponent value. This may require shifting the radix point on one of the operands to achieve alignment. Multiplication and division are more straightforward.

Table 11.6 Floating-Point Numbers and Arithmetic Operations

Floating-Point Numbers	Arithmetic Operations
$X = X_S \times B^{X_E}$ $Y = Y_S \times B^{Y_E}$	$X + Y = X_S \times B^{X_E - Y_E} + Y_S \times B^{Y_E}$ $X - Y = X_S \times B^{X_E - Y_E} - Y_S \times B^{Y_E}$ $X_E \leq Y_E$
	$X \times Y = (X_S \times Y_S) \times B^{X_E + Y_E}$
	$X \div Y = \frac{X_S}{Y_S} \times B^{X_E - Y_E}$

A floating-point operation may produce one of these conditions:

- **Exponent overflow:** A positive exponent exceeds the maximum possible exponent value. In some systems, this may be designated as $+\infty$ or $-\infty$.
- **Exponent underflow:** A negative exponent is less than the minimum possible exponent value (e.g., -200 is less than -127). This means that the number is too small to be represented, and it may be reported as 0.

Examples:

$$\begin{aligned} X &= 0.3 \times 10^2 = 30 \\ Y &= 0.2 \times 10^3 = 200 \\ X + Y &= (0.3 \times 10^{-2}) + 0.2 \times 10^3 = 0.23 \times 10^3 = 230 \\ X - Y &= (0.3 \times 10^{-2}) - 0.2 \times 10^3 = (-0.17) \times 10^3 = -170 \\ X \times Y &= (0.3 \times 0.2) \times 10^{2+} = 0.06 \times 10^5 = 6000 \\ X \div Y &= (0.3 \div 0.2) \times 10^{-2} = 1.5 \times 10^{-1} = 0.15 \end{aligned}$$

- **Significand underflow:** In the process of aligning significands, digits may flow off the right end of the significand. As we will discuss, some form of rounding is required.
- **Significand overflow:** The addition of two significands of the same sign may result in a carry out of the most significant bit. This can be fixed by realignment, as we will explain.

Addition and Subtraction

In floating-point arithmetic, addition and subtraction are more complex than multiplication and division.

This is because of the need for alignment. There are four basic phases of the algorithm for addition and subtraction:

1. Check for zeros.
2. Align the significands.
3. Add or subtract the significands.
4. Normalize the result.

A typical flowchart is shown in **Figure 11.22**. A step-by-step narrative highlights the main functions required for floating-point addition and subtraction. We assume a format similar to those of **Figure 11.21**. For the addition or subtraction operation, the two operands must be transferred to registers that will be used by the ALU. If the floating-point format includes an implicit significand bit, that bit must be made explicit for the operation.

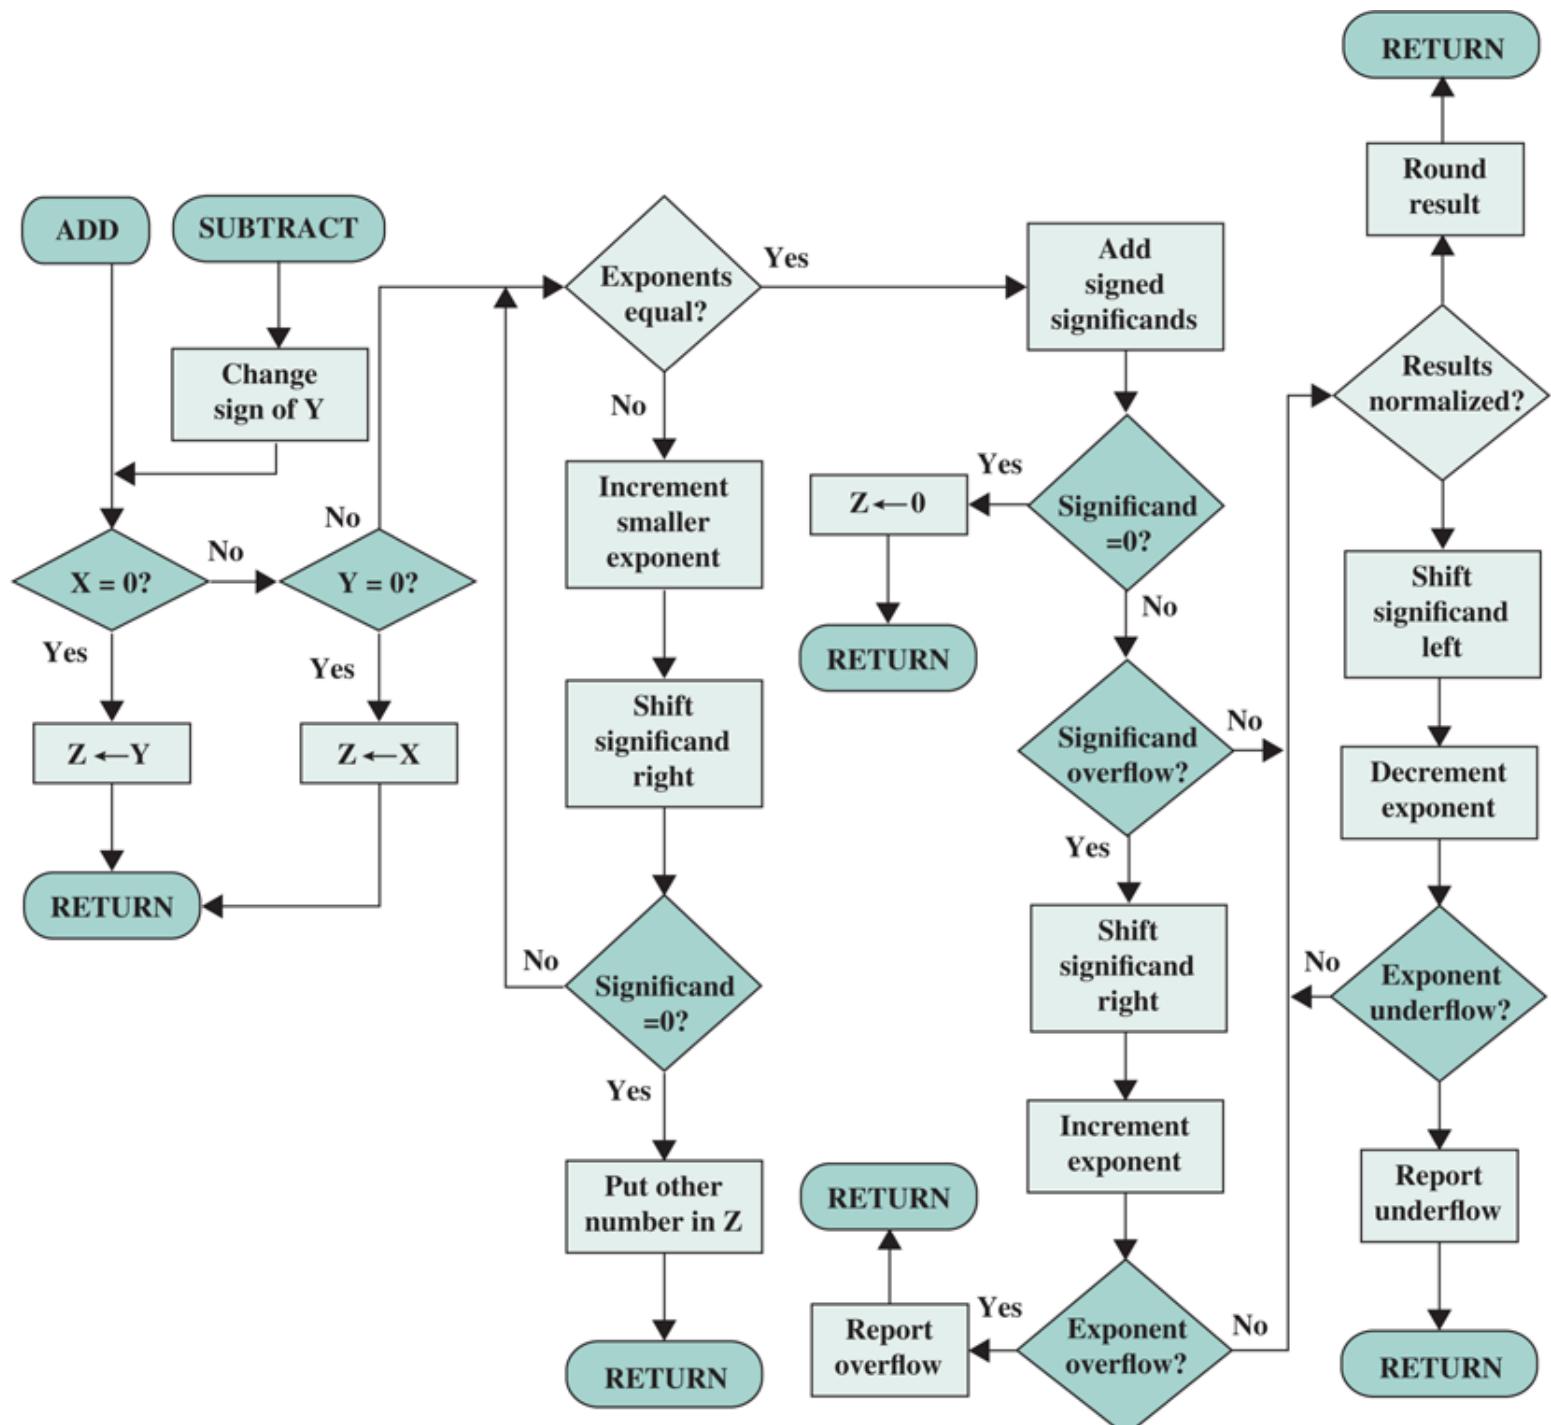

Figure 11.22 Floating-Point Addition and Subtraction ($Z \leftarrow X \pm Y$)

Phase 1. Zero check: Because addition and subtraction are identical except for a sign change, the process begins by changing the sign of the subtrahend if it is a subtract operation. Next, if either operand is 0, the other is reported as the result.

Phase 2. Significand alignment: The next phase is to manipulate the numbers so that the two exponents are equal.

To see the need for aligning exponents, consider the following decimal addition:

$$(123 \times 10^0) + (456 \times 10^{-2})$$

Clearly, we cannot just add the significands. The digits must first be set into equivalent positions, that is, the 4 of the second number must be aligned with the 3 of the first. Under these conditions, the two exponents will be equal, which is the mathematical condition under which two numbers in this form can be added. Thus,

$$(123 \times 10^0) + (456 \times 10^{-2}) = (123 \times 10^0) + (4.56 \times 10^0) = 127.56 \times 10^0$$

Alignment may be achieved by shifting either the smaller number to the right (increasing its exponent) or shifting the larger number to the left. Because either operation may result in the loss of digits, it is the smaller number that is shifted; any digits that are lost are therefore of relatively small significance. The alignment is achieved by repeatedly shifting the magnitude portion of the significand right 1 digit and incrementing the exponent until the two exponents are equal. (Note that if the implied base is 16, a shift of 1 digit is a shift of 4 bits.) If this process results in a 0 value for the significand, then the other number is reported as the result. Thus, if two numbers have exponents that differ significantly, the lesser number is lost.

Phase 3. Addition: Next, the two significands are added together, taking into account their signs. Because the signs may differ, the result may be 0. There is also the possibility of significand overflow by 1 digit. If so, the significand of the result is shifted right and the exponent is incremented. An exponent overflow could occur as a result; this would be reported and the operation halted.

Phase 4. Normalization: The final phase normalizes the result. Normalization consists of shifting significand digits left until the most significant digit (bit, or 4 bits for base-16 exponent) is nonzero. Each shift causes a decrement of the exponent and thus could cause an exponent underflow. Finally, the result must be rounded off and then reported. We defer a discussion of rounding until after a discussion of multiplication and division.

Multiplication and Division

Floating-point multiplication and division are much simpler processes than addition and subtraction, as the following discussion indicates.

We first consider multiplication, illustrated in [Figure 11.23](#). First, if either operand is 0, 0 is reported as the result. The next step is to add the exponents. If the exponents are stored in biased form, the exponent sum would have doubled the bias. Thus, the bias value must be subtracted from the sum. The result could be either an exponent overflow or underflow, which would be reported, ending the algorithm.

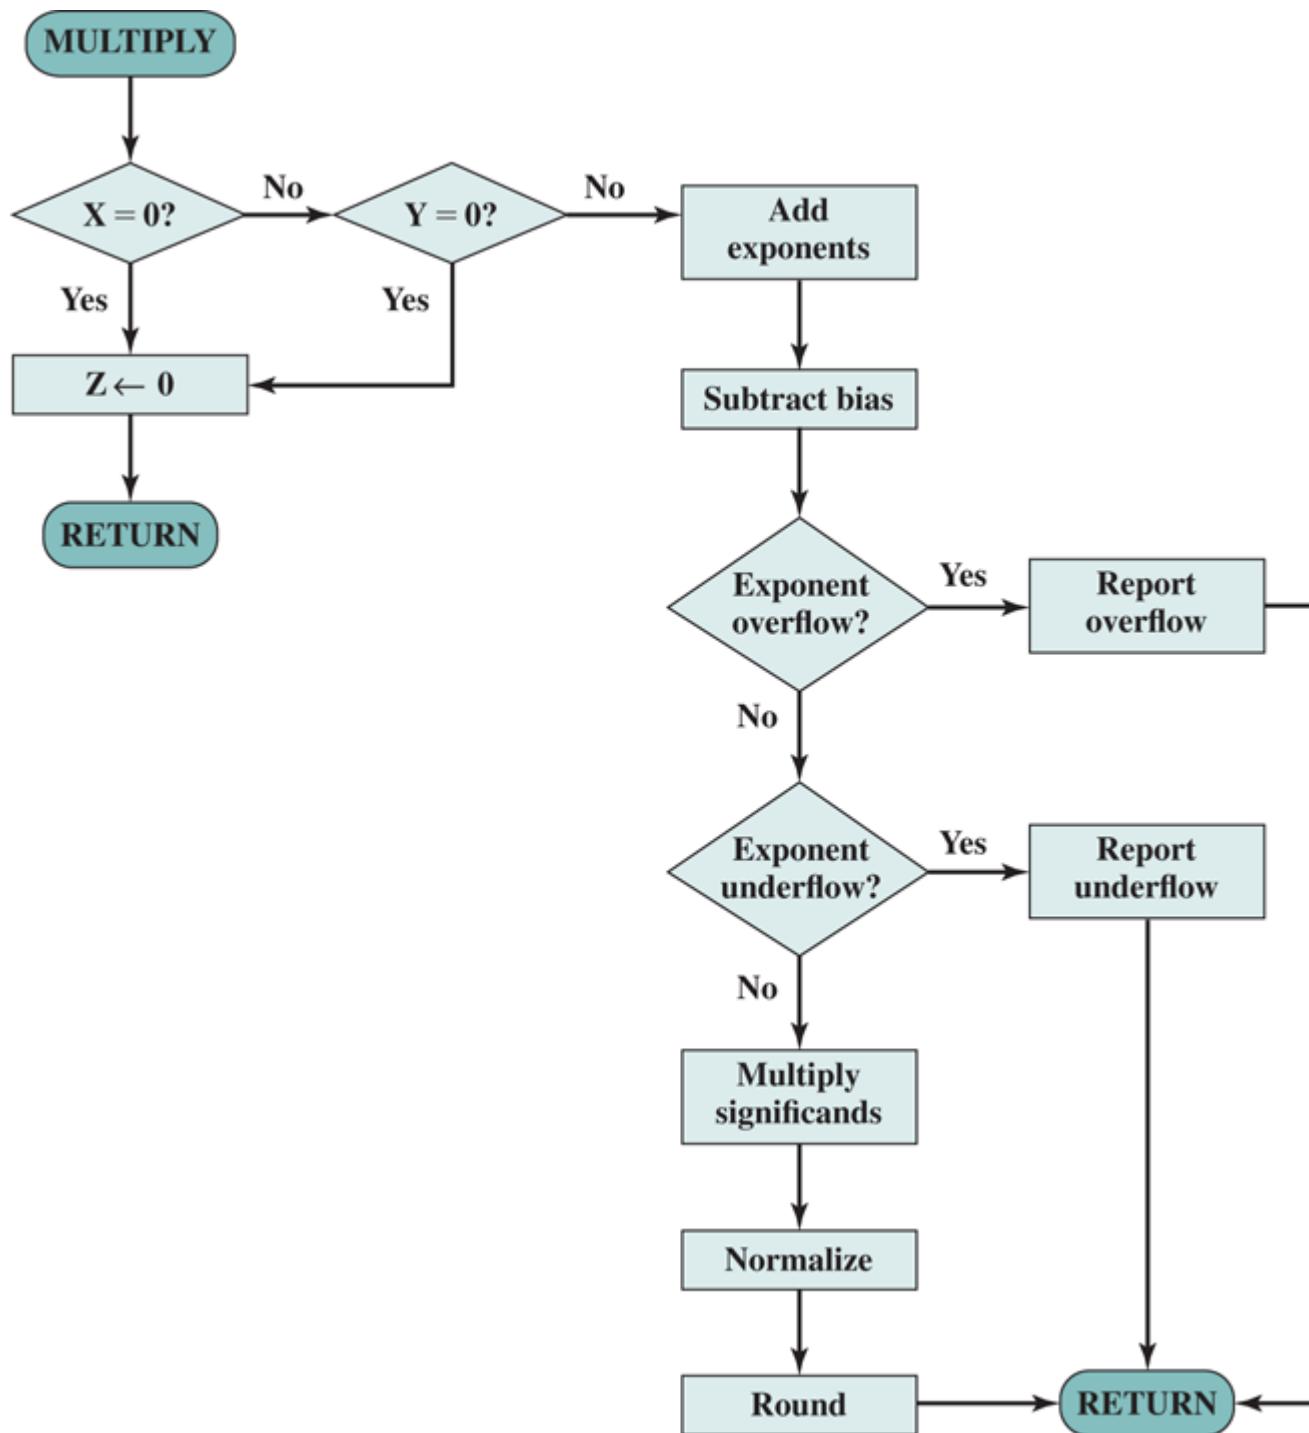

Figure 11.23 Floating-Point Multiplication ($Z \leftarrow X \pm Y$)

If the exponent of the product is within the proper range, the next step is to multiply the significands, taking into account their signs. The multiplication is performed in the same way as for integers. In this case, we are dealing with a signmagnitude representation, but the details are similar to those for two's complement representation. The product will be double the length of the multiplier and multiplicand. The extra bits will be lost during rounding.

After the product is calculated, the result is then normalized and rounded, as was done for addition and subtraction. Note that normalization could result in exponent underflow.

Finally, let us consider the flowchart for division depicted in [Figure 11.24](#). Again, the first step is testing for 0. If the divisor is 0, an error report is issued, or the result is set to infinity, depending on the implementation. A dividend of 0 results in 0. Next, the divisor exponent is subtracted from the dividend exponent. This removes the bias, which must be added back in. Tests are then made for exponent

underflow or overflow.

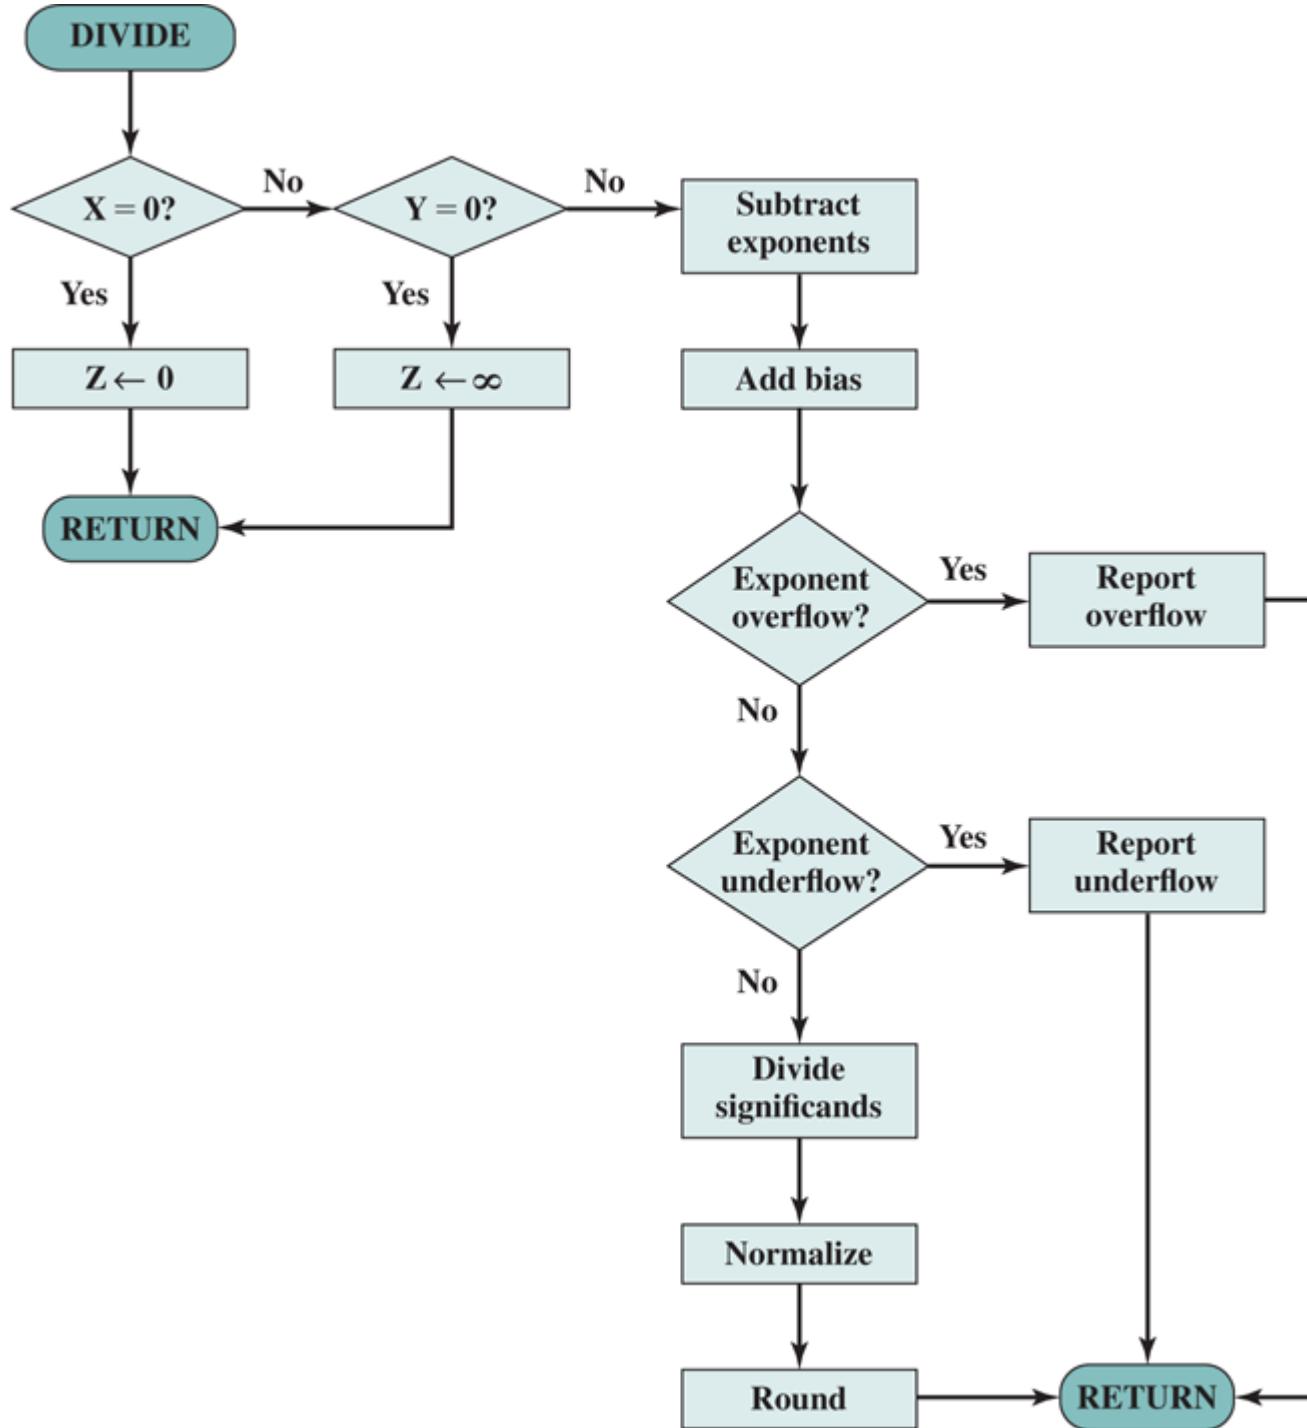

Figure 11.24 Floating-Point Division ($Z \leftarrow X / Y$)

The next step is to divide the significands. This is followed with the usual normalization and rounding.

Precision Considerations

GUARD BITS

We mentioned that, prior to a floating-point operation, the exponent and significand of each operand are loaded into ALU registers. In the case of the significand, the length of the register is almost always greater than the length of the significand plus an implied bit. The register contains additional bits, called guard bits, which are used to pad out the right end of the significand with 0s.

The reason for the use of guard bits is illustrated in [Figure 11.25](#). Consider numbers in the IEEE format, which has a 24-bit significand, including an implied 1 bit to the left of the binary point. Two numbers that are very close in value are $x = 1.00 \dots 00 \times 2^1$ and $y = 1.11 \dots 11 \times 2^0$. If the smaller number is to be subtracted from the larger, it must be shifted right 1 bit to align the exponents. This is shown in [Figure 11.25a](#). In the process, y loses 1 bit of significance; the result is 2^{-22} . The same operation is repeated in part (b) with the addition of guard bits. Now the least significant bit is not lost due to alignment, and the result is 2^{-23} , a difference of a factor of 2 from the previous answer. When the radix is 16, the loss of precision can be greater. As [Figures 11.25c](#) and [\(d\)](#) show, the difference can be a factor of 16.

$$\begin{aligned}x &= 1.000 \dots 00 \times 2^1 \\-y &= \underline{0.111 \dots 11} \times 2^1 \\z &= 0.000 \dots 01 \times 2^1 \\&= 1.000 \dots 00 \times 2^{-22}\end{aligned}$$

(a) Binary example, without guard bits

$$\begin{aligned}x &= .100000 \times 16^1 \\-y &= \underline{.0FFFFF} \times 16^1 \\z &= .000001 \times 16^1 \\&= .100000 \times 16^{-4}\end{aligned}$$

(c) Hexadecimal example, without guard bits

$$\begin{aligned}x &= 1.000 \dots 00 0000 \times 2^1 \\-y &= \underline{0.111 \dots 11 1000} \times 2^1 \\z &= 0.000 \dots 00 1000 \times 2^1 \\&= 1.000 \dots 00 0000 \times 2^{-23}\end{aligned}$$

(b) Binary example, with guard bits

$$\begin{aligned}x &= .100000 00 \times 16^1 \\-y &= \underline{.0FFFFF F0} \times 16^1 \\z &= .000000 10 \times 16^1 \\&= .100000 00 \times 16^{-5}\end{aligned}$$

(d) Hexadecimal example, with guard bits

Figure 11.25 The Use of Guard Bits

ROUNDING

Another detail that affects the precision of the result is the rounding policy. The result of any operation on the significands is generally stored in a longer register. When the result is put back into the floating-point format, the extra bits must be eliminated in such a way as to produce a result that is close to the exact result. This process is called [rounding](#).

A number of techniques have been explored for performing rounding. In fact, the IEEE standard lists four alternative approaches:

- **Round to nearest:** The result is rounded to the nearest representable number.
- **Round toward $+\infty$:** The result is rounded up toward plus infinity.
- **Round toward $-\infty$:** The result is rounded down toward negative infinity.
- **Round toward 0:** The result is rounded toward zero.

Let us consider each of these policies in turn. [Round to nearest](#) is the default rounding mode listed in the standard and is defined as follows: The representable value nearest to the infinitely precise result shall be delivered.

If the extra bits, beyond the 23 bits that can be stored, are 10010, then the extra bits amount to more than one-half of the last representable bit position. In this case, the correct answer is to add binary 1 to the last representable bit, rounding up to the next representable number. Now consider that the extra bits are 01111. In this case, the extra bits amount to less than one-half of

the last representable bit position. The correct answer is simply to drop the extra bits (truncate), which has the effect of rounding down to the next representable number.

The standard also addresses the special case of extra bits of the form 10000.... Here the result is exactly halfway between the two possible representable values. One possible technique here would be to always truncate, as this would be the simplest operation. However, the difficulty with this simple approach is that it introduces a small but cumulative bias into a sequence of computations. What is required is an unbiased method of rounding. One possible approach would be to round up or down on the basis of a random number so that, on average, the result would be unbiased. The argument against this approach is that it does not produce predictable, deterministic results. The approach taken by the IEEE standard is to force the result to be even: If the result of a computation is exactly midway between two representable numbers, the value is rounded up if the last representable bit is currently 1 and not rounded up if it is currently 0.

The next two options, **rounding to plus** and **minus infinity**, are useful in implementing a technique known as interval arithmetic. Interval arithmetic provides an efficient method for monitoring and controlling errors in floating-point computations by producing two values for each result. The two values correspond to the lower and upper endpoints of an interval that contains the true result. The width of the interval, which is the difference between the upper and lower endpoints, indicates the accuracy of the result. If the endpoints of an interval are not representable, then the interval endpoints are rounded down and up, respectively. Although the width of the interval may vary according to implementation, many algorithms have been designed to produce narrow intervals. If the range between the upper and lower bounds is sufficiently narrow, then a sufficiently accurate result has been obtained. If not, at least we know this and can perform additional analysis.

The final technique specified in the standard is **round toward zero**. This is, in fact, simple truncation: The extra bits are ignored. This is certainly the simplest technique. However, the result is that the magnitude of the truncated value is always less than or equal to the more precise original value, introducing a consistent bias toward zero in the operation. This is a serious bias because it affects every operation for which there are nonzero extra bits.

IEEE Standard for Binary Floating-Point Arithmetic

IEEE 754 goes beyond the simple definition of a format to lay down specific practices and procedures so that floating-point arithmetic produces uniform, predictable results independent of the hardware platform. One aspect of this has already been discussed, namely rounding. This subsection looks at three other topics: infinity, NaNs, and subnormal numbers.

INFINITY

Infinity arithmetic is treated as the limiting case of real arithmetic, with the infinity values given the following interpretation:

$$-\infty < (\text{every finite number}) < +\infty$$

With the exception of the special cases discussed subsequently, any arithmetic operation involving infinity yields the obvious result.

For example:

$$\begin{aligned} 5 + (+\infty) &= +\infty & 5 \div (+\infty) &= +0 \\ 5 - (+\infty) &= -\infty & (+\infty) + (+\infty) &= +\infty \\ 5 + (-\infty) &= -\infty & (-\infty) + (-\infty) &= -\infty \\ 5 - (-\infty) &= +\infty & (-\infty) - (+\infty) &= -\infty \end{aligned}$$

$$5 \times (+\infty) = +\infty \quad (+\infty) - (-\infty) = +\infty$$

QUIET AND SIGNALING NANS

A NaN is a symbolic entity encoded in floating-point format, of which there are two types: signaling and quiet. A signaling NaN signals an invalid operation exception whenever it appears as an operand. Signaling NaNs afford values for uninitialized variables and arithmetic-like enhancements that are not the subject of the standard. A quiet NaN propagates through almost every arithmetic operation without signaling an exception. **Table 11.7** indicates operations that will produce a quiet NaN.

Table 11.7 Operations that Produce a Quiet NaN

Operation	Quiet NaN Produced By
Any	Any operation on a signaling NaN
Add or subtract	Magnitude subtraction of infinities: $(+\infty) + (-\infty)$ $(-\infty) + (+\infty)$ $(+\infty) - (+\infty)$ $(-\infty) - (-\infty)$
Multiply	$0 \times \infty$
Division	$\frac{0}{0}$ or $\frac{\infty}{\infty}$
Remainder	$x \text{ REM } 0$ or $\infty \text{ REM } y$
Square root	\sqrt{x} , where $x < 0$

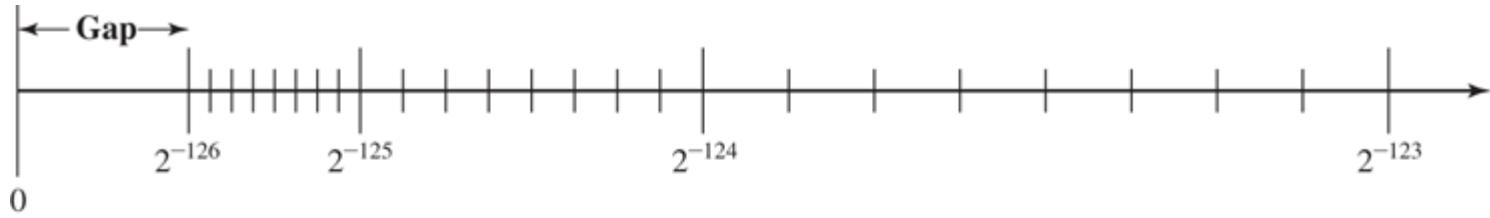

Note that both types of NaNs have the same general format (**Table 11.4**): an exponent of all ones and a nonzero fraction. The actual bit pattern of the nonzero fraction is implementation dependent; the fraction values can be used to distinguish quiet NaNs from signaling NaNs and to specify particular exception conditions.

SUBNORMAL NUMBERS

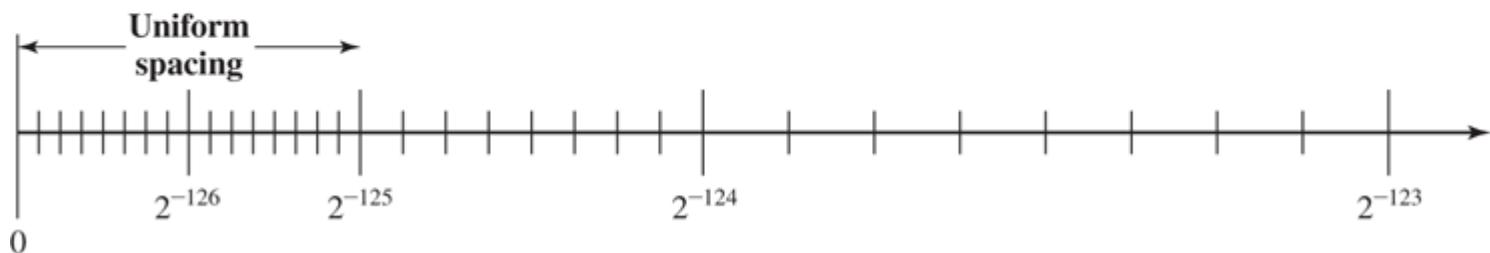

Subnormal numbers are included in IEEE 754 to handle cases of exponent underflow. When the exponent of the result becomes too small (a negative exponent with too large a magnitude), the result is subnormalized by right shifting the fraction and incrementing the exponent for each shift until the exponent is within a representable range.

Figure 11.26 illustrates the effect of including subnormal numbers. The representable numbers can be grouped into intervals of the form $2^n, 2^{n+1}$. Within each such interval, the exponent portion of the number remains constant while the fraction varies, producing a uniform spacing of representable numbers within the interval. As we get closer to zero, each successive interval is half the width of the

preceding interval, but contains the same number of representable numbers. Hence the density of representable numbers increases as we approach zero. However, if only normal numbers are used, there is a gap between the smallest normal number and 0. In the case of the 32-bit IEEE 754 format, there are 2^{23} representable numbers in each interval, and the smallest representable positive number is 2^{-126} . With the addition of subnormal numbers, an additional $2^{23} - 1$ numbers are uniformly added between 0 and 2^{-126} .

(a) 32-bit format without subnormal numbers

(b) 32-bit format with subnormal numbers

Figure 11.26 The Effect of IEEE 754 Subnormal Numbers

The use of subnormal numbers is referred to as *gradual underflow* [COON81]. Without subnormal numbers, the gap between the smallest representable nonzero number and zero is much wider than the gap between the smallest representable nonzero number and the next larger number. Gradual underflow fills in that gap and reduces the impact of exponent underflow to a level comparable with roundoff among the normal numbers.

Review Questions

11.1 Briefly explain the following representations: sign magnitude, twos complement, biased.

11.2 Explain how to determine if a number is negative in the following representations: sign magnitude, twos complement, biased.

11.3 What is the sign-extension rule for twos complement numbers?

11.4 How can you form the negation of an integer in twos complement representation?

11.5 In general terms, when does the twos complement operation on an n -bit integer produce the same integer?

11.6 What is the difference between the twos complement representation of a number and the twos complement of a number?

11.7 If we treat two twos complement numbers as unsigned integers for purposes of addition, the result is correct if interpreted as a twos complement number. This is not true for multiplication. Why?

11.8 What are the four essential elements of a number in floating-point notation?

11.9 What is the benefit of using biased representation for the exponent portion of a floating-point number?

11.10 What are the differences among positive overflow, exponent overflow, and significand overflow?

11.11 What are the basic elements of floating-point addition and subtraction?

11.12 Give a reason for the use of guard bits.

11.13 List four alternative methods of rounding the result of a floating-point operation.

Problems

11.1 Represent the following decimal numbers in both binary sign/magnitude and twos complement using 16 bits: +512 ; – 29.

11.2 Represent the following twos complement values in decimal: 1101011; 0101101.

11.3 Another representation of binary integers that is sometimes encountered is **ones complement**. Positive integers are represented in the same way as sign magnitude. A negative integer is represented by taking the Boolean complement of each bit of the corresponding positive number.

- a. Provide a definition of ones complement numbers using a weighted sum of bits, similar to **Equations (11.1) and (11.2)**.
- b. What is the range of numbers that can be represented in ones complement?
- c. Define an algorithm for performing addition in ones complement arithmetic.

Note: Ones complement arithmetic disappeared from hardware in the 1960s, but still survives checksum calculations for the Internet Protocol (IP) and the Transmission Control Protocol (TCP).

11.4 Add columns to **Table 11.1** for sign magnitude and ones complement.

11.5 Consider the following operation on a binary word. Start with the least significant bit. Copy all bits that are 0 until the first bit is reached and copy that bit, too. Then take the complement of each bit thereafter. What is the result?

11.6 In **Section 11.3**, the twos complement operation is defined as follows. To find the twos complement of X , take the Boolean complement of each bit of X , and then add 1.

- Show that the following is an equivalent definition. For an n -bit integer X , the twos complement of X is formed by treating X as an unsigned integer and calculating $(2^n - X)$.
- Demonstrate that **Figure 11.5** can be used to support graphically the claim in part (a), by showing how a clockwise movement is used to achieve subtraction.

11.7 The r 's complement of an n -digit number N in base r is defined as $r^n - N$ for $N \neq 0$ and 0 for $N = 0$. Find the tens complement of the decimal number 13,250.

11.8 Calculate $(72,530 - 13,250)$ using tens complement arithmetic. Assume rules similar to those for twos complement arithmetic.

11.9 Consider the twos complement addition of two n -bit numbers:

Assume that bitwise addition is performed with a carry bit c_i generated by the addition of x_i , y_i , and c_{i-1} . Let v be a binary variable indicating overflow when $v = 1$. Fill in the values in the table.

Input	x_{n-1}	0	0	0	0	1	1	1	1
	y_{n-1}	0	0	1	1	0	0	1	1
	c_{n-2}	0	1	0	1	0	1	0	1
Output	z_{n-1}								
	n								

11.10 Assume numbers are represented in 8-bit twos complement representation. Show the calculation of the following:

- $6 + 13$
- $-6 + 13$
- $6 - 13$
- $-6 - 13$

11.11 Find the following differences using twos complement arithmetic:

- -110011
11001100
- -101110
111100001111

- c. -11001110011
11000011
- d. -11101000

11.12 Is the following a valid alternative definition of overflow in two's complement arithmetic? If the exclusive-OR of the carry bits into and out of the leftmost column is 1, then there is an overflow condition. Otherwise, there is not.

11.13 Compare [Figures 11.9](#) and [11.12](#). Why is the C bit not used in the latter?

11.14 Given $x = 0101$ and $y = 1010$ in two's complement notation (i.e., $x = 5$, $y = -6$), compute the product $p = x \times y$ with Booth's algorithm.

11.15 Use the Booth algorithm to multiply 23 (multiplicand) by 29 (multiplier), where each number is represented using 6 bits.

11.16 Prove that the multiplication of two n -digit numbers in base B gives a product of no more than $2n$ digits.

11.17 Verify the validity of the unsigned binary division algorithm of [Figure 11.16](#) by showing the steps involved in calculating the division depicted in [Figure 11.15](#). Use a presentation similar to that of [Figure 11.17](#).

11.18 The two's complement integer division algorithm described in [Section 11.3](#) is known as the restoring method because the value in the A register must be restored following unsuccessful subtraction. A slightly more complex approach, known as nonrestoring, avoids the unnecessary subtraction and addition. Propose an algorithm for this latter approach.

11.19 Under computer integer arithmetic, the quotient J/K of two integers J and K is less than or equal to the usual quotient. True or false?

11.20 Divide -145 by 13 in binary two's complement notation, using 12-bit words. Use the algorithm described in [Section 11.3](#).

11.21

- a. Consider a fixed-point representation using decimal digits, in which the implied radix point can be in any position (to the right of the least significant digit, to the right of the most significant digit, and so on). How many decimal digits are needed to represent the approximations of both Planck's constant 6.63×10^{-27} and Avogadro's number (6.02×10^{23}) ? The implied radix point must be in the same position for both numbers.
- b. Now consider a decimal floating-point format with the exponent stored in a biased representation with a bias of 50. A normalized representation is assumed. How many decimal digits are needed to represent these constants in this floating-point format?

11.22 Assume that the exponent e is constrained to lie in the range $0 \leq e \leq X$, with a bias of q , that the base is b , and that the significand is p digits in length.

- a. What are the largest and smallest positive values that can be written?
- b. What are the largest and smallest positive values that can be written as normalized floating-point numbers?

11.23 Express the following numbers in IEEE 32-bit floating-point format:

- a. -5
- b. -6
- c. -1.5
- d. 384
- e. 1/16
- f. -1/32

11.24 The following numbers use the IEEE 32-bit floating-point format. What is the equivalent decimal value?

- a. 1 10000011 11000000000000000000000000000000
- b. 0 01111110 10100000000000000000000000000000
- c. 0 10000000 00000000000000000000000000000000

11.25 Consider a reduced 7-bit IEEE floating-point format, with 3 bits for the exponent and 3 bits for the significand. List all 127 values.

11.26 Express the following numbers in IBM's 32-bit floating-point format, which uses a 7-bit exponent with an implied base of 16 and an exponent bias of 64 (40 hexadecimal). A normalized floating-point number requires that the leftmost hexadecimal digit be nonzero; the implied radix point is to the left of that digit.

- a. 1.0
- b. 0.5
- c. 1/64
- d. 0.0
- e. -15.0
- f. 5.4×10^{-79}
- g. 7.2×10^{75}
- h. 65,535

11.27 Let 5BCA0000 be a floating-point number in IBM format, expressed in hexadecimal. What is the decimal value of the number?

11.28 What would be the bias value for

- a. A base-2 exponent ($B = 2$) in a 6-bit field?
- b. A base-8 exponent ($B = 8$) in a 7-bit field?

11.29 Draw a number line similar to that in [Figure 11.19b](#) for the floating-point format of [Figure 11.21b](#).

11.30 Consider a floating-point format with 8 bits for the biased exponent and 23 bits for the significand. Show the bit pattern for the following numbers in this format:

- a. -720
- b. 0.645

11.31 The text mentions that a 32-bit format can represent a maximum of 2^{32} different numbers. How many different numbers can be represented in the IEEE 32-bit format? Explain.

11.32 Any floating-point representation used in a computer can represent only certain real numbers exactly; all others must be approximated. If A' is the stored value approximating the real value A , then the relative error, r , is expressed as

$$r = \frac{A' - A}{A}$$

Represent the decimal quantity +0.4 in the following floating-point format: base = 2; exponent: biased, 4 bits; significand, 7 bits. What is the relative error?

11.33 If $A = 1.427$, find the relative error if A is truncated to 1.42 and if it is rounded to 1.43.

11.34 When people speak about inaccuracy in floating-point arithmetic, they often ascribe errors to cancellation that occurs during the subtraction of nearly equal quantities. But when X and Y are approximately equal, the difference $X - Y$ is obtained exactly, with no error. What do these

people really mean?

11.35 Numerical values A and B are stored in the computer as approximations A' and B'

Neglecting any further truncation or roundoff errors, show that the relative error of the product is approximately the sum of the relative errors in the factors.

11.36 One of the most serious errors in computer calculations occurs when two nearly equal numbers are subtracted. Consider $A = 0.22288$ and $B = 0.22211$. The computer truncates all values to four decimal digits. Thus $A' = 0.2228$ and $B' = 0.2221$.

- a. What are the relative errors for A' and B' ?
- b. What is the relative error for $C' = A' - B'$?

11.37 To get some feel for the effects of denormalization and gradual underflow, consider a decimal system that provides 6 decimal digits for the significand and for which the smallest normalized number is 10^{-99} . A normalized number has one nonzero decimal digit to the left of the decimal point. Perform the following calculations and denormalize the results. Comment on the results.

- a. $2.50000 \times 10^{-60} \times 3.50000 \times 10^{-43}$
- b. $2.50000 \times 10^{-60} \times 3.50000 \times 10^{-60}$
- c. $5.67834 \times 10^{-97} - 5.67812 \times 10^{-97}$

11.38 Show how the following floating-point additions are performed (where significands are truncated to 4 decimal digits). Show the results in normalized form.

- a. $5.566 \times 10^2 + 7.777 \times 10^2$
- b. $3.344 \times 10^1 + 8.877 \times 10^{-2}$

11.39 Show how the following floating-point subtractions are performed (where significands are truncated to 4 decimal digits). Show the results in normalized form.

- a. $7.744 \times 10^{-3} - 6.666 \times 10^{-3}$
- b. $8.844 \times 10^{-1} - 2.233 \times 10^{-1}$

11.40 Show how the following floating-point calculations are performed (where significands are truncated to 4 decimal digits). Show the results in normalized form.

- a. $(2.255 \times 10^1) \times (1.234 \times 10^0)$
- b. $(8.833 \times 10^2) \div (5.555 \times 10^4)$

12.6 Key Terms and Problems

Learning Objectives

After studying this chapter, you should be able to:

- Understand the basic operations of **Boolean algebra**.
- Distinguish among the different types of **flip-flops**.
- Use a Karnaugh map to simplify a Boolean expression.
- Present an overview of **programmable logic devices**.

*The operation of the digital computer is based on the storage and processing of binary data. Throughout this book, we have assumed the existence of storage elements that can exist in one of two stable states, and of circuits that can operate on binary data under the control of control signals to implement the various computer functions. In this chapter, we suggest how these storage elements and circuits can be implemented in digital logic, specifically with combinational and sequential circuits. The chapter begins with a brief review of Boolean algebra, which is the mathematical foundation of digital logic. Next, the concept of a gate is introduced. Finally, combinational and sequential circuits, which are constructed from **gates**, are described.*

12.1 Boolean Algebra

The digital circuitry in digital computers and other digital systems is designed, and its behavior is analyzed, with the use of a mathematical discipline known as **Boolean algebra**. The name is in honor of English mathematician George Boole, who proposed the basic principles of this algebra in 1854 in his treatise, *An Investigation of the Laws of Thought on Which to Found the Mathematical Theories of Logic and Probabilities*. In 1938, Claude Shannon, a research assistant in the Electrical Engineering Department at M.I.T., suggested that Boolean algebra could be used to solve problems in relay-switching circuit design [SHAN38].¹ Shannon's techniques were subsequently used in the analysis and design of electronic digital circuits. Boolean algebra turns out to be a convenient tool in two areas:

¹ The paper is available at box.com/COA11e.

- **Analysis:** It is an economical way of describing the function of digital circuitry.
- **Design:** Given a desired function, Boolean algebra can be applied to develop a simplified implementation of that function.

As with any algebra, Boolean algebra makes use of variables and operations. In this case, the variables and operations are logical variables and operations. Thus, a variable may take on the value 1 (TRUE) or 0 (FALSE). The basic logical operations are AND, OR, and NOT, which are symbolically represented by dot, plus sign, and overbar:²

² Logical NOT is often indicated by an apostrophe: $\text{NOT } A = A'$.

$$\text{A AND B} = A \cdot B$$

$$\text{A OR B} = A + B$$

$$\text{NOT A} = \overline{A}$$

The operation AND yields true (binary value 1) if and only if both of its operands are true. The operation OR yields true if either or both of its operands are true. The unary operation NOT inverts the value of its operand. For example, consider the equation

$$D = A + (B \cdot C)$$

D is equal to 1 if A is 1 or if both B = 0 and C = 1. Otherwise D is equal to 0.

Several points concerning the notation are needed. In the absence of parentheses, the AND operation takes precedence over the OR operation. Also, when no ambiguity will occur, the AND operation is represented by simple concatenation instead of the dot operator. Thus,

$$A + B \cdot C = A + (B \cdot C) = A + BC$$

all mean: Take the AND of B and C; then take the OR of the result and A.

Table 12.1a defines the basic logical operations in a form known as a *truth table*, which lists the value of an operation for every possible combination of values of operands. The table also lists three other useful operators: XOR, NAND, and NOR. The exclusive-or (XOR) of two logical operands is 1 if and

only if exactly one of the operands has the value 1. The NAND function is the complement (NOT) of the AND function, and the NOR is the complement of OR:

$$A \text{ NAND } B = \text{NOT} (A \text{ AND } B) = A\bar{B}$$

$$A \text{ NOR } B = \text{NOT} (A \text{ OR } B) = A + \bar{B}$$

Table 12.1 Boolean Operators

(a) Boolean Operators of Two Input Variables							
A	B	NOT A (\bar{A})	$A \text{ AND } B$ ($A \cdot B$)	$A \text{ OR } B$ ($A + B$)	$A \text{ NAND } B$ ($\bar{A} \cdot \bar{B}$)	$A \text{ NOR } B$ ($\bar{A} + B$)	$A \text{ XOR } B$ ($\bar{A} \oplus B$)
0	0	1	0	0	1	1	0
0	1	1	0	1	1	0	1
1	0	0	0	1	1	0	1
1	1	0	1	1	0	0	0

(b) Boolean Operators Extended to More than Two Inputs (A, B, ...)		
Operation	Expression	Output = 1 if
AND	$A \cdot B \cdot \dots$	All of the set {A, B, ...} are 1.
OR	$A + B + \dots$	Any of the set {A, B, ...} are 1.
NAND	$\bar{A} \cdot \bar{B} \cdot \dots$	Any of the set {A, B, ...} are 0.
NOR	$\bar{A} + \bar{B} + \dots$	All of the set {A, B, ...} are 0.
XOR	$\bar{A} \oplus B \oplus \dots$	The set {A, B, ...} contains an odd number of ones.

As we shall see, these three new operations can be useful in implementing certain digital circuits.

The logical operations, with the exception of NOT, can be generalized to more than two variables, as shown in **Table 12.1b**.

The Algebra of Sets

It can be helpful for visualizing Boolean operations to illustrate corresponding operations on sets. We can define a **set** as a collection of elements S, together with a rule that determines what elements belong to S. For example, the set of positive integers less than 5 is {1, 2, 3, 4}.

Logical operations can be performed on sets in much the same way as on Boolean variables. Corresponding to the basic Boolean operations of AND, OR, and NOT are the logical set operations of intersection, union, and complement; these are shown in [Table 12.2](#).

Table 12.2 Correspondence Between Boolean Algebra and Operations on Sets

Boolean		Sets	
Function	Description	Function	Description
A AND B	1 if and only if A and B are 1	$A \cap B$	Set of elements that belong to both A and B (intersection)
A OR B	1 if A or B or both are 1; 0 if both A and B are 0	$A \cup B$	Set of elements that belong to A or B or both (union)
A OR B	1 if and only if A is 0	\bar{A}	Set of elements not in A (complement of A)

The **intersection** of two sets A and B is the set of all elements that belong to both A and B. This operation is designated with the operator \cap . For example, if A is the set of positive integers less than 5 and B is the set of even positive integers less than 10, then $A \cap B = \{2, 4\}$. Intersection corresponds to the Boolean operator AND.

The **union** of two sets A and B is the set of all elements that belong to A or B or both. This operation is designated with the operator \cup . For A and B defined in the preceding paragraph, $A \cup B = \{1, 2, 3, 4, 6, 8\}$. Union corresponds to the Boolean operator OR.

The **complement** of a set A depends on the context. Generally, attention is confined to subsets of some given set X, which is considered as the universal set for this context. The complement of a set S, designated by an \bar{S} , consists of all the elements in the universal set not found in S. For example, if X is the set of all positive integers, then for A and B defined above, A is the set of all integers greater than 4, and B is the set consisting of all odd positive integers plus all even positive integers greater than 9. Complement corresponds to the Boolean operator NOT.

With these definitions in mind, we can visualize the Boolean operators defined in [Table 12.1a](#) using [Figure 12.1](#). The Boolean variables are represented by circles, which can also be viewed as sets depicted in a Venn diagram. From the perspective of Boolean algebra, the surrounding rectangle, including the circles, represents all possible combinations of values of A and B. From a set perspective, the surrounding rectangle represents the universal set.

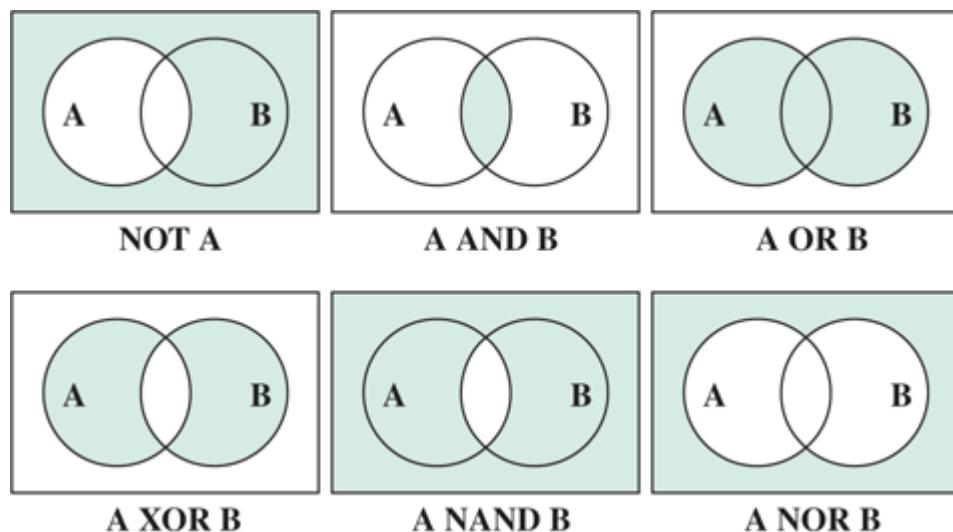

Figure 12.1 Basic Boolean Functions of Two Variables

Figure 12.2 depicts Venn diagrams corresponding to three Boolean variables. The three-bit numbers give the Boolean values for ABC in the different regions.

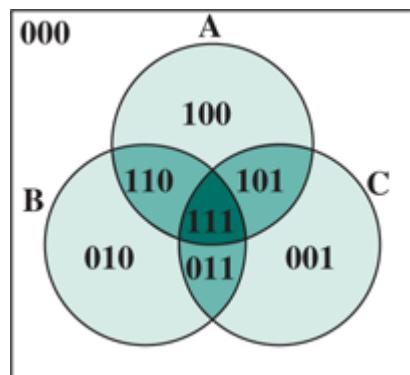

Figure 12.2 Venn Diagram for Three Boolean Variables

Table 12.3 summarizes key identities of Boolean algebra. The equations have been arranged in two columns to show the complementary, or dual, nature of the AND and OR operations. There are two classes of identities: basic rules (or *postulates*), which are stated without proof, and other identities that can be derived from the basic postulates. The postulates define the way in which Boolean expressions are interpreted. One of the two distributive laws is worth noting because it differs from what we would find in ordinary algebra:

$$A + (B \cdot C) = (A + B) \cdot (A + C)$$

Table 12.3 Basic Identities of Boolean Algebra

Basic Postulates		
$A \cdot B = B \cdot A$	$A + B = B + A$	Commutative Laws
$A \cdot (B + C) = (A \cdot B) + (A \cdot C)$	$A + (B \cdot C) = (A + B) \cdot (A + C)$	Distributive Laws
$1 \cdot A = A$	$0 + A = A$	Identity Elements
$A \cdot A = 0$	$A + \bar{A} = 1$	

		Inverse Elements
Other Identities		
$0 \cdot A = 0$	$1 + A = 1$	
$A \cdot A = A$	$A + A = A$	
$A \cdot (B \cdot C) = (A \cdot B) \cdot C$	$A + (B + C) = (A + B) + C$	Associative Laws
$A \bar{\cdot} B = \bar{A} + B$	$A \bar{+} B = \bar{A} \cdot B$	DeMorgan's Theorem

The two bottom-most expressions are referred to as DeMorgan's theorem. We can restate them as follows:

$$\begin{aligned} A \text{ NOR } B &= A \text{ AND } B \\ A \text{ NAND } B &= A \text{ OR } B \end{aligned}$$

The reader is invited to verify the expressions in [Table 12.3](#) by substituting actual values (1s and 0s) for the variables A, B, and C.

Boolean Identities

We now give three examples of simplifying Boolean expressions using the identities of [Table 12.3](#).

Example 1: $F = A + BA$

The second component BA is negated and we must use DeMorgan's theorem: $AB = A + B$. We can now write

$$F = A + B\bar{A} = A + B + \bar{A}$$

From the Inverse Elements Postulate: $A + \bar{A} = 1$; therefore, $F = A + \bar{A} + B = 1 + B$

From the Identity Elements Postulate, $1 + B = 1$; therefore, $F = 1$.

The final result is $F = 1$, which means that the expression is true and independent of variables A and B.

Example 2: $F = (A + B) \bullet (A + C)$

$$F = A \bullet A + A \bullet C + A \bullet B + B \bullet C$$

We have the identity $A \bullet A = A$. The terms are redundant because if $A = 0$ then both these terms are 0, and if $A = 1$, then

$$A \bullet A + A \bullet C + A \bullet B = 1 + C + B = 1$$

Consequently, we are left with: $F = A + B \times C$

Example 3: $F = A \bullet B \bullet C + (A \bullet B \bar{+} A \bullet C)$

We can use DeMorgan's theorem repeatedly to simplify the last term:

$$(A \bullet B \bar{+} A \bullet C) = (A \bullet B) \bullet (A \bar{\bullet} B) = (\bar{A} + B) \bullet (\bar{A} + C)$$

Using the distributed law repeatedly:

$$\begin{aligned}(A + B) \bullet (\bar{A} + C) &= ((A + B) \bullet \bar{A}) + ((A + B) \bullet C) \\&= \bar{A}A + B\bar{A} + \bar{A}C + BC \\&= A + B\bar{A} + \bar{A}C + BC = A + BC\end{aligned}$$

The final simplification eliminates the redundant middle terms, similar to what was done in [Example 2](#). Plugging this result into the original equation:

$$F = \bar{A} \bullet B \bullet C + A + BC = A + BC$$

Again, the first term is redundant and was eliminated.

In all three examples, the original Boolean expression is simplified. This is important because Boolean expressions are used to define digital functions used in processor and memory circuitry. Thus, whereas an original expression may clearly define a desired function, simplifying the expression can lead to simpler circuits. [Section 12.3](#) explores systematic techniques for simplifying expressions.

12.2 Gates

The fundamental building block of all digital logic circuits is the gate. Logical functions are implemented by the interconnection of gates.

A gate is an electronic circuit that produces an output signal that is a simple Boolean operation on its input signals. The basic gates used in digital logic are AND, OR, NOT, NAND, NOR, and XOR. **Figure 12.3** depicts these six gates. Each gate is defined in three ways: graphic symbol, algebraic notation, and truth table. The symbology used in this chapter is from the IEEE standard, IEEE Std 91. Note that the inversion (NOT) operation is indicated by a circle.

Name	Graphical Symbol	Algebraic Function	Truth Table															
AND		$F = A \cdot B$ or $F = AB$	<table border="1"> <thead> <tr> <th>A</th><th>B</th><th>F</th></tr> </thead> <tbody> <tr><td>0</td><td>0</td><td>0</td></tr> <tr><td>0</td><td>1</td><td>0</td></tr> <tr><td>1</td><td>0</td><td>0</td></tr> <tr><td>1</td><td>1</td><td>1</td></tr> </tbody> </table>	A	B	F	0	0	0	0	1	0	1	0	0	1	1	1
A	B	F																
0	0	0																
0	1	0																
1	0	0

Figure 12.3 Basic Logic Gates

Each gate shown in **Figure 12.3** has one or two inputs and one output. However, as indicated in **Table 12.1b**, all of the gates except NOT can have more than two inputs. Thus, $(X + Y + Z)$ can be implemented with a single **OR gate** with three inputs. When one or more of the values at the input are changed, the correct output signal appears almost instantaneously, delayed only by the propagation

time of signals through the gate (known as the *gate delay*). The significance of this delay is discussed in [Section 12.3](#). In some cases, a gate is implemented with two outputs, one output being the negation of the other output.

Here we introduce a common term: we say that to **assert** a signal is to cause a signal line to make a transition from its logically false (0) state to its logically true (1) state. The true (1) state is either a high or low voltage state, depending on the type of electronic circuitry.

Typically, not all gate types are used in implementation. Design and fabrication are simpler if only one or two types of gates are used. Thus, it is important to identify *functionally complete* sets of gates. This means that any Boolean function can be implemented using only the gates in the set. The following are functionally complete sets:

- AND, OR, NOT
- AND, NOT
- OR, NOT
- NAND
- NOR

It should be clear that AND, OR, and NOT gates constitute a functionally complete set, because they represent the three operations of Boolean algebra. For the AND and NOT gates to form a functionally complete set, there must be a way to synthesize the OR operation from the AND and NOT operations. This can be done by applying DeMorgan's theorem:

$$\begin{aligned} A + B &= \overline{\overline{A} \cdot \overline{B}} \\ A \text{ OR } B &= \text{NOT} ((\text{NOT } A) \text{ AND } (\text{NOT } B)) \end{aligned}$$

Similarly, the OR and NOT operations are functionally complete because they can be used to synthesize the AND operation.

[Figure 12.4](#) shows how the AND, OR, and NOT functions can be implemented solely with NAND gates, and [Figure 12.5](#) shows the same thing for NOR gates. For this reason, digital circuits can be, and frequently are, implemented solely with NAND gates or solely with NOR gates.

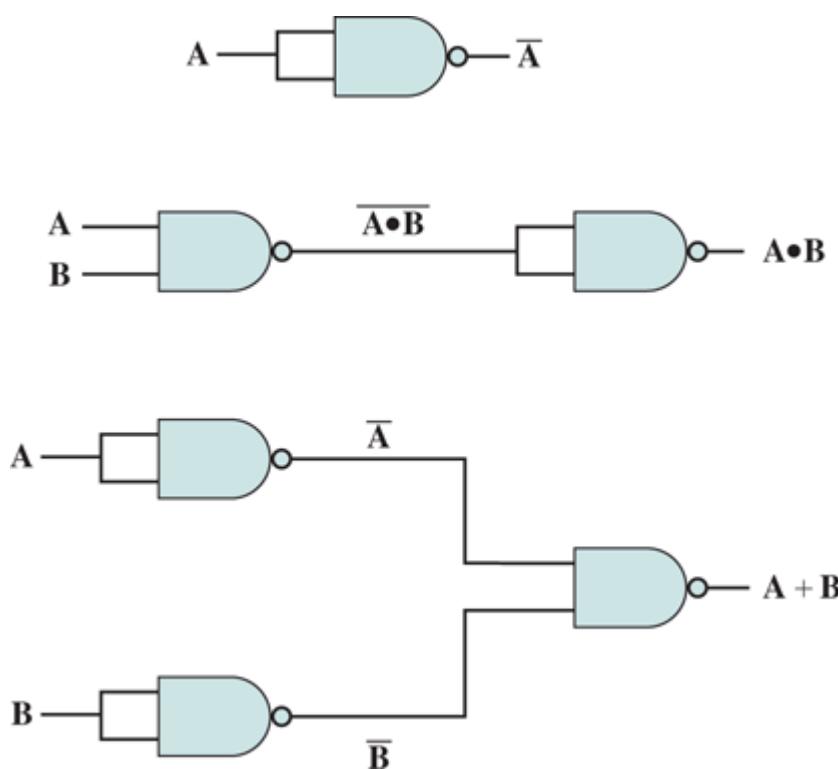

Figure 12.4 Some Uses of NAND Gates

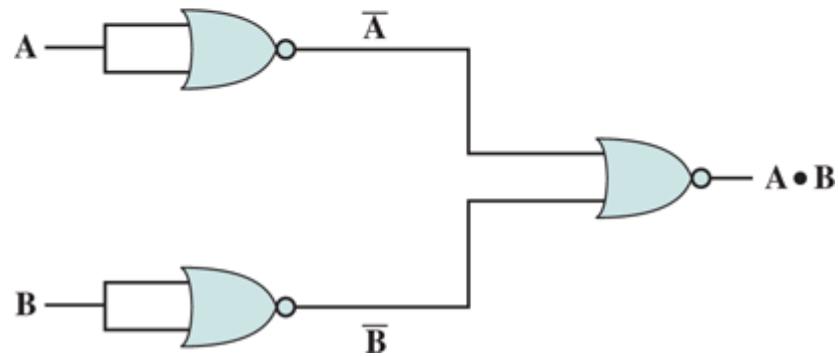

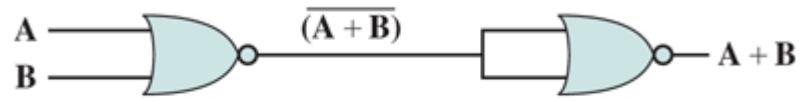

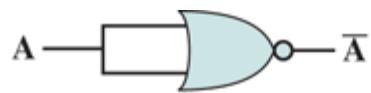

Figure 12.5 Some Uses of NOR Gates

With gates, we have reached the most primitive circuit level of computer hardware. An examination of the transistor combinations used to construct gates departs from that realm and enters the realm of electrical engineering. For our purposes, however, we are content to describe how gates can be used as building blocks to implement the essential logical circuits of a digital computer.

12.3 Combinational Circuits

A **combinational circuit** is an interconnected set of gates whose output at any time is a function only of the input at that time. As with a single gate, the appearance of the input is followed almost immediately by the appearance of the output, with only gate delays.

In general terms, a combinational circuit consists of n binary inputs and m binary outputs. As with a gate, a combinational circuit can be defined in three ways:

- **Truth table:** For each of the 2^n possible combinations of input signals, the binary value of each of the m output signals is listed.
- **Graphical symbols:** The interconnected layout of gates is depicted.
- **Boolean equations:** Each output signal is expressed as a Boolean function of its input signals.

Implementation of Boolean Functions

Any Boolean function can be implemented in electronic form as a network of gates. For any given function, there are a number of alternative realizations. Consider the Boolean function represented by the truth table in **Table 12.4**. We can express this function by simply itemizing the combinations of values of A, B, and C that cause F to be 1:

$$F = ABC + ABC + ABC \quad (12.1)$$

Table 12.4 A Boolean Function of Three Variables

A	B	C	F
0	0	0	0
0	0	1	0
0	1	0	1
0	1	1	1
1	0	0	0
1	0	1	0
1	1	0	1
1	1	1	0

There are three combinations of input values that cause F to be 1, and if any one of these combinations occurs, the result is 1. This form of expression, for self-evident reasons, is known as the **sum of products (SOP)** form. **Figure 12.6** shows a straightforward implementation with AND, OR, and NOT gates.

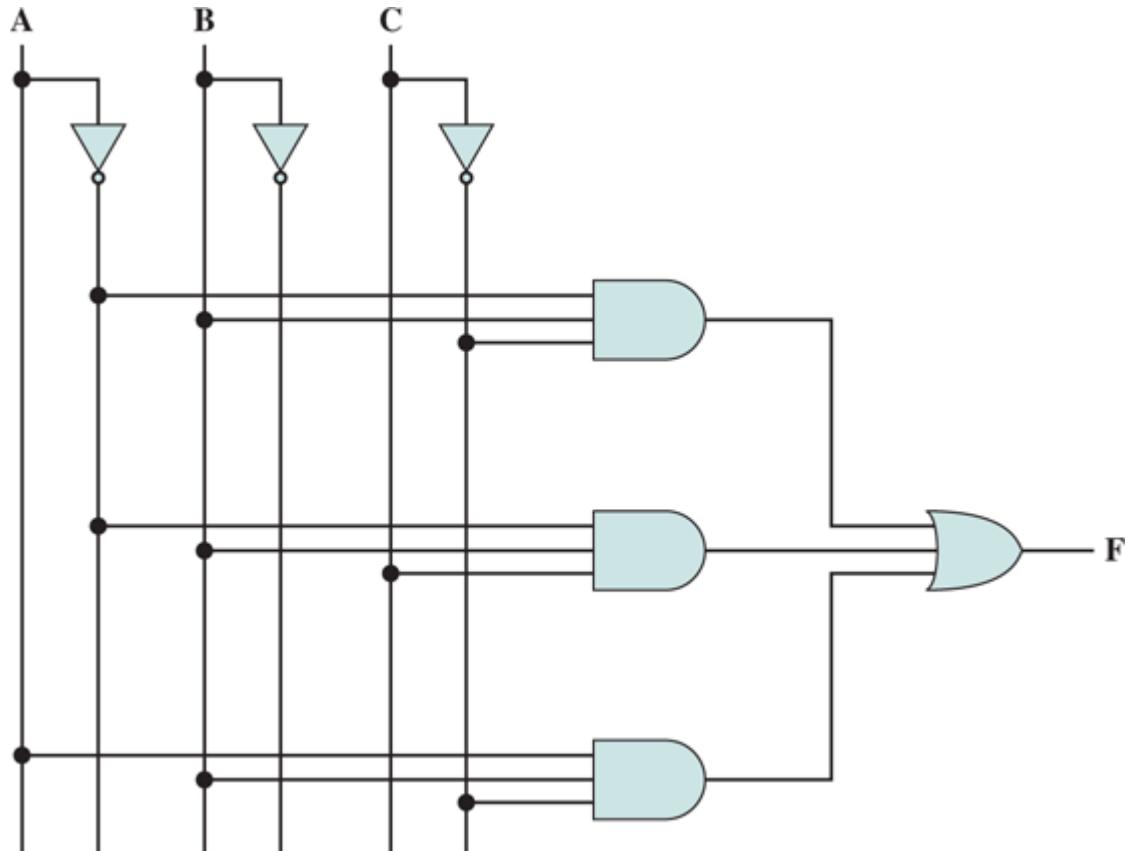

Figure 12.6 Sum-of-Products Implementation of Table 12.4

Another form can also be derived from the truth table. The SOP form expresses that the output is 1 if any of the input combinations that produce 1 is true. We can also say that the output is 1 if none of the input combinations that produce 0 is true. Thus,

$$F = (\bar{A}\bar{B}C) \cdot (\bar{A}\bar{B}C\bar{C}) \cdot (\bar{A}\bar{B}\bar{C}) \cdot (\bar{A}\bar{B}\bar{C}\bar{C}) \cdot (ABC)$$

This can be rewritten using a generalization of DeMorgan's theorem:

$$(X \cdot Y \cdot Z) = X + Y + Z$$

Thus,

$$\begin{aligned} F &= (\bar{A} + \bar{B} + \bar{C}) \cdot (\bar{A} + \bar{B} + C) \cdot (A + \bar{B} + \bar{C}) \cdot (A + \bar{B} + C) \cdot (A + B + C) \\ &= (A + B + C) \cdot (A + B + C) \cdot (\bar{A} + B + C) \cdot (A + B + C) \cdot (\bar{A} + B + C) \end{aligned} \quad (12.2)$$

This is in the **product of sums (POS)** form, which is illustrated in **Figure 12.7**. For clarity, NOT gates are not shown. Rather, it is assumed that each input signal and its complement are available. This simplifies the logic diagram and makes the inputs to the gates more readily apparent.

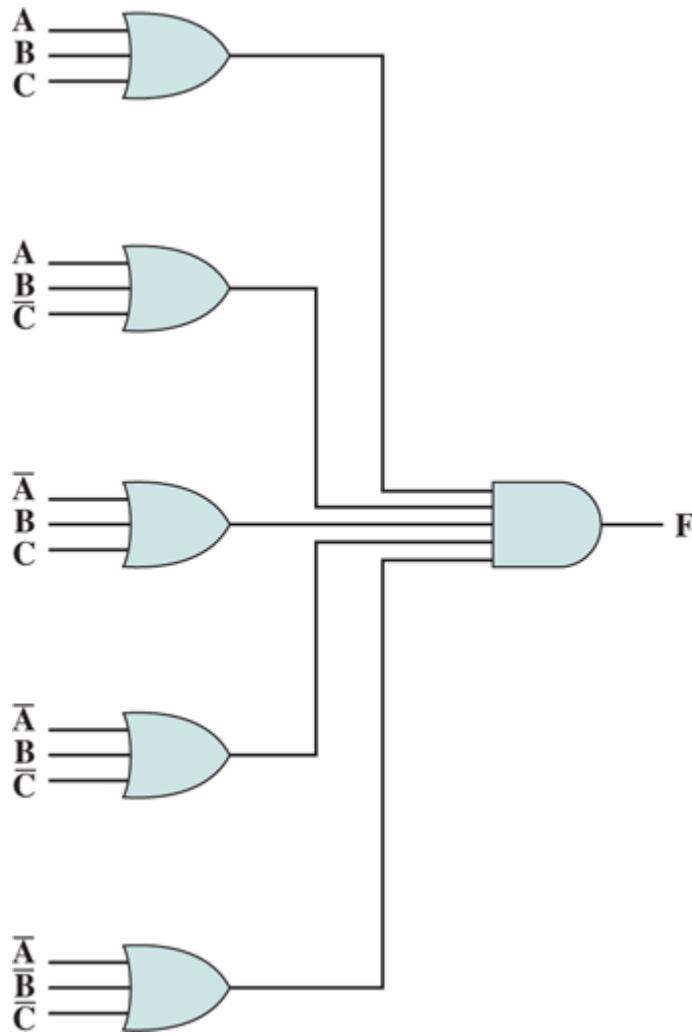

Figure 12.7 Product-of-Sums Implementation of Table 12.4

Thus, a Boolean function can be realized in either SOP or POS form. At this point, it would seem that the choice would depend on whether the truth table contains more 1s or 0s for the output function: The SOP has one term for each 1, and the POS has one term for each 0. However, there are other considerations:

- It is often possible to derive a simpler Boolean expression from the truth table than either SOP or POS.
- It may be preferable to implement the function with a single gate type (NAND or NOR).

The significance of the first point is that, with a simpler Boolean expression, fewer gates will be needed to implement the function. Three methods that can be used to achieve simplification are

- Algebraic simplification
- Karnaugh maps
- Quine–McCluskey tables

ALGEBRAIC SIMPLIFICATION

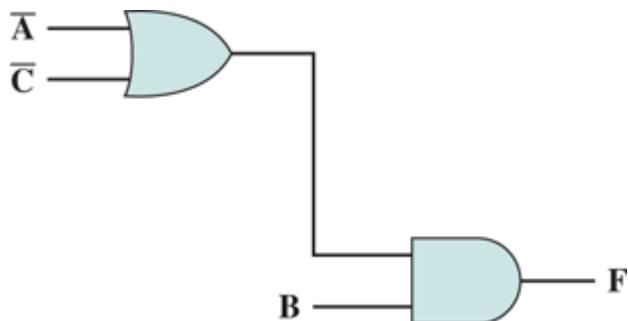

Algebraic simplification involves the application of the identities of **Table 12.3** to reduce the Boolean expression to one with fewer elements. For example, consider again **Equation (12.1)**. Some thought should convince the reader that an equivalent expression is

$$F = AB + BC \quad (12.3)$$

Or, even simpler,

$$F = B(A + C)$$

This expression can be implemented as shown in [Figure 12.8](#). The simplification of [Equation \(12.1\)](#) was done essentially by observation. For more complex expressions, a more systematic approach is needed.

[Figure 12.8 Simplified Implementation of Table 12.4](#)

KARNAUGH MAPS

For purposes of simplification, the **Karnaugh map** is a convenient way of representing a Boolean function of a small number (up to four) of variables. The map is an array of 2^n squares, representing all possible combinations of values of n binary variables. [Figure 12.9a](#) shows the map of four squares for a function of two variables. It is essential for later purposes to list the combinations in the order 00, 01, 11, 10. Because the squares corresponding to the combinations are to be used for recording information, the combinations are customarily written above the squares. In the case of three variables, the representation is an arrangement of eight squares ([Figure 12.9b](#)), with the values for one of the variables to the left and for the other two variables above the squares. For four variables, 16 squares are needed, with the arrangement indicated in [Figure 12.9c](#).

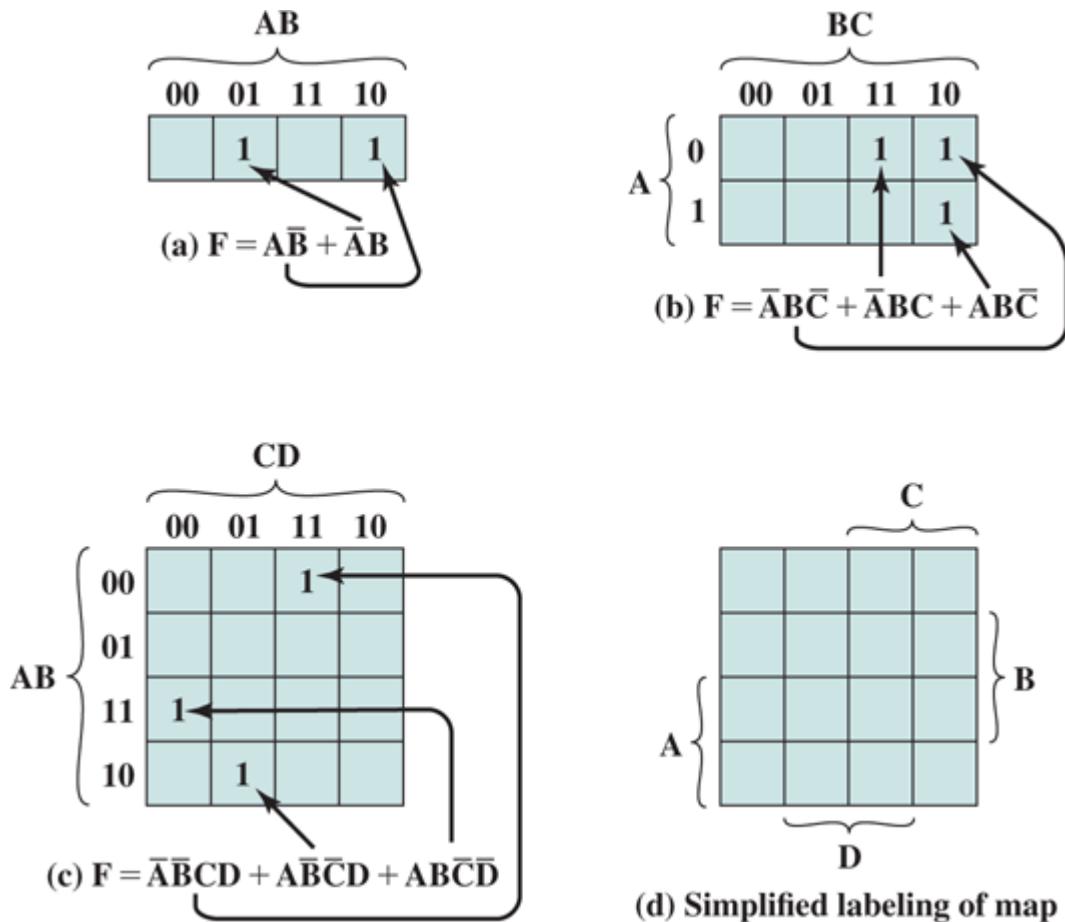

Figure 12.9 The Use of Karnaugh Maps to Represent Boolean Functions

The map can be used to represent any Boolean function in the following way. Each square corresponds to a unique product in the sum-of-products form, with a 1 value corresponding to the variable and a 0 value corresponding to the NOT of that variable. Thus, the product AB corresponds to the fourth square in [Figure 12.9a](#). For each such product in the function, 1 is placed in the corresponding square. Thus, for the two-variable example, the map corresponds to $AB + AB̄$. Given the truth table of a Boolean function, it is an easy matter to construct the map: for each combination of values of variables that produce a result of 1 in the truth table, fill in the corresponding square of the map with 1. [Figure 12.9b](#) shows the result for the truth table of [Table 12.4](#). To convert from a Boolean expression to a map, it is first necessary to put the expression into what is referred to as *canonical* form: each term in the expression must contain each variable. So, for example, if we have [Equation \(12.3\)](#), we must first expand it into the full form of [Equation \(12.1\)](#) and then convert this to a map.

The labeling used in [Figure 12.9d](#) emphasizes the relationship between variables and the rows and columns of the map. Here the two rows embraced by the symbol A are those in which the variable A has the value 1; the rows not embraced by the symbol A are those in which A is 0; similarly for B, C, and D.

Once the map of a function is created, we can often write a simple algebraic expression for it by noting the arrangement of the 1s on the map. The principle is as follows. Any two squares that are adjacent differ in only one of the variables. If two adjacent squares both have an entry of one, then the corresponding product terms differ in only one variable. In such a case, the two terms can be merged by eliminating that variable. For example, in [Figure 12.10a](#), the two adjacent squares correspond to the two terms $ABCD$ and $ABCD̄$. Thus, the function expressed is

$$ABCD + ABCD̄ = ABD$$

This process can be extended in several ways. First, the concept of adjacency can be extended to include wrapping around the edge of the map. Thus, the top square of a column is adjacent to the bottom square, and the leftmost square of a row is adjacent to the rightmost square. These conditions are illustrated in **Figures 12.10b** and **c**. Second, we can group not just 2 squares but 2^n adjacent squares (i.e., 2, 4, 8, etc.). The next three examples in **Figure 12.10** show groupings of 4 squares. Note that in this case, two of the variables can be eliminated. The last three examples show groupings of 8 squares, which allows three variables to be eliminated.

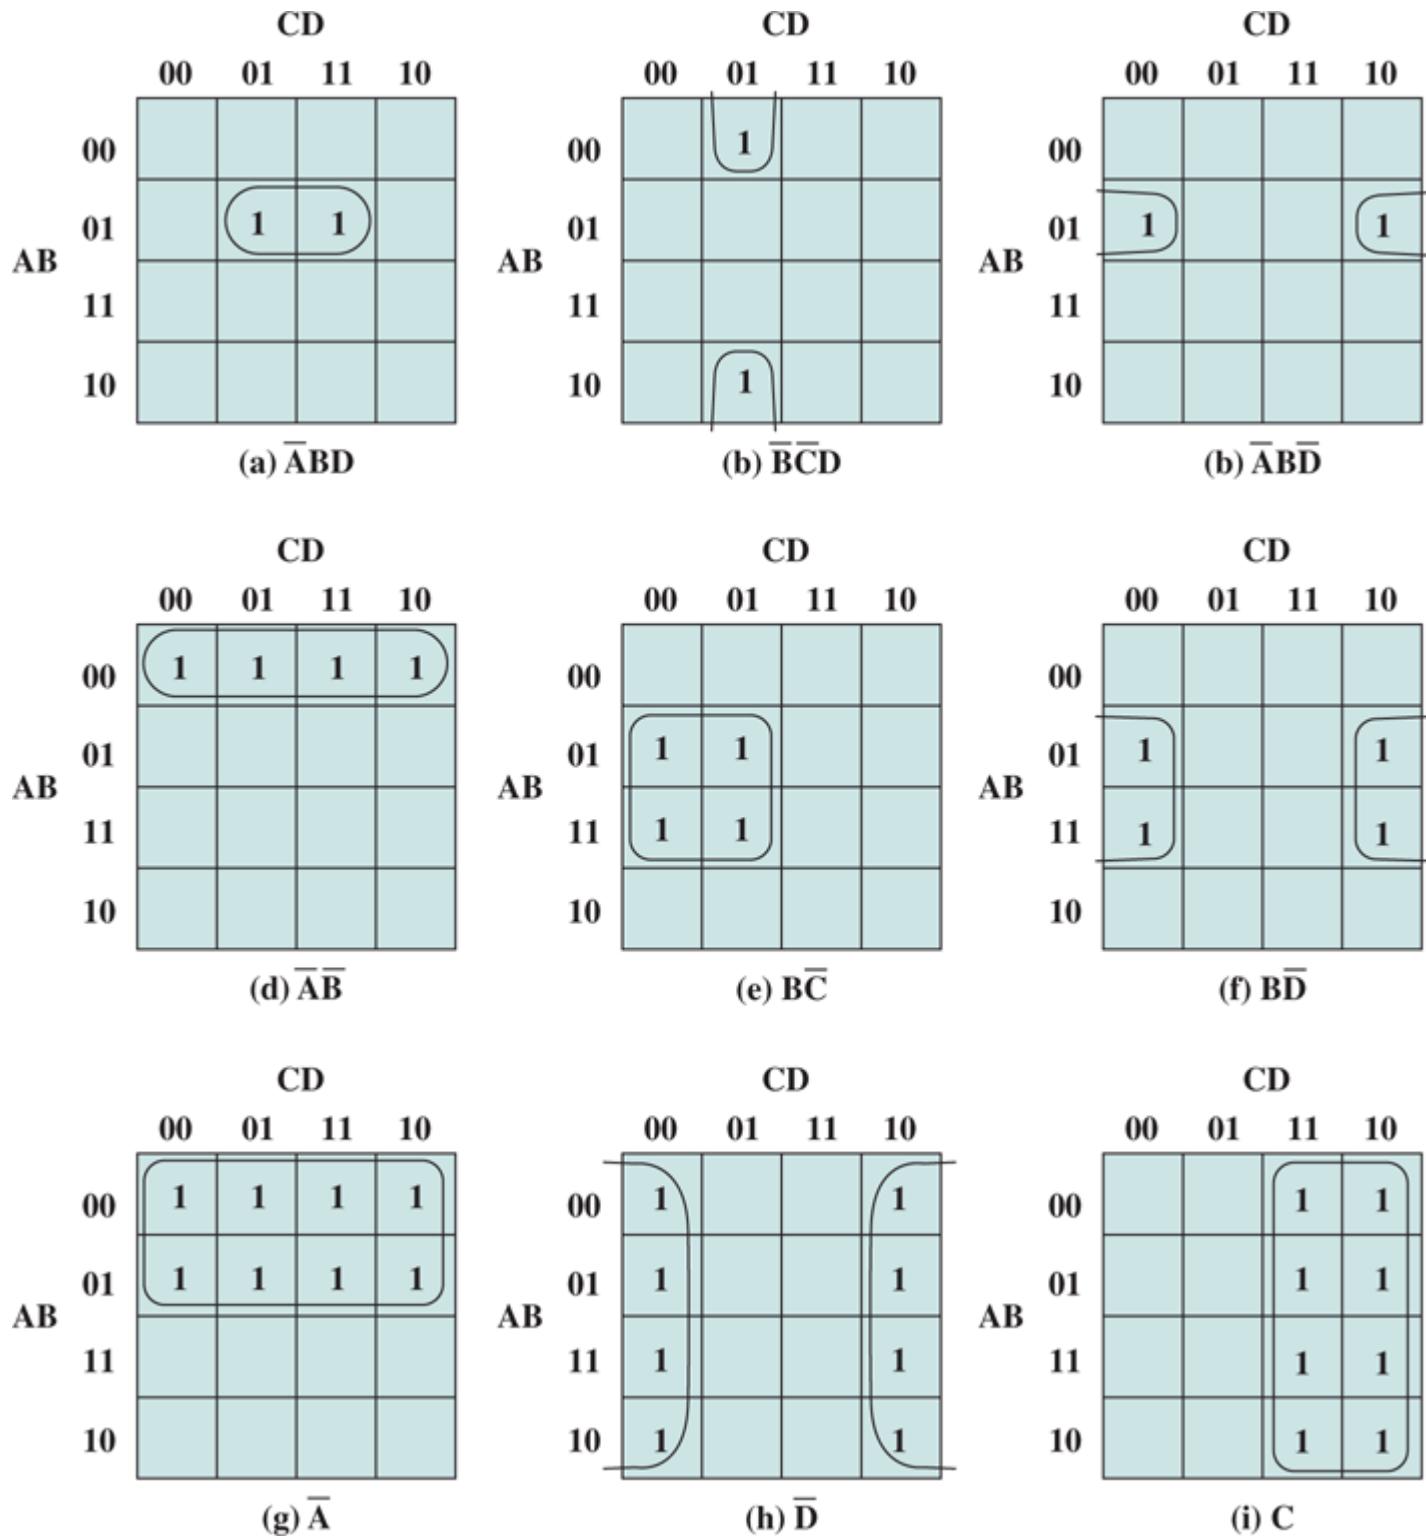

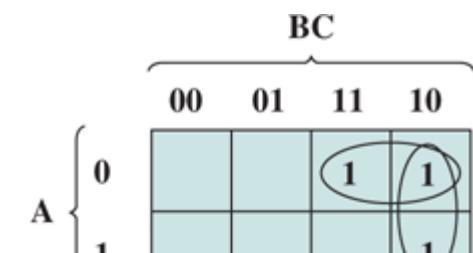

Figure 12.10 The Use of Karnaugh Maps

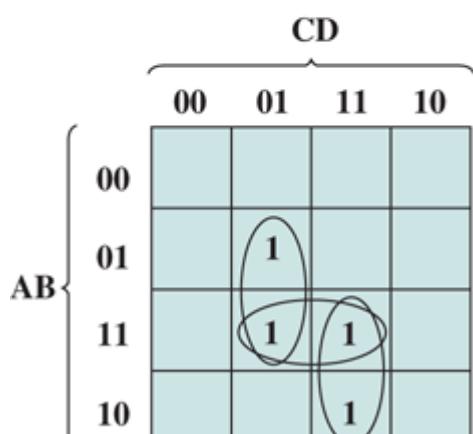

We can summarize the rules for simplification as follows:

1. Among the marked squares (squares with a 1), find those that belong to a unique largest block of 1, 2, 4, or 8 and circle those blocks.
2. Select additional blocks of marked squares that are as large as possible and as few in number as possible, but include every marked square at least once. The results may not be unique in some cases. For example, if a marked square combines with exactly two other squares, and there is no fourth marked square to complete a larger group, then there is a choice to be made as to which of the two groupings to choose. When you are circling groups, you are allowed to use the same 1 value more than once.
3. Continue to draw loops around single marked squares, or pairs of adjacent marked squares, or groups of four, eight, and so on in such a way that every marked square belongs to at least one loop; then use as few of these blocks as possible to include all marked squares.

Figure 12.11a, based on **Table 12.4**, illustrates the simplification process. If any isolated 1s remain after the groupings, then each of these is circled as a group of 1s. Finally, before going from the map to a simplified Boolean expression, any group of 1s that is completely overlapped by other groups can be eliminated. This is shown in **Figure 12.11b**. In this case, the horizontal group is redundant and may be ignored in creating the Boolean expression.

$$(a) F = \bar{A}\bar{B} + \bar{B}\bar{C}$$

$$(b) F = \bar{B}\bar{C}\bar{D} + A\bar{C}D$$

Figure 12.11 Overlapping Groups

One additional feature of Karnaugh maps needs to be mentioned. In some cases, certain combinations of values of variables never occur, and therefore the corresponding output never occurs. These are referred to as “don’t care” conditions. For each such condition, the letter “d” is entered into the corresponding square of the map. In doing the grouping and simplification, each “d” can be treated as a 1 or 0, whichever leads to the simplest expression.

An example, presented in [HAYE98], illustrates the points we have been discussing. We would like to develop the Boolean expressions for a circuit that adds 1 to a packed decimal digit. For packed

decimal, each decimal digit is represented by a 4-bit code, in the obvious way. Thus, $0 = 0000$, $1 = 0001$, ..., $8 = 1000$, and $9 = 1001$. The remaining 4-bit values, from 1010 to 1111, are not used. This code is also referred to as **Binary Coded Decimal (BCD)**.

Table 12.5 shows the truth table for producing a 4-bit result that is one more than a 4-bit BCD input. The addition is modulo 10. Thus, $9 + 1 = 0$. Also, note that six of the input codes produce “don’t care” results, because those are not valid BCD inputs. **Figure 12.12** shows the resulting Karnaugh maps for each of the output variables. The d squares are used to achieve the best possible groupings.

Table 12.5 Truth Table for the One-Digit Packed Decimal Incrementer

Number	Input				Number	Output			
	A	B	C	D		W	X	Y	Z
0	0	0	0	0	1	0	0	0	1
1	0	0	0	1	2	0	0	1	0
2	0	0	1	0	3	0	0	1	1
3	0	0	1	1	4	0	1	0	0
4	0	1	0	0	5	0	1	0	1
5	0	1	0	1	6	0	1	1	0

9	1	0	0	1	0	0	0	0	0
Don't care condition	1	0	1	0		d	d	d	d
	1	0	1	1		d	d	d	d
	1	1	0	0		d	d	d	d
	1	1	0	1		d	d	d	d
	1	1	1	0		d	d	d	d
	1	1	1	1		d	d	d	d

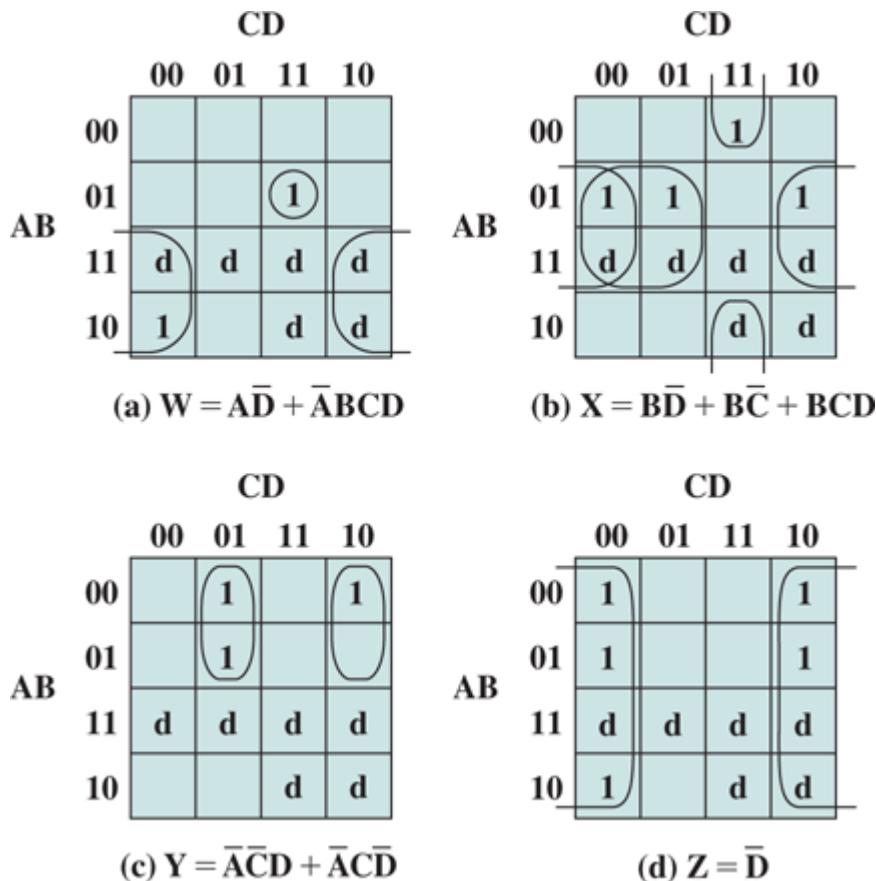

Figure 12.12 Karnaugh Maps for the Incrementer

THE QUINE-MCCLUSKEY METHOD

For more than four variables, the Karnaugh map method becomes increasingly cumbersome. With five variables, two 16×16 maps are needed, with one map considered to be on top of the other in three dimensions to achieve adjacency. Six variables require the use of four 16×16 tables in four dimensions! An alternative approach is a tabular technique, referred to as the Quine–McCluskey method. The method is suitable for programming on a computer to give an automatic tool for producing minimized Boolean expressions.

The method is best explained by means of an example. Consider the following expression:

$$ABCD + ABCD + ABCD + ABCD + ABCD + ABCD + ABCD + ABCD$$

Let us assume that this expression was derived from a truth table. We would like to produce a minimal expression suitable for implementation with gates.

The first step is to construct a table in which each row corresponds to one of the product terms of the expression. The terms are grouped according to the number of complemented variables. That is, we start with the term with no complements, if it exists, then all terms with one complement, and so on. **Table 12.6** shows the list for our example expression, with horizontal lines used to indicate the grouping. For clarity, each term is represented by a 1 for each uncomplemented variable and a 0 for each complemented variable. Thus, we group terms according to the number of 1s they contain. The index column is simply the decimal equivalent and is useful in what follows.

Table 12.6 First Stage of Quine–McCluskey Method
(for $F = ABCD + ABCD$)

Product Term	Index	A	B	C	D
ABCD	1	0	0	0	1
ABCD	5	0	1	0	1
ABCD	6	0	1	1	0
ABCD	12	1	1	0	0
ABCD	7	0	1	1	1
ABCD	11	1	0	1	1
ABCD	13	1	1	0	1
ABCD	15	1	1	1	1

The next step is to find all pairs of terms that differ in only one variable, that is, all pairs of terms that are the same except that one variable is 0 in one of the terms and 1 in the other. Because of the way in which we have grouped the terms, we can do this by starting with the first group and comparing each term of the first group with every term of the second group. Then compare each term of the second group with all of the terms of the third group, and so on. Whenever a match is found, place a check next to each term, combine the pair by eliminating the variable that differs in the two terms, and add that to a new list. Thus, for example, the terms ABCD and ABCD are combined to produce ABC.

This process continues until the entire original table has been examined. The result is a new table with the following entries:

ACD	ABC	ABD	✓
BCD	✓	ACD	
ABC	BCD	✓	
ABD	✓		

The new table is organized into groups, as indicated, in the same fashion as the first table. The second table is then processed in the same manner as the first. That is, terms that differ in only one variable are checked and a new term produced for a third table. In this example, the third table that is produced contains only one term: BD.

In general, the process would proceed through successive tables until a table with no matches was produced. In this case, this has involved three tables.

Once the process just described is completed, we have eliminated many of the possible terms of the expression. Those terms that have not been eliminated are used to construct a matrix, as illustrated in **Table 12.7**. Each row of the matrix corresponds to one of the terms that have not been eliminated (has no check) in any of the tables used so far. Each column corresponds to one of the terms in the original expression. An X is placed at each intersection of a row and a column, such that the row element is “compatible” with the column element. That is, the variables present in the row element have the same value as the variables present in the column element. Next, circle each X that is alone

in a column. Then place a square around each X in any row in which there is a circled X. If every column now has either a squared or a circled X, then we are done, and those row elements whose Xs have been marked constitute the minimal expression. Thus, in our example, the final expression is

Table 12.7 Last Stage of Quine–McCluskey Method
(for $F = \overline{ABCD} + \overline{ABC}\overline{D} + \overline{AB}\overline{CD} + \overline{AB}\overline{C}\overline{D} + \overline{A}\overline{B}\overline{C}\overline{D} + \overline{A}\overline{B}\overline{C}D + A\overline{B}\overline{C}D + A\overline{B}CD + ABC\overline{D}$)

	ABCD	ABCD	ABCD	ABCD	ABCD	ABCD	ABCD	ABCD
BD	X	X			X		X	
$A\overline{C}D$							X	\otimes
ABC					X	\otimes		
ABC		X	\otimes					
ACD	X			\otimes				

$$ABC + ACD + ABC + ACD$$

In cases in which some columns have neither a circle nor a square, additional processing is required. Essentially, we keep adding row elements until all columns are covered.

Let us summarize the Quine–McCluskey method to try to justify intuitively why it works. The first phase of the operation is reasonably straightforward. The process eliminates unneeded variables in product terms. Thus, the expression $ABC + ABC$ is equivalent to AB , because

$$ABC + ABC = AB(C + C) = AB$$

After the elimination of variables, we are left with an expression that is clearly equivalent to the original expression. However, there may be redundant terms in this expression, just as we found redundant groupings in Karnaugh maps. The matrix layout assures that each term in the original expression is covered, and does so in a way that minimizes the number of terms in the final expression.

NAND AND NOR IMPLEMENTATIONS

Another consideration in the implementation of Boolean functions concerns the types of gates used. It is sometimes desirable to implement a Boolean function solely with NAND gates or solely with NOR gates. Although this may not be the minimum-gate implementation, it has the advantage of regularity, which can simplify the manufacturing process. Consider again [Equation \(12.3\)](#):

$$F = B(A + C)$$

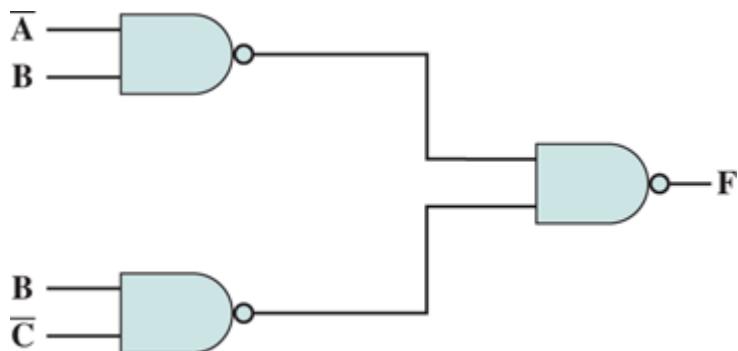

Because the complement of the complement of a value is just the original value,

$$F = B(A + C) = (\overline{AB} + \overline{BC})$$

Applying DeMorgan's theorem,

$$F = (\overline{A}\overline{B}) \bullet (\overline{B}\overline{C})$$

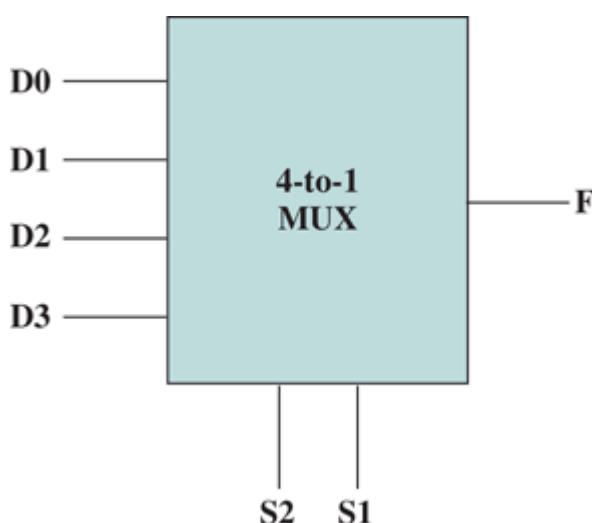

which has three NAND forms, as illustrated in [Figure 12.13](#).

[Figure 12.13](#) NAND Implementation of [Table 12.4](#)

Multiplexers

The **multiplexer** connects multiple inputs to a single output. At any time, one of the inputs is selected to be passed to the output. A general block diagram representation is shown in [Figure 12.14](#). This represents a 4-to-1 multiplexer. There are four input lines, labeled D0, D1, D2, and D3. One of these lines is selected to provide the output signal F. To select one of the four possible inputs, a 2-bit selection code is needed, and this is implemented as two select lines labeled S1 and S2.

[Figure 12.14](#) 4-to-1 Multiplexer Representation

An example 4-to-1 multiplexer is defined by the truth table in [Table 12.8](#). This is a simplified form of a truth table. Instead of showing all possible combinations of input variables, it shows the output as data from line D0, D1, D2, or D3. [Figure 12.15](#) shows an implementation using AND, OR, and NOT gates. S1 and S2 are connected to the AND gates in such a way that, for any combination of S1 and S2, three of the AND gates will output 0. The fourth **AND gate** will output the value of the selected line, which is either 0 or 1. Thus, three of the inputs to the OR gate are always 0, and the output of the OR gate will equal the value of the selected input gate. Using this regular organization, it is easy to construct multiplexers of size 8-to-1, 16-to-1, and so on.

[Table 12.8](#) 4-to-1 Multiplexer Truth Table

S2	S1	F
0	0	0
0	1	0
1	0	0
1	1	1

0	0	D0
0	1	D1
1	0	D2
1	1	D3

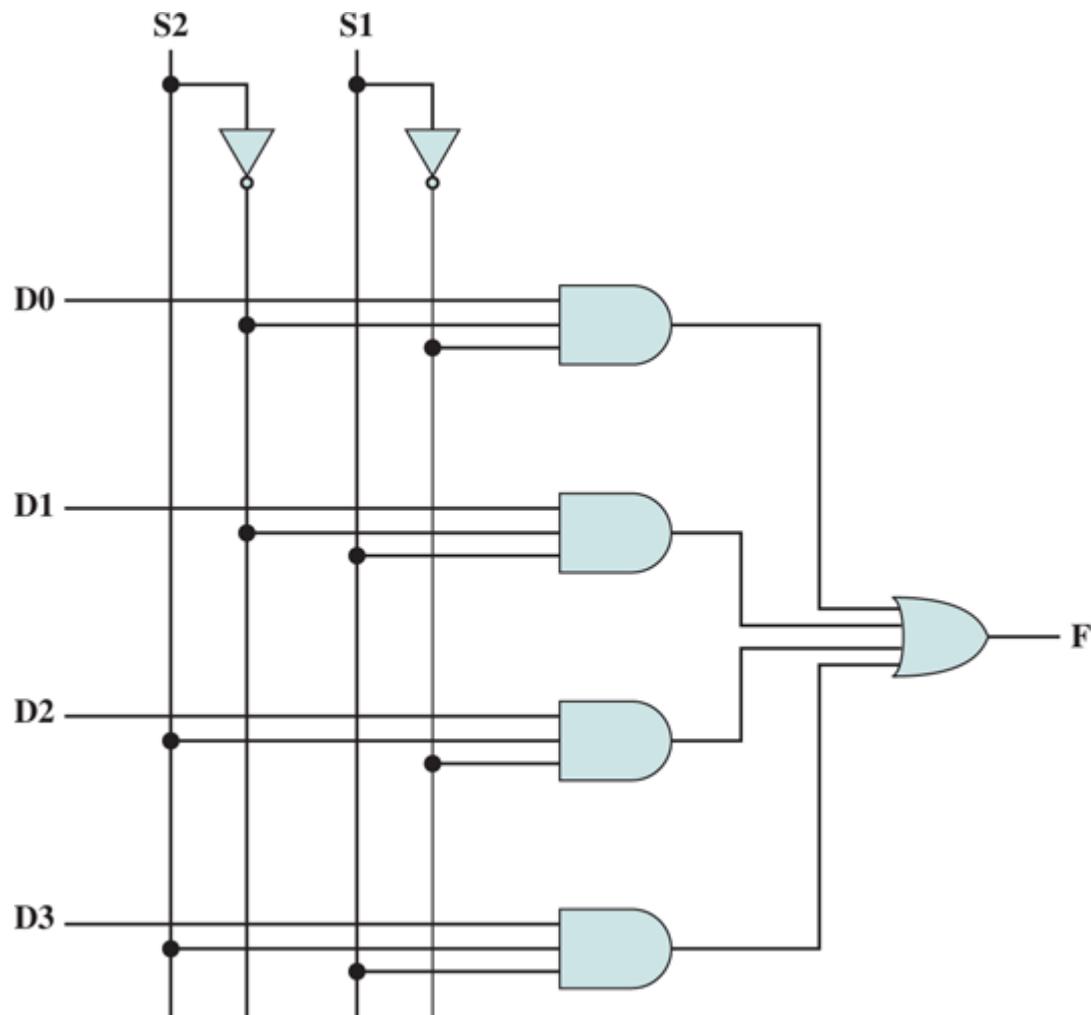

Figure 12.15 Multiplexer Implementation

Multiplexers are used in digital circuits to control signal and data routing. An example is the loading of the program **counter** (PC). The value to be loaded into the program counter may come from one of several different sources:

- A binary counter, if the PC is to be incremented for the next instruction.
- The instruction **register**, if a branch instruction using a direct address has just been executed.
- The output of the ALU, if the branch instruction specifies the address using a displacement mode.

These various inputs could be connected to the input lines of a multiplexer, with the PC connected to the output line. The select lines determine which value is loaded into the PC. Because the PC contains multiple bits, multiple multiplexers are used, one per bit. **Figure 12.16** illustrates this for 16-bit addresses.

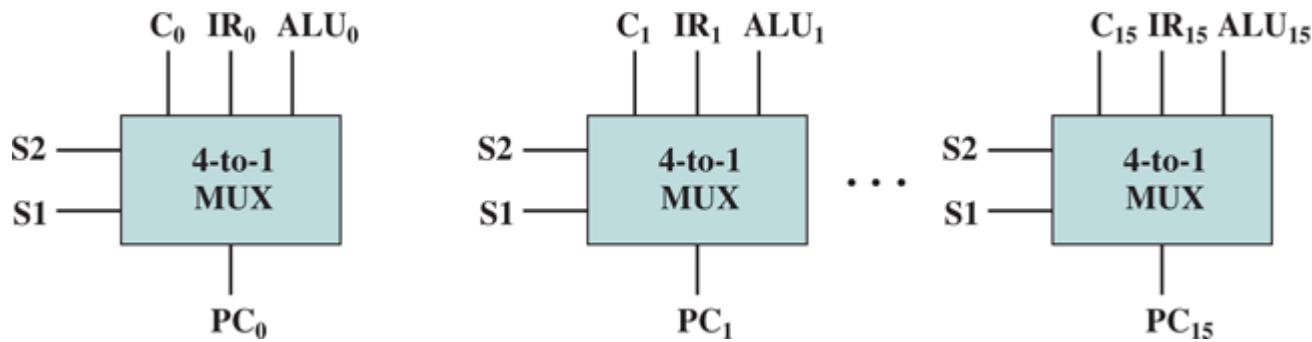

Figure 12.16 Multiplexer Input to Program Counter

Decoders

A **decoder** is a combinational circuit with a number of output lines, only one of which is asserted at any time. Which output line is asserted depends on the pattern of input lines. In general, a decoder has n inputs and 2^n outputs. [Figure 12.17](#) shows a decoder with three inputs and $2^3 = 8$ outputs.

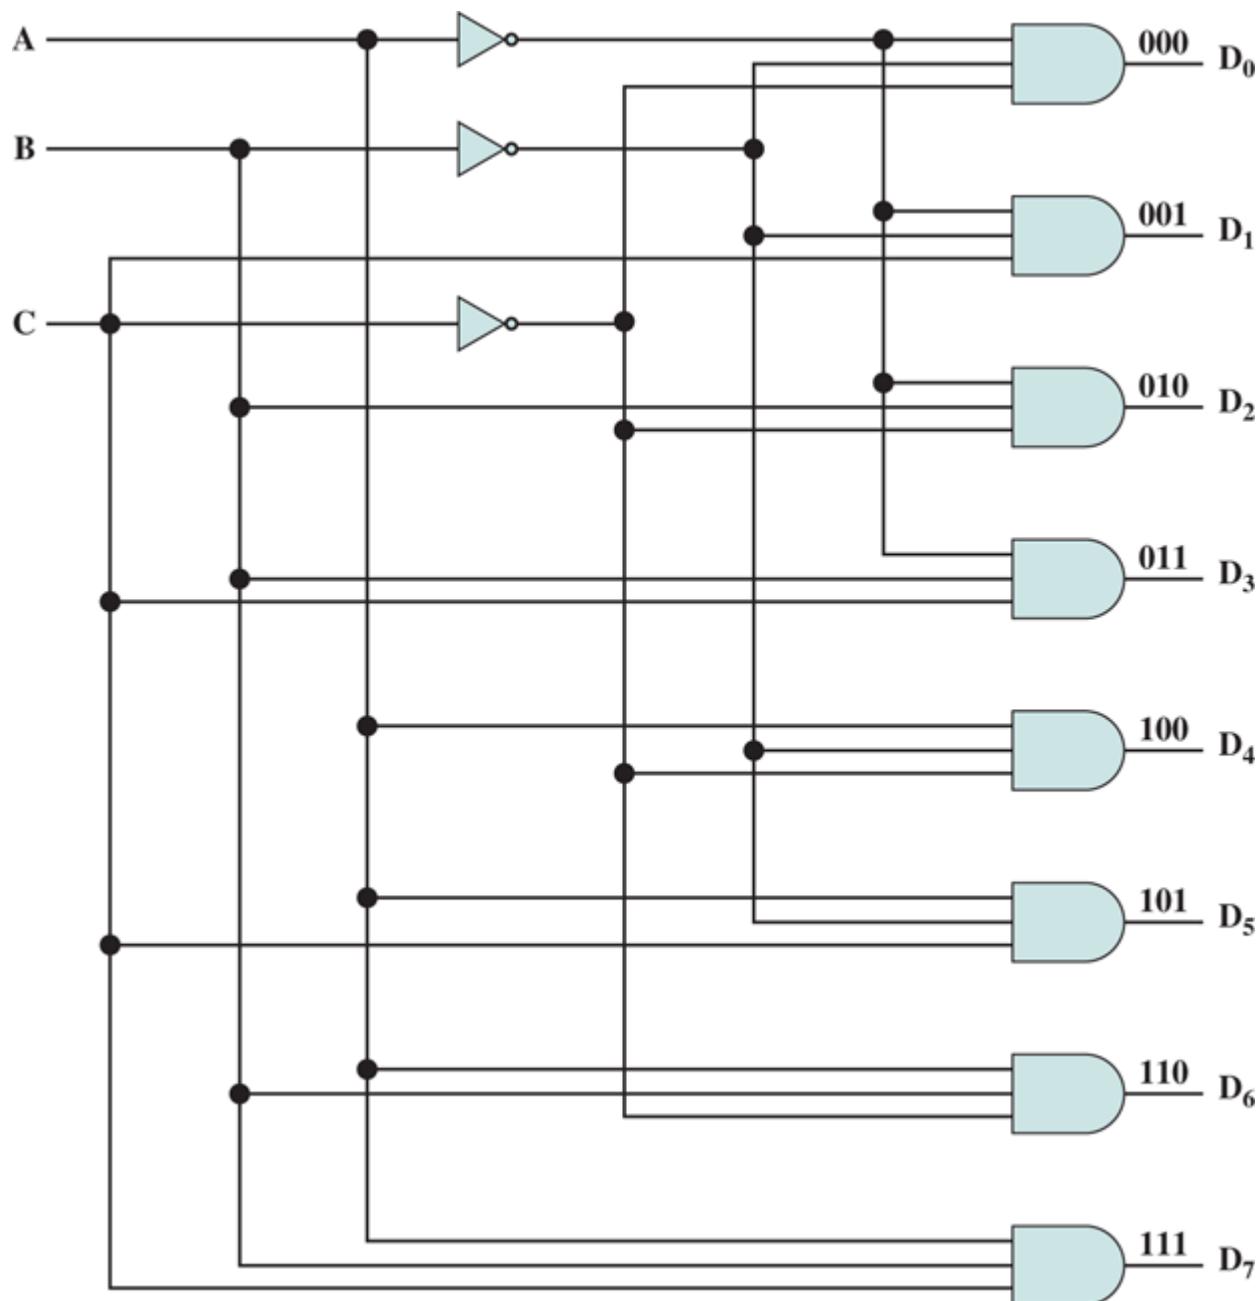

Figure 12.17 Decoder with 3 Inputs and $2^3 = 8$ Outputs

Decoders find many uses in digital computers. One example is address decoding. Suppose we wish to construct a 1K-byte memory using four 256×8 -bit RAM chips. We want a single unified address space, which can be broken down as follows:

Address	Chip
0000–00FF	0
0100–01FF	1
0200–02FF	2
0300–03FF	3

Each chip requires 8 address lines, and these are supplied by the lower-order 8 bits of the address. The higher-order 2 bits of the 10-bit address are used to select one of the four RAM chips. For this purpose, a 2-to-4 decoder is used whose output enables one of the four chips, as shown in [Figure 12.18](#).

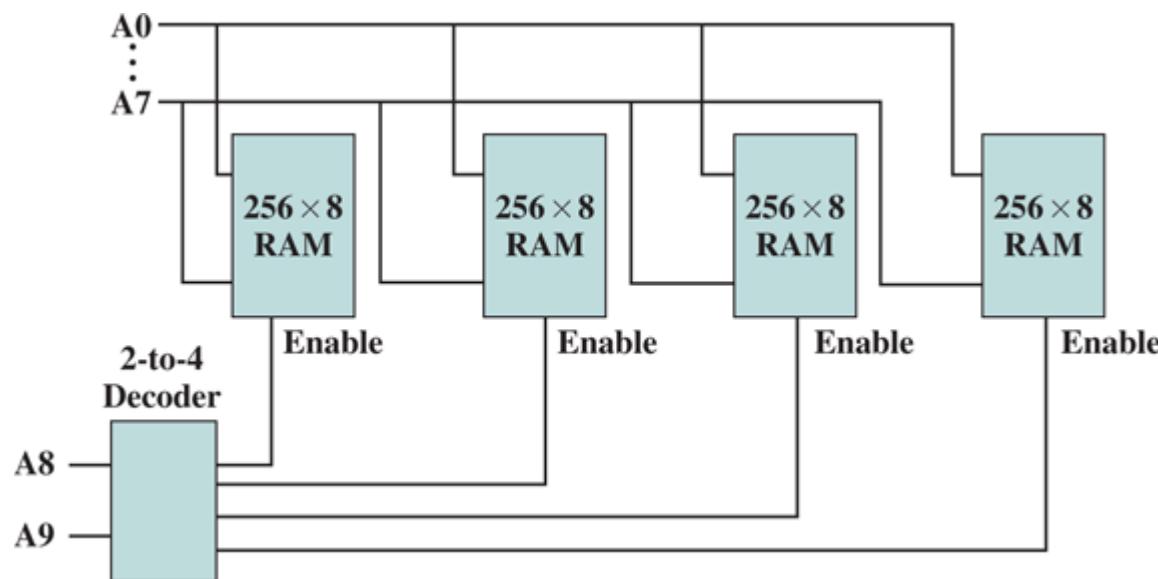

Figure 12.18 Address Decoding

With an additional input line, a decoder can be used as a demultiplexer. The demultiplexer performs the inverse function of a multiplexer; it connects a single input to one of several outputs. This is shown in [Figure 12.19](#). As before, n inputs are decoded to produce a single one of 2^n outputs. All of the 2^n output lines are ANDed with a data input line. Thus, the n inputs act as an address to select a particular output line, and the value on the data input line (0 or 1) is routed to that output line.

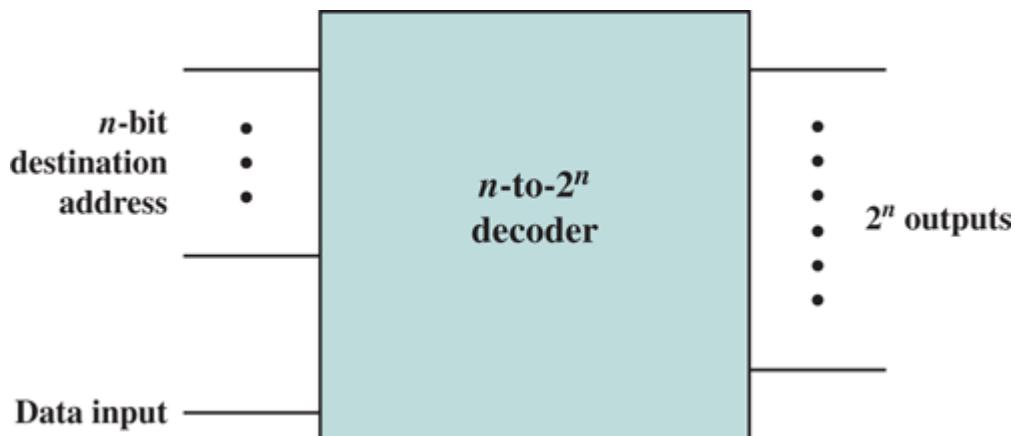

Figure 12.19 Implementation of a Demultiplexer Using a Decoder

The configuration in [Figure 12.19](#) can be viewed in another way. Change the label on the new line from *Data Input* to *Enable*. This allows for the control of the timing of the decoder. The decoded output appears only when the encoded input is present *and* the enable line has a value of 1.

Read-Only Memory

Combinational circuits are often referred to as “memoryless” circuits, because their output depends only on their current input and no history of prior inputs is retained. However, there is one sort of memory that is implemented with combinational circuits, namely **read-only memory (ROM)**.

Recall that a ROM is a memory unit that performs only the read operation. This implies that the binary information stored in a ROM is permanent and was created during the fabrication process. Thus, a given input to the ROM (address lines) always produces the same output (data lines). Because the outputs are a function only of the present inputs, the ROM is in fact a combinational circuit.

A ROM can be implemented with a decoder and a set of OR gates. As an example, consider [Table 12.9](#). This can be viewed as a truth table with four inputs and four outputs. For each of the 16 possible input values, the corresponding set of values of the outputs is shown. It can also be viewed as defining the contents of a 64-bit ROM consisting of 16 words of 4 bits each. The four inputs specify an address, and the four outputs specify the contents of the location specified by the address. [Figure 12.20](#) shows how this memory could be implemented using a 4-to-16 decoder and four OR gates. As with the PLA, a regular organization is used, and the interconnections are made to reflect the desired result.

Table 12.9 Truth Table for a ROM

Input				Output			
X ₁	X ₂	X ₃	X ₄	Z ₁	Z ₂	Z ₃	Z ₄
0	0	0	0	0	0	0	0
0	0	0	1	0	0	0	1

1	1	1	1	1	0	0	0

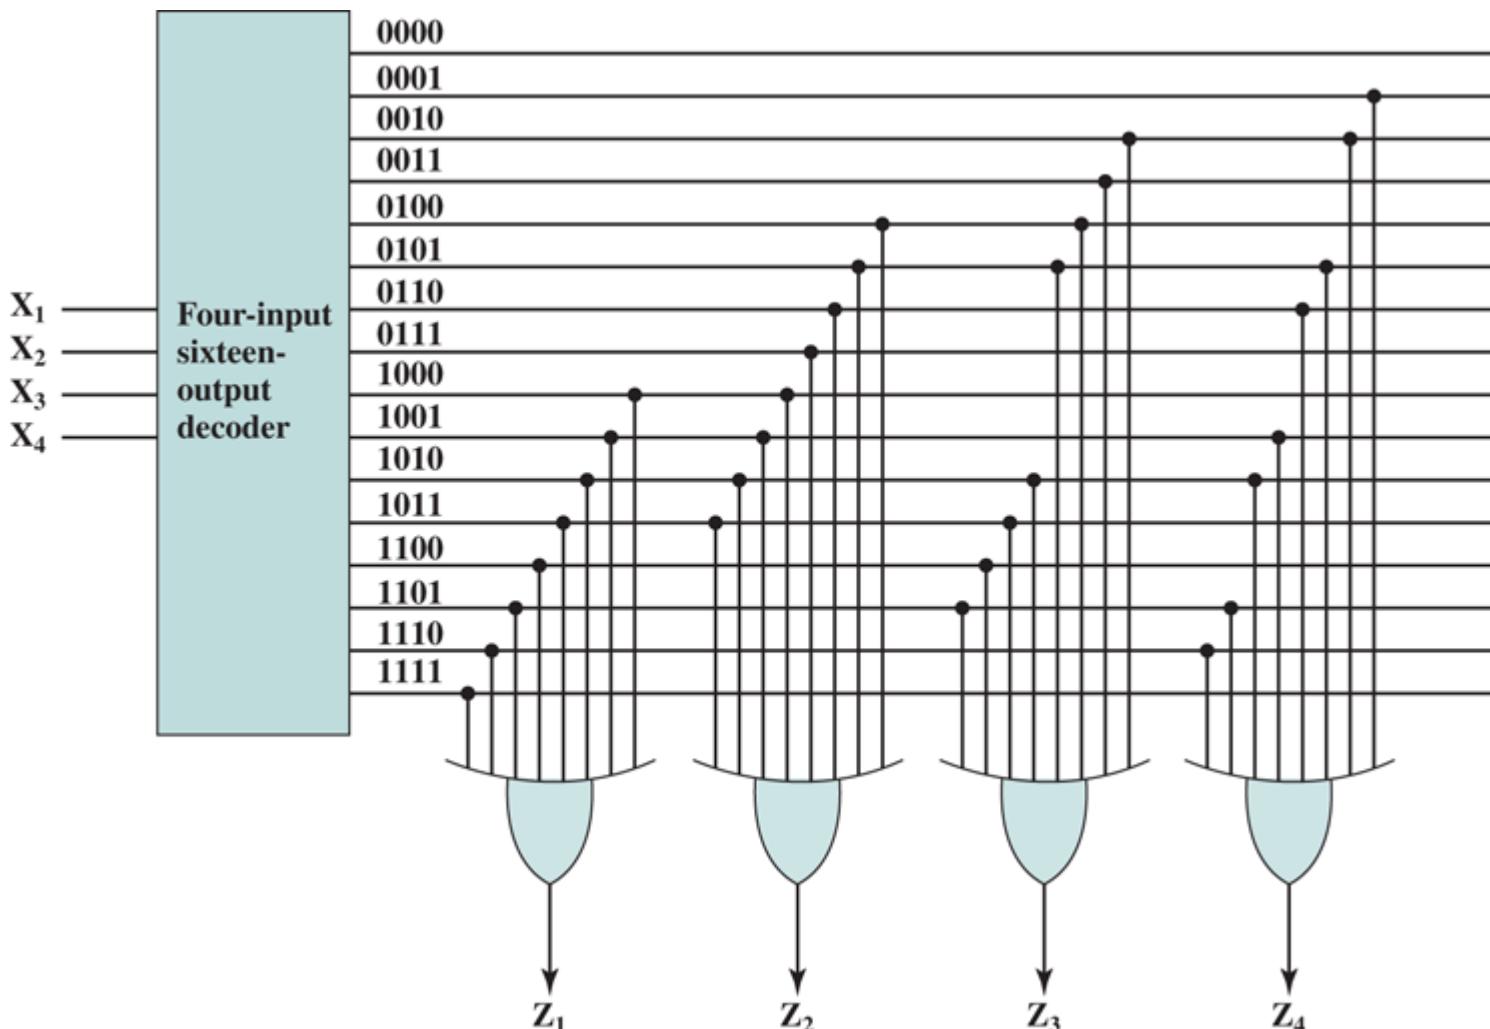

Figure 12.20 A 64-Bit ROM

Adders

So far, we have seen how interconnected gates can be used to implement such functions as the routing of signals, decoding, and ROM. One essential area not yet addressed is that of arithmetic. In this brief overview, we will content ourselves with looking at the addition function.

Binary addition differs from Boolean algebra in that the result includes a carry term. Thus for binary addition: $0 + 0 = 0$; $0 + 1 = 1$; $1 + 0 = 1$; $1 + 1 = 10$. However, addition can still be dealt with in Boolean terms. In [Table 12.10a](#), we show the logic for adding two input bits to produce a 1-bit sum and a carry bit. This truth table could easily be implemented in digital logic. However, we are not interested in performing addition on just a single pair of bits. Rather, we wish to add two n -bit numbers. This can be done by putting together a set of adders so that the carry from one **adder** is provided as input to the next. A 4-bit adder is depicted in [Figure 12.21](#).

Table 12.10 Binary Addition Truth Tables

(a) Single-Bit Addition				
A	B	Sum	Carry	
0	0	0	0

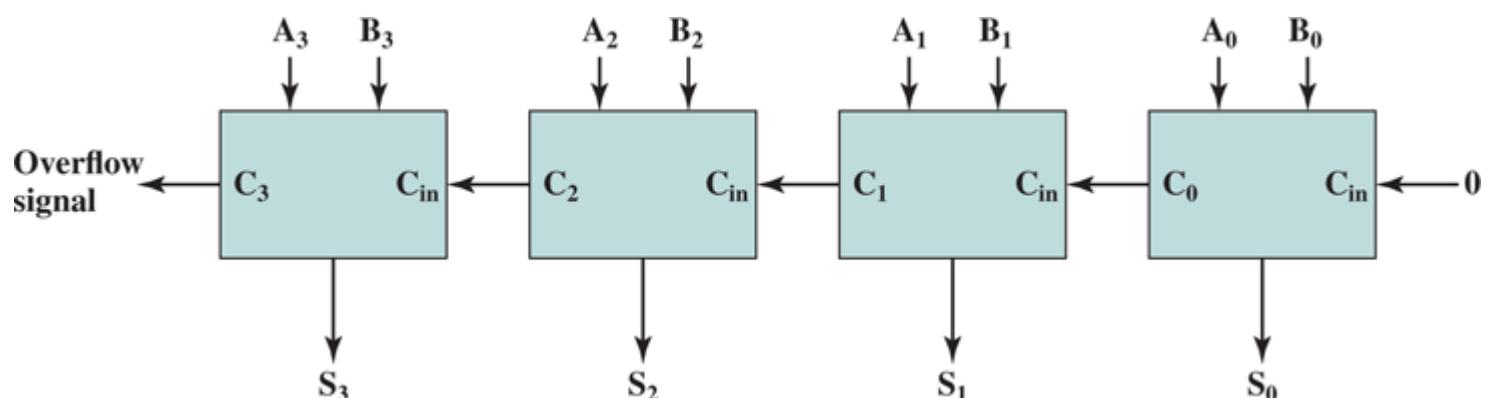

Figure 12.21 4-Bit Adder

For a multiple-bit adder to work, each of the single-bit adders must have three inputs, including the carry from the next-lower-order adder. The revised truth table appears in **Table 12.10b**. The two outputs can be expressed:

$$\begin{aligned} \text{Sum} &= ABC + \bar{A}BC + A\bar{B}C + ABC \\ \text{Carry} &= AB + AC + BC \end{aligned}$$

Figure 12.22 is an implementation using AND, OR, and NOT gates.

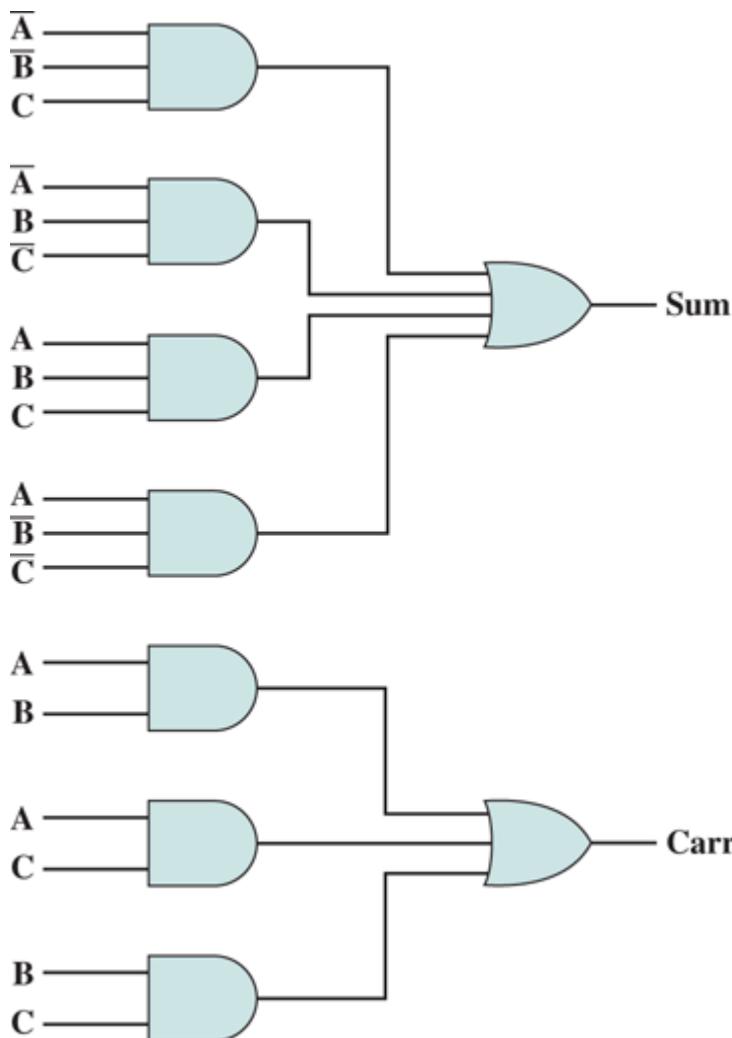

Figure 12.22 Implementation of an Adder

Thus we have the necessary logic to implement a multiple-bit adder such as shown in **Figure 12.23**. Note that because the output from each adder depends on the carry from the previous adder, there is an increasing delay from the least significant to the most significant bit. Each single-bit adder experiences a certain amount of gate delay, and this gate delay accumulates. For larger adders, the accumulated delay can become unacceptably high.

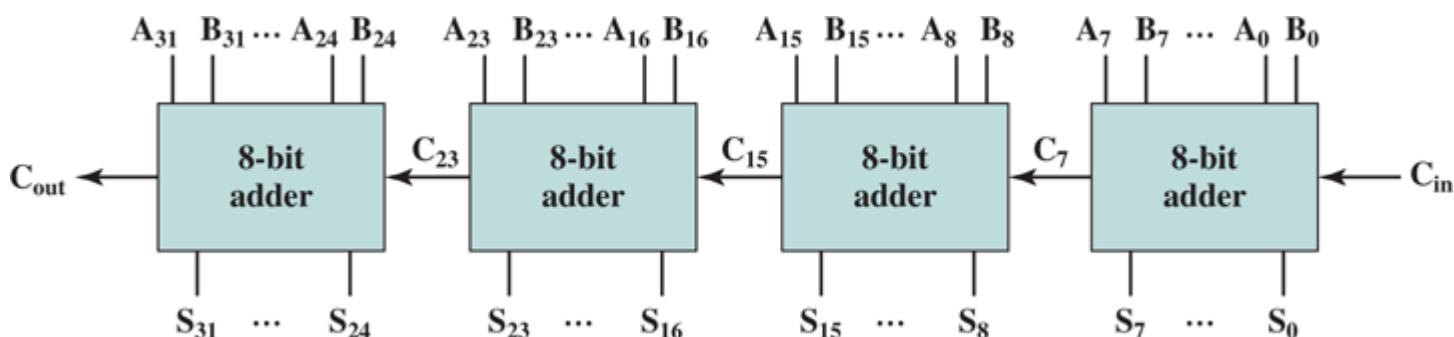

Figure 12.23 Construction of a 32-Bit Adder Using 8-Bit Adders

If the carry values could be determined without having to ripple through all the previous stages, then each single-bit adder could function independently, and delay would not accumulate. This can be achieved with an approach known as *carry lookahead*. Let us look again at the 4-bit adder to explain

this approach.

We would like to come up with an expression that specifies the carry input to any stage of the adder without reference to previous carry values. We have

$$C_0 = A_0 B_0 \quad (12.4)$$

$$C_1 = A_1 B_1 + A_1 A_0 B_0 + B_1 A_0 B_0 \quad (12.5)$$

Following the same procedure, we get

$$\begin{aligned} C_2 = & A_2 B_2 + A_2 A_1 B_1 + A_2 A_1 A_0 B_0 + A_2 B_1 A_0 B_0 + B_2 A_1 B_1 \\ & + B_2 A_1 A_0 B_0 + B_2 B_1 A_0 B_0 \end{aligned}$$

This process can be repeated for arbitrarily long adders. Each carry term can be expressed in SOP form as a function only of the original inputs, with no dependence on the carries. Thus, only two levels of gate delay occur regardless of the length of the adder.

For long numbers, this approach becomes excessively complicated. Evaluating the expression for the most significant bit of an n -bit adder requires an OR gate with $2^n - 1$ inputs and $2^n - 1$ AND gates with from 2 to $n + 1$ inputs. Accordingly, full carry lookahead is typically done only 4 to 8 bits at a time.

Figure 12.23 shows how a 32-bit adder can be constructed out of four 8-bit adders. In this case, the carry must ripple through the four 8-bit adders, but this will be substantially quicker than a ripple through thirty-two 1-bit adders.

12.4 Sequential Circuits

Combinational circuits implement the essential functions of a digital computer. However, except for the special case of ROM, they provide no memory or state information, elements also essential to the operation of a digital computer. For the latter purposes, a more complex form of digital logic circuit is used: the **sequential circuit**. The current output of a sequential circuit depends not only on the current input, but also on the past history of inputs. Another and generally more useful way to view it is that the current output of a sequential circuit depends on the current input and the current state of that circuit.

In this section, we examine some simple but useful examples of sequential circuits. As will be seen, the sequential circuit makes use of combinational circuits.

Flip-Flops

The simplest form of sequential circuit is the **flip-flop**. There are a variety of flip-flops, all of which share two properties:

- The flip-flop is a bistable device. It exists in one of two states and, in the absence of input, remains in that state. Thus, the flip-flop can function as a 1-bit memory.
- The flip-flop has two outputs, which are always the complements of each other. These are generally labeled Q and \bar{Q} .

The S—R LATCH

Figure 12.24 shows a common configuration known as the S—R flip-flop or **S—R latch**. The circuit has two inputs, S (Set) and R (Reset), and two outputs, Q and \bar{Q} , and consists of two NOR gates connected in a feedback arrangement.

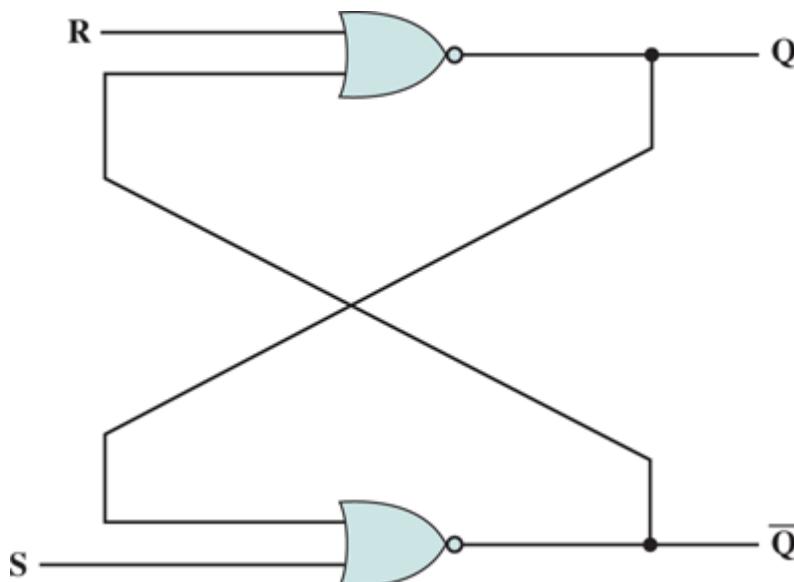

Figure 12.24 The S—R Latch Implemented with NOR Gates

First, let us show that the circuit is bistable. Assume that both S and R are 0 and that Q is 0. The inputs to the lower NOR gate are $Q = 0$ and $S = 0$. Thus, the output $Q = 1$ means that the inputs to the upper NOR gate are $Q = 1$ and $R = 0$, which has the output $Q = 0$. Thus, the state of the circuit is

internally consistent and remains stable as long as $S = R = 0$. A similar line of reasoning shows that the state $Q = 1, Q = 0$ is also stable for $R = S = 0$.

Thus, this circuit can function as a 1-bit memory. We can view the output Q as the “value” of the bit. The inputs S and R serve to write the values 1 and 0, respectively, into memory. To see this, consider the state $Q = 0, Q = 1, S = 0, R = 0$. Suppose that S changes to the value 1. Now the inputs to the lower NOR gate are $S = 1, Q = 0$. After some time delay Δt , the output of the lower NOR gate will be $Q = 0$ (see [Figure 12.25](#)). So, at this point in time, the inputs to the upper NOR gate become $R = 0, Q = 0$. After another gate delay of Δt the output Q becomes 1. This is again a stable state. The inputs to the lower gate are now $S = 1, Q = 1$, which maintain the output $Q = 0$. As long as $S = 1$ and $R = 0$, the outputs will remain $Q = 1, Q = 0$. Furthermore, if S returns to 0, the outputs will remain unchanged.

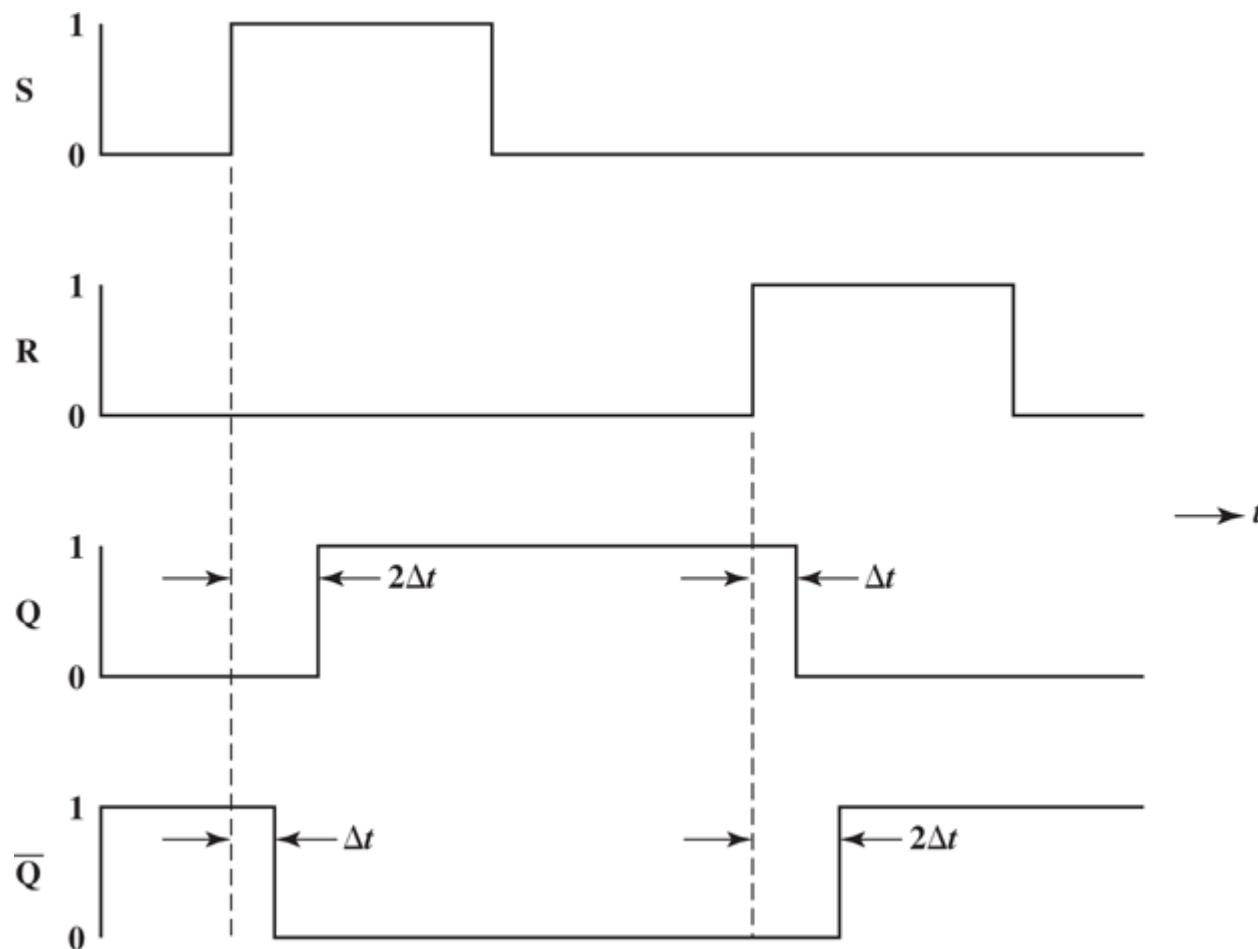

Figure 12.25 NOR S–R Latch Timing Diagram

The R output performs the opposite function. When R goes to 1, it forces $Q = 0, Q = 1$ regardless of the previous state of Q and Q . Again, a time delay of $2\Delta t$ occurs before the final state is established ([Figure 12.25](#)).

The S–R latch can be defined with a table similar to a truth table, called a *characteristic table*, which shows the next state or states of a sequential circuit as a function of current states and inputs. In the case of the S–R latch, the state can be defined by the value of Q . [Table 12.12a](#) shows the resulting characteristic table. Observe that the inputs $S = 1, R = 1$ are not allowed, because these would

produce an inconsistent output (both Q and \bar{Q} equal 0). The table can be expressed more compactly, as in **Table 12.10b**. An illustration of the behavior of the S–R latch is shown in **Table 12.12c**.

Table 12.12 The S-R Latch

(a) Characteristic Table			
Current Inputs	Current State	Next State

0	0	Q_n
0	1	0
1	0	1
1	1	—

R	0	0	0	1	0	0	1	0	0	0
Q_{n+1}	1	1	1	0	0	0	0	0	1	1

CLOCKED S-R FLIP-FLOP

The output of the S–R latch changes, after a brief time delay, in response to a change in the input. This is referred to as asynchronous operation. More typically, events in the digital computer are synchronized to a clock pulse, so that changes occur only when a clock pulse occurs. **Figure 12.26** shows this arrangement. This device is referred to as a **clocked S–R flip-flop**. Note that the R and S inputs are passed to the NOR gates only during the clock pulse.

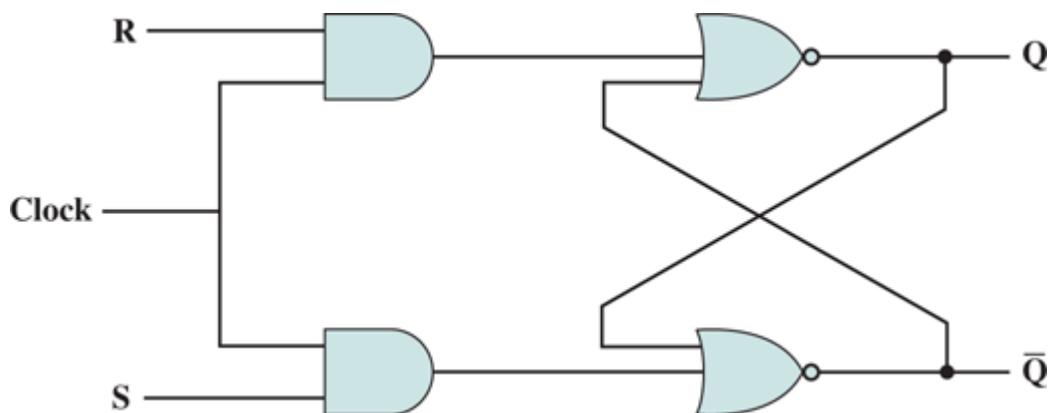

Figure 12.26 Clocked S–R Flip-Flop

D FLIP-FLOP

One problem with S–R flip-flop is that the condition $R = 1, S = 1$ must be avoided. One way to do this is to allow just a single input. The **D flip-flop** accomplishes this. **Figure 12.27** shows a gate implementation of the D flip-flop. By using an inverter, the nonclock inputs to the two AND gates are guaranteed to be the opposite of each other.

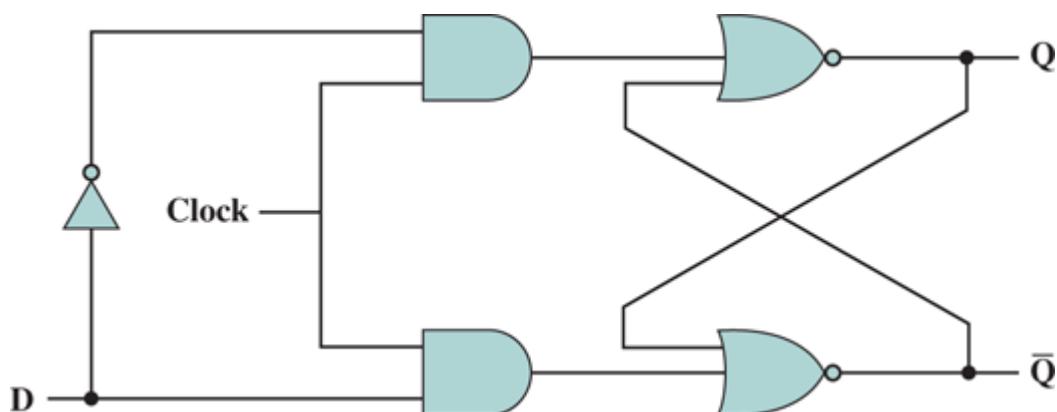

Figure 12.27 D Flip-Flop

The D flip-flop is sometimes referred to as the data flip-flop because it is, in effect, storage for one bit of data. The output of the D flip-flop is always equal to the most recent value applied to the input. Hence, it remembers and produces the last input. It is also referred to as the delay flip-flop, because it delays a 0 or 1 applied to its input for a single clock pulse. We can capture the logic of the D flip-flop in

the following truth table:

D	Q_{n+1}
0	0
1	1

J-K FLIP-FLOP

Another useful flip-flop is the **J-K flip-flop**. Like the S-R flip-flop, it has two inputs. However, in this case all possible combinations of input values are valid. [Figure 12.28](#) shows a gate implementation of the J-K flip-flop, and [Figure 12.29](#) shows its characteristic table (along with those for the S-R and D flip-flops). Note that the first three combinations are the same as for the S-R flip-flop. With no input asserted, the output is stable. If only the J input is asserted, the result is a set function, causing the output to be 1; if only the K input is asserted, the result is a reset function, causing the output to be 0. When both J and K are 1, the function performed is referred to as the toggle function: the output is reversed. Thus, if Q is 1 and 1 is applied to J and K, then Q becomes 0. The reader should verify that the implementation of [Figure 12.28](#) produces this characteristic function.

Figure 12.29 Basic Flip-Flops

Registers

As an example of the use of flip-flops, let us first examine one of the essential elements of the CPU: the register. As we know, a register is a digital circuit used within the CPU to store one or more bits of data. Two basic types of registers are commonly used: parallel registers and shift registers.

PARALLEL REGISTERS

A **parallel register** consists of a set of 1-bit memories that can be read or written simultaneously. It is used to store data. The registers that we have discussed throughout this book text are parallel registers.

The 8-bit register of [Figure 12.30](#) illustrates the operation of a parallel register using D flip-flops. A control signal, labeled *load*, controls writing into the register from signal lines, D11 through D18. These lines might be the output of multiplexers, so that data from a variety of sources can be loaded into the register.

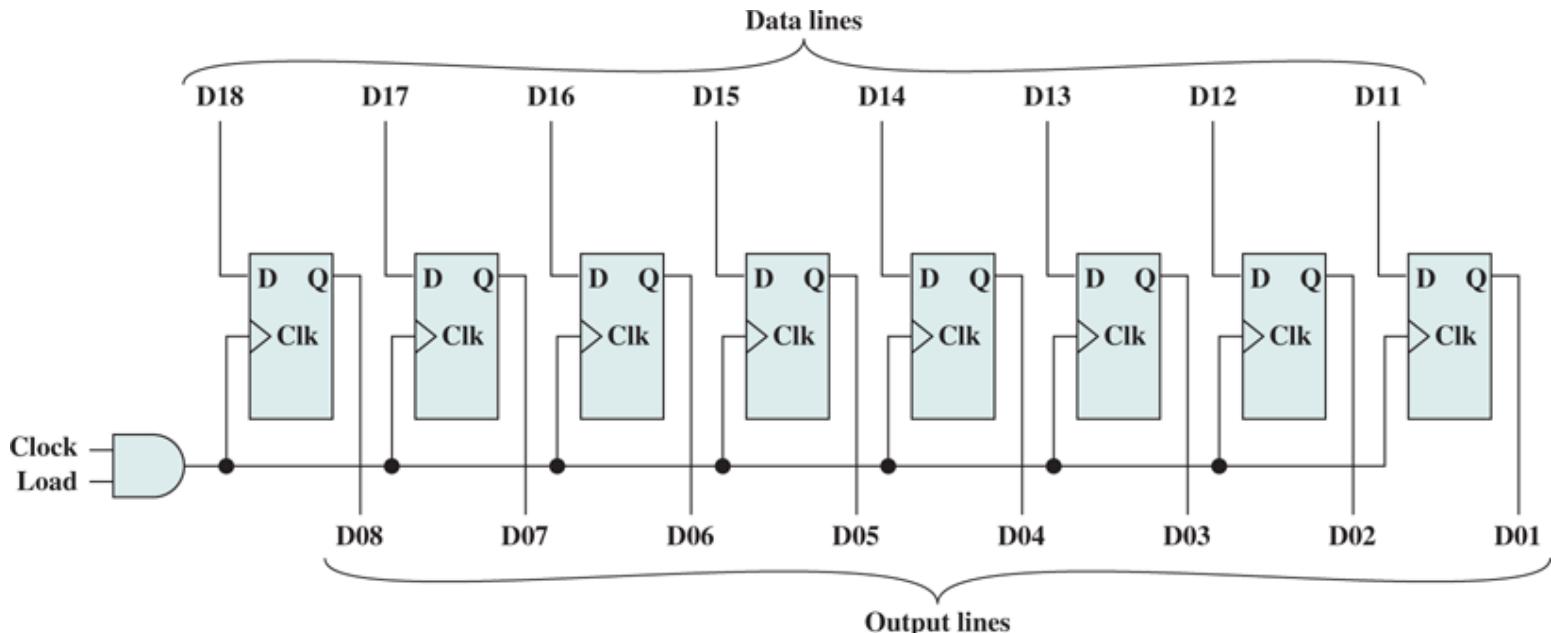

Figure 12.30 8-Bit Parallel Register

SHIFT REGISTER

A **shift register** accepts and/or transfers information serially. Consider, for example, **Figure 12.31**, which shows a 5-bit shift register constructed from clocked D flip-flops. Data are input only to the leftmost flip-flop. With each clock pulse, data are shifted to the right one position, and the rightmost bit is transferred out.

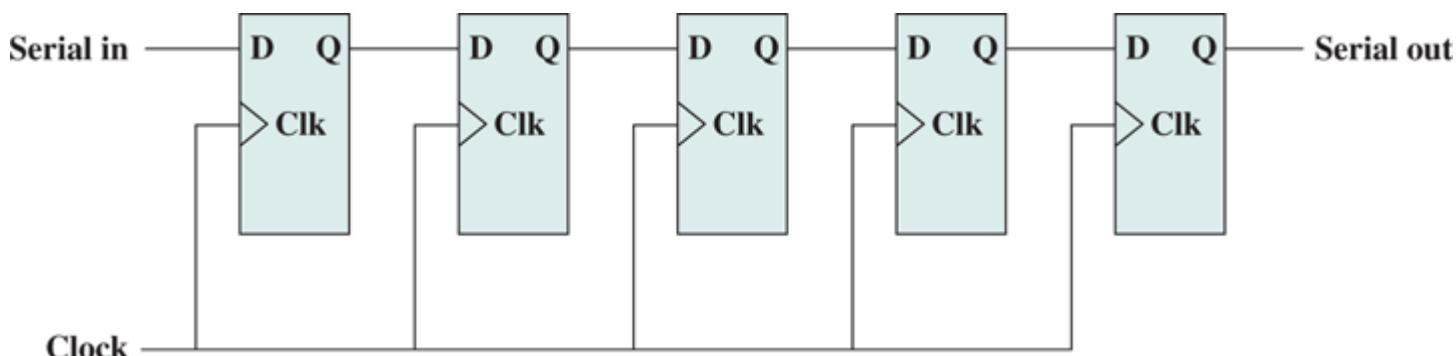

Figure 12.31 5-Bit Shift Register

Shift registers can be used to interface to serial I/O devices. In addition, they can be used within the ALU to perform logical shift and rotate functions. In this latter capacity, they need to be equipped with parallel read/write circuitry as well as serial.

Counters

Another useful category of sequential circuit is the counter. A counter is a register whose value is easily incremented by 1 modulo the capacity of the register; that is, after the maximum value is achieved the next increment sets the counter value to 0. Thus, a register made up of n flip-flops can count up to $2^n - 1$. An example of a counter in the CPU is the program counter.

Counters can be designated as asynchronous or synchronous, depending on the way in which they operate. Asynchronous counters are relatively slow because the output of one flip-flop triggers a

change in the status of the next flip-flop. In a **synchronous counter**, all of the flip-flops change state at the same time. Because the latter type is much faster, it is the kind used in CPUs. However, it is useful to begin the discussion with a description of an asynchronous counter.

RIPPLE COUNTER

An asynchronous counter is also referred to as a **ripple counter**, because the change that occurs to increment the counter starts at one end and “ripples” through to the other end. **Figure 12.32** shows an implementation of a 4-bit counter using J–K flip-flops, together with a timing diagram that illustrates its behavior. The timing diagram is idealized in that it does not show the propagation delay that occurs as the signals move down the series of flip-flops. The output of the leftmost flip-flop (Q_0) is the least significant bit. The design could clearly be extended to an arbitrary number of bits by cascading more flip-flops.

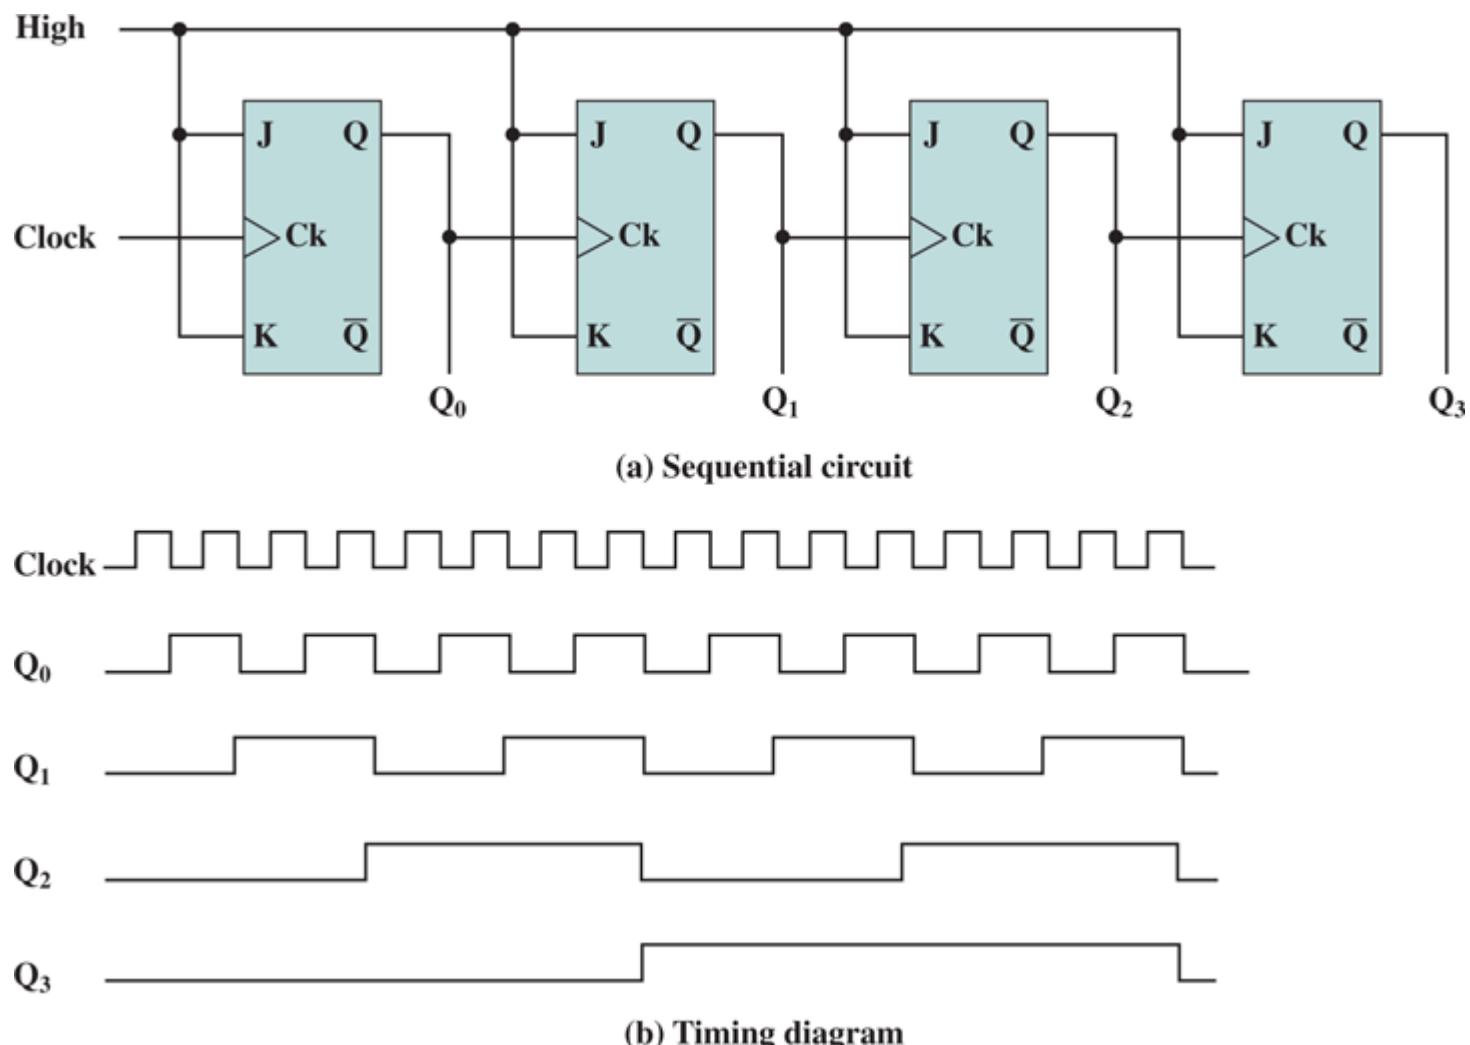

Figure 12.32 Ripple Counter

In the illustrated implementation, the counter is incremented with each clock pulse. The J and K inputs to each flip-flop are held at a constant 1. This means that, when there is a clock pulse, the output at Q will be inverted (1 to 0; 0 to 1). Note that the change in state is shown as occurring with the falling edge of the clock pulse; this is known as an edge-triggered flip-flop. Using flip-flops that respond to the transition in a clock pulse rather than the pulse itself provides better timing control in complex circuits. If one looks at patterns of output for this counter, it can be seen that it cycles through 0000, 0001, ..., 1110, 1111, 0000, and so on.

SYNCHRONOUS COUNTERS

The ripple counter has the disadvantage of the delay involved in changing value, which is proportional to the length of the counter. To overcome this disadvantage, CPUs make use of synchronous counters, in which all of the flip-flops of the counter change at the same time. In this subsection, we present a design for a 3-bit synchronous counter. In doing so, we illustrate some basic concepts in the design of a synchronous circuit.

For a 3-bit counter, three flip-flops will be needed. Let us use J–K flip-flops. Label the uncomplemented output of the three flip-flops C, B, and A, respectively, with C representing the most significant bit. The first step is to construct a truth table that relates the J–K inputs and outputs, to allow us to design the overall circuit. Such a truth table is shown in [Figure 12.33a](#). The first three columns show the possible combinations of outputs C, B, and A. They are listed in the order that they will appear as the counter is incremented. Each row lists the current value of C, B, and A and the inputs to the three flip-flops that will be required to reach the next value of C, B, and A.

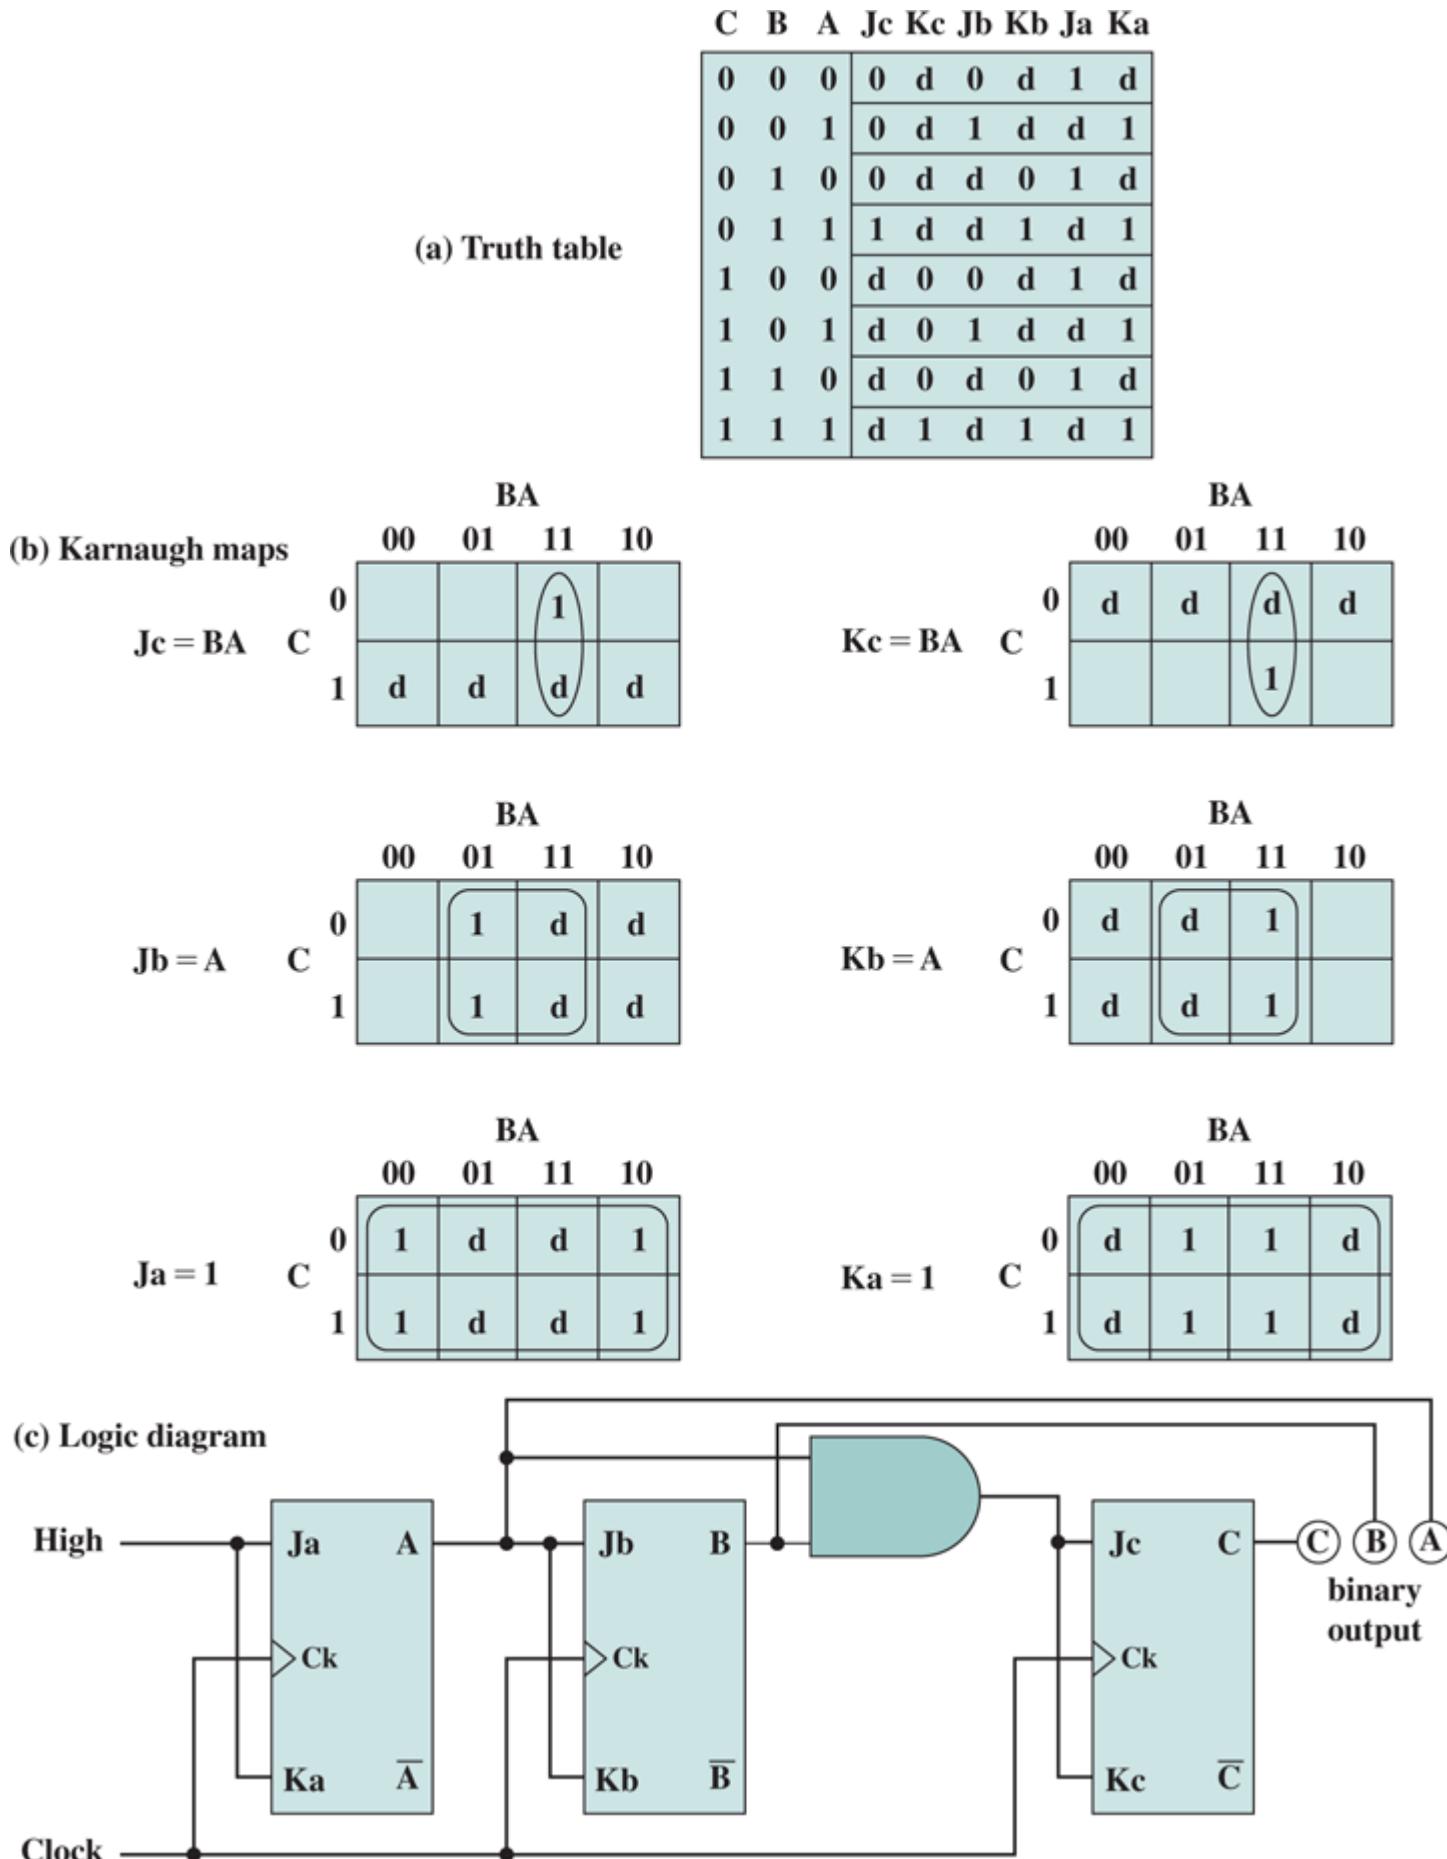

Figure 12.33 Design of a Synchronous Counter

To understand the way in which the truth table of [Figure 12.33a](#) is constructed, it may be helpful to recast the characteristic table for the J–K flip-flop. Recall that this table was presented as follows:

J	K	Q_{n+1}
0	0	Q_n
0	1	0
1	0	1
1	1	Q_{n+1}^{-}

In this form, the table shows the effect that the J and K inputs have on the output. Now consider the following organization of the same information:

Q_n	J	K	Q_{n+1}
0	0	d	0
0	1	d	1
1	d	1	0
1	d	0	1

In this form, the table provides the value of the next output when the inputs and the present output are known. This is exactly the information needed to design the counter or, indeed, any sequential circuit. In this form, the table is referred to as an **excitation table**.

Let us return to **Figure 12.33a**. Consider the first row. We want the value of C to remain 0, the value of B to remain 0, and the value of A to go from 0 to 1 with the next application of a clock pulse. The excitation table shows that to maintain an output of 0, we must have inputs of J = 0 and don't care for K. To effect a transition from 0 to 1, the inputs must be J = 1 and K = d. These values are shown in the first row of the table. By similar reasoning, the remainder of the table can be filled in.

Having constructed the truth table of **Figure 12.33a**, we see that the table shows the required values of all of the J and K inputs as functions of the current values of C, B, and A. With the aid of Karnaugh maps, we can develop Boolean expressions for these six functions. This is shown in part b of the figure. For example, the Karnaugh map for the variable Ja (the J input to the flip-flop that produces the A output) yields the expression $Ja = BC$. When all six expressions are derived, it is a straightforward matter to design the actual circuit, as shown in part c of the figure.

12.5 Programmable Logic Devices

Thus far, we have treated individual gates as building blocks, from which arbitrary functions can be realized. The designer could pursue a strategy of minimizing the number of gates to be used by manipulating the corresponding Boolean expressions.

As the level of integration provided by integrated circuits increases, other considerations apply. Early integrated circuits, using small-scale integration (SSI), provided from one to ten gates on a chip. Each gate is treated independently, in the building-block approach described so far. To construct a logic function, a number of these chips are laid out on a printed circuit board and the appropriate pin interconnections are made.

Increasing levels of integration made it possible to put more gates on a chip and to make gate interconnections on the chip as well. This yields the advantages of decreased cost, decreased size, and increased speed (because on-chip delays are of shorter duration than off-chip delays). A design problem arises, however. For each particular logic function or set of functions, the layout of gates and interconnections on the chip must be designed. The cost and time involved in such custom chip design is high. Thus, it becomes attractive to develop a general-purpose chip that can be readily adapted to specific purposes. This is the intent of the *programmable logic device* (PLD).

There are a number of different types of PLDs in commercial use. **Table 12.13** lists some of the key terms and defines some of the most important types. In this section, we first look at one of the simplest such devices, the *programmable logic array* (PLA) and then introduce perhaps the most important and widely used type of PLD, the field-programmable gate array (FPGA).

Table 12.13 PLD Terminology

Programmable Logic Device (PLD) A general term that refers to any type of integrated circuit used for implementing digital hardware, where the chip can be configured by the end user to realize different designs. Programming of such a device often involves placing the chip into a special programming unit, but some chips can also be configured “in-system.” Also referred to as a field-programmable device (FPD).
Programmable Logic Array (PLA) A relatively small PLD that contains two levels of logic, an AND-plane and an OR-plane, where both levels are programmable.
Programmable Array Logic (PAL) A relatively small PLD that has a programmable AND-plane followed by a fixed OR-plane.
Simple PLD (SPLD) A PLA or PAL.
Complex PLD (CPLD)

A more complex PLD that consists of an arrangement of multiple SPLD-like blocks on a single chip.

Field-Programmable Gate Array (FPGA)

A PLD featuring a general structure that allows very high logic capacity. Whereas CPLDs feature logic resources with a wide number of inputs (AND planes), FPGAs offer more narrow logic resources. FPGAs also offer a higher ratio of flip-flops to logic resources than do CPLDs.

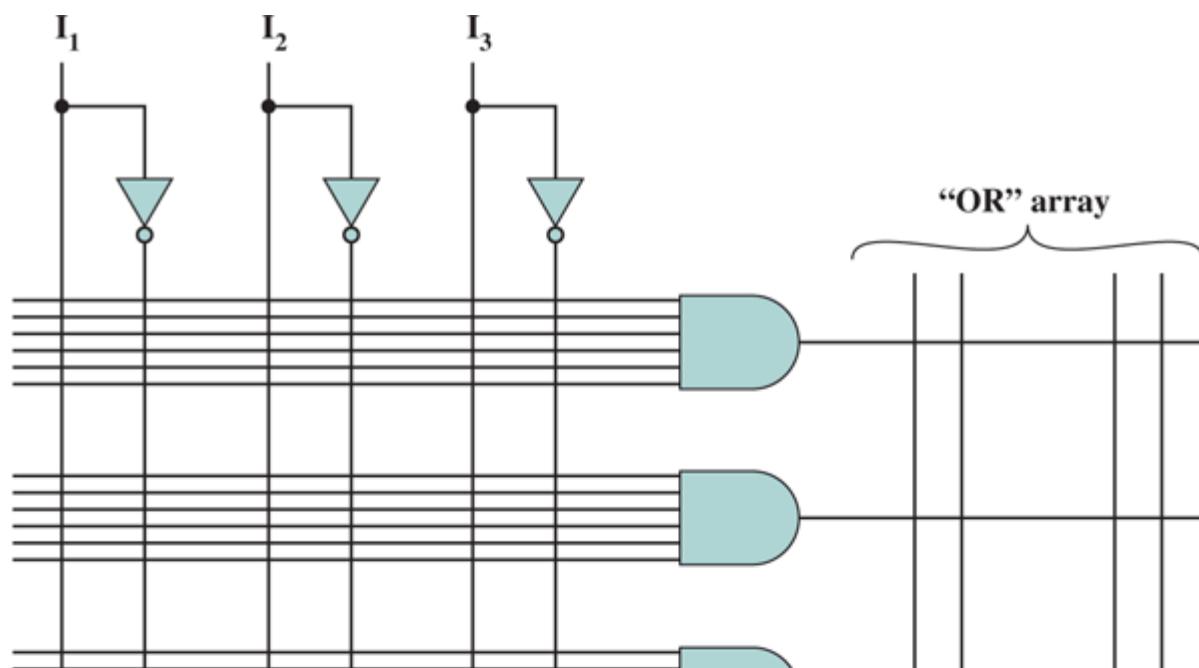

Logic Block

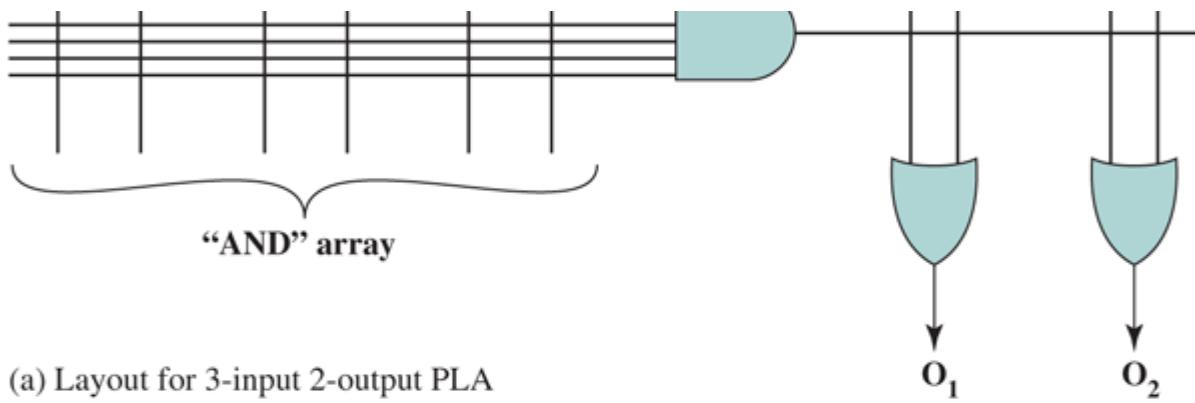

A relatively small circuit block that is replicated in an array in an FPD. When a circuit is implemented in an FPD, it is first decomposed into smaller subcircuits that can each be mapped into a logic block. The term *logic block* is mostly used in the context of FPGAs, but it could also refer to a block of circuitry in a CPLD.

Programmable Logic Array

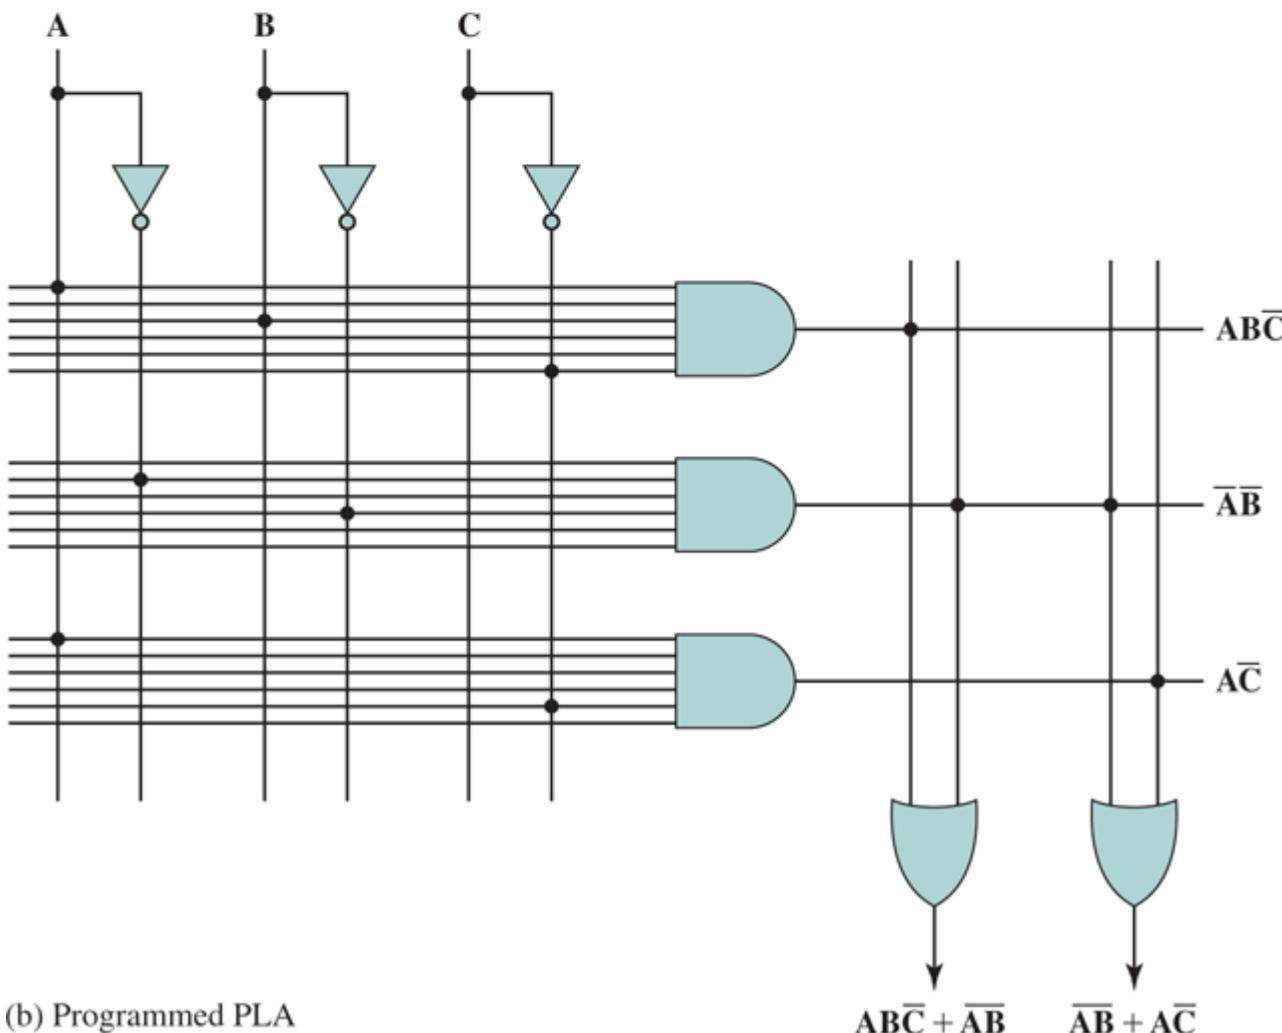

The PLA is based on the fact that any Boolean function (truth table) can be expressed in a sum-of-products (SOP) form, as we have seen. The PLA consists of a regular arrangement of NOT, AND, and OR gates on a chip. Each chip input is passed through a NOT gate so that each input and its complement are available to each AND gate. The output of each AND gate is available to each OR gate, and the output of each OR gate is a chip output. By making the appropriate connections, arbitrary SOP expressions can be implemented.

Figure 12.34a shows a PLA with three inputs, eight gates, and two outputs. On the left is a programmable AND array. The AND array is programmed by establishing a connection between any PLA input or its negation and any AND gate input by connecting the corresponding lines at their point of intersection. On the right is a programmable OR array, which involves connecting AND gate outputs to OR gate inputs. Most larger PLAs contain several hundred gates, 15 to 25 inputs, and 5 to 15 outputs. The connections from the inputs to the AND gates, and from the AND gates to the OR gates, are not specified until programming time.

(a) Layout for 3-input 2-output PLA

(b) Programmed PLA

Figure 12.34 An Example of a Programmable Logic Array (PLA)

PLAs are manufactured in two different ways to allow easy programming (making of connections). In the first, every possible connection is made through a fuse at every intersection point. The undesired connections can then be removed by blowing the fuses. This type of PLA is referred to as a *field-programmable logic array (FPLA)*. Alternatively, the proper connections can be made during chip fabrication by using an appropriate mask supplied for a particular interconnection pattern. In either case, the PLA provides a flexible, inexpensive way of implementing digital logic functions.

Figure 12.34b shows a programmed PLA that realizes two Boolean expressions.

Field-Programmable Gate Array

The PLA is an example of a simple PLD (SPLD). The difficulty with increasing capacity of a strict

SPLD architecture is that the structure of the programmable logic-planes grows too quickly in size as the number of inputs is increased. The only feasible way to provide large capacity devices based on SPLD architectures is to integrate multiple SPLDs onto a single chip, and provide interconnect to programmably connect the SPLD blocks together. Many commercial PLD products exist on the market today with this basic structure, and are collectively referred to as Complex PLDs (CPLDs). The most important type of CPLD is the FPGA.

An FPGA consists of an array of uncommitted circuit elements, called **logic blocks**, and interconnect resources. An illustration of a typical FPGA architecture is shown in [Figure 12.35](#). The key components of an FPGA are:

- **Logic block:** The configurable logic blocks are where the computation of the user's circuit takes place.
- **I/O block:** The I/O blocks connect I/O pins to the circuitry on the chip.
- **Interconnect:** These are signal paths available for establishing connections among I/O blocks and logic blocks.

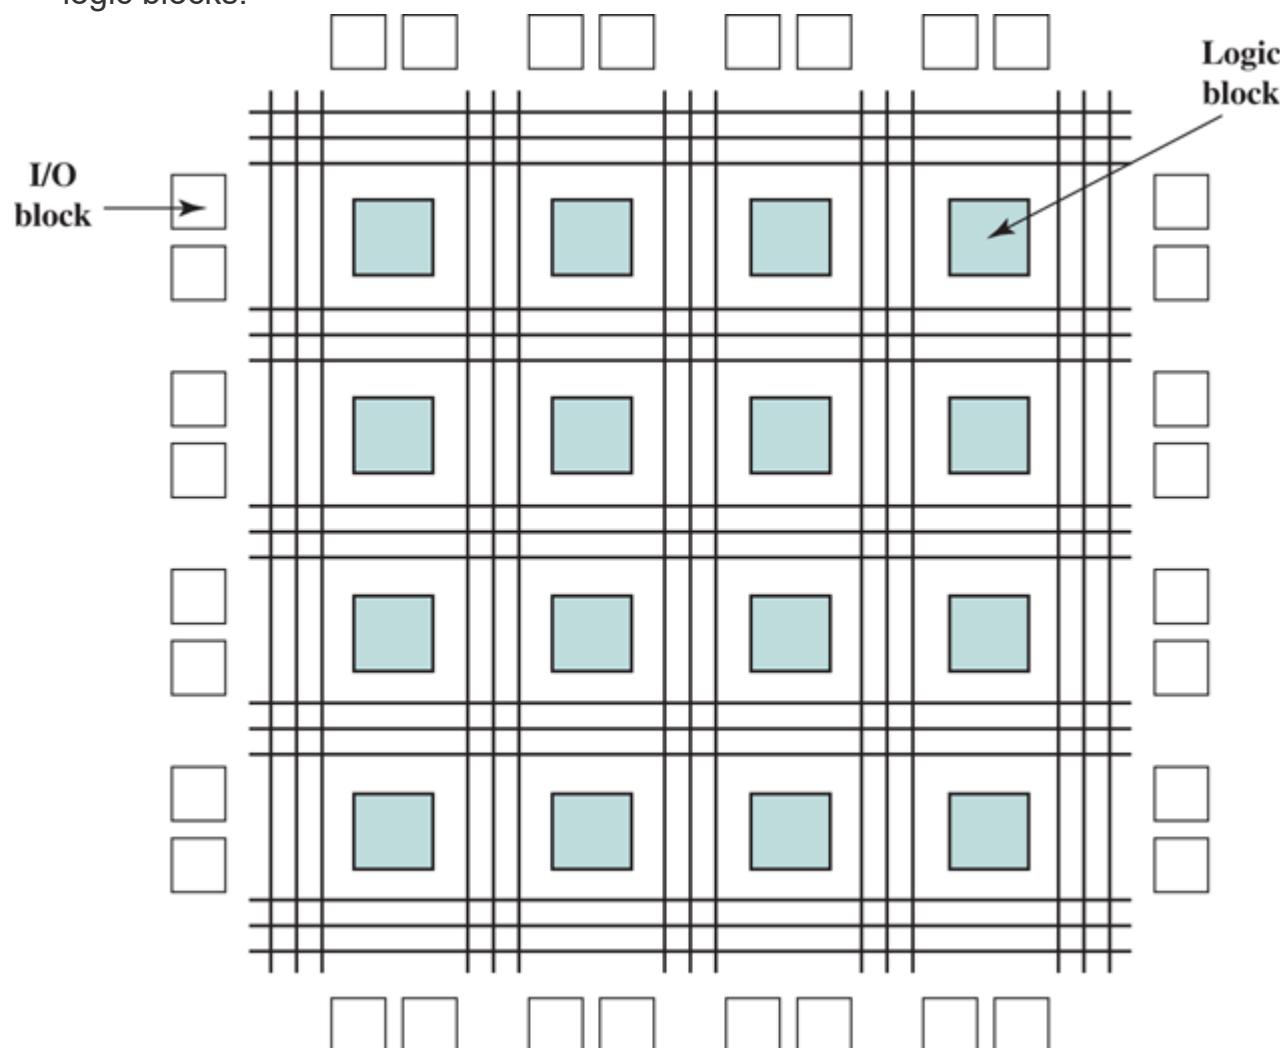

Figure 12.35 Structure of an FPGA

The logic block can be either a combinational circuit or a sequential circuit. In essence, the programming of a logic block is done by downloading the contents of a truth table for a logic function. [Figure 12.36](#) shows an example of a simple logic block consisting of a D flip-flop, a 2-to-1 multiplexer, and a 16-bit **lookup table**. The lookup table is a memory consisting of 16 1-bit elements, so that 4 input lines are required to select one of the 16 bits. Larger logic blocks have larger lookup tables and multiple interconnected lookup tables. The combinational logic realized by the lookup table can be output directly or stored in the D flip-flop and output synchronously. A separate one-bit memory

controls the multiplexer to determine whether the output comes directly from the lookup table or from the flip-flop.

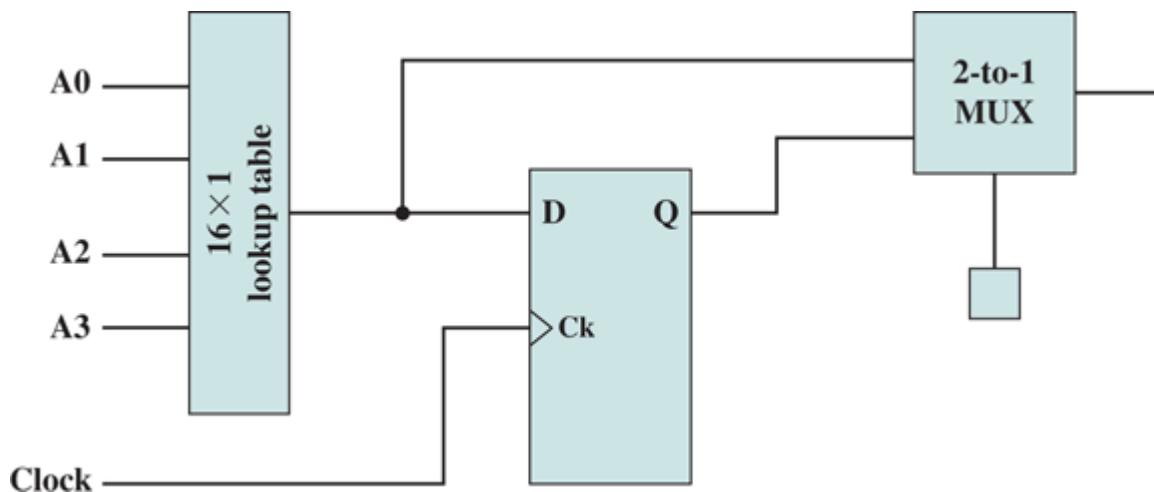

Figure 12.36 A Simple FPGA Logic Block

By interconnecting numerous logic blocks, very complex logic functions can be easily implemented.

Problems

12.1 Construct a truth table for the following Boolean expressions:

- a. $ABC + \bar{A}BC$
- b. $ABC + \bar{A}BC + ABC$
- c. $A(BC + \bar{B}\bar{C})$
- d. $(A + B)(\bar{A} + C)(\bar{A} + B)$

12.2 Simplify the following expressions according to the commutative law:

- a. $A \cdot B + B \cdot A + C \cdot D \cdot E + C \cdot D \cdot \bar{E} + \bar{E} \cdot C \cdot D$
- b. $A \cdot B + A \cdot C + B \cdot A$
- c. $(L \cdot M \cdot N)(A \cdot B)(C \cdot D \cdot E)(M \cdot N \cdot L)$
- d. $F \cdot (K + R) + S \cdot V + W \cdot X + V \cdot S + X \cdot W + (R + K) \cdot F$

12.3 Apply DeMorgan's theorem to the following equations:

- a. $F = V + \bar{A} + L$
- b. $F = \bar{A} + B + C + D$

12.4 Simplify the following expressions:

- a. $A = S \cdot T + V \cdot W + R \cdot S \cdot T$
- b. $A = T \cdot U \cdot V + X \cdot Y + Y$
- c. $A = F \cdot (E + F + G)$
- d. $A = (P \cdot Q + R + S \cdot T)T \cdot S$
- e. $A = D \cdot \bar{D} \cdot E$
- f. $A = Y \cdot (W + X + \bar{Y} + Z) \cdot Z$
- g. $A = (B \cdot E + C + F) \cdot C$

- 12.5 Construct the operation XOR from the basic Boolean operations AND, OR, and NOT.
 12.6 Given a NOR gate and NOT gates, draw a logic diagram that will perform the three-input AND function.

12.7 Write the Boolean expression for a four-input **NAND gate**.

- 12.8 A combinational circuit is used to control a seven-segment display of decimal digits, as shown in **Figure 12.37**. The circuit has four inputs, which provide the four-bit code used in packed decimal representation ($0_{10} = 0000$, ..., $9_{10} = 1001$). The seven outputs define which segments will be activated to display a given decimal digit. Note that some combinations of inputs and outputs are not needed.

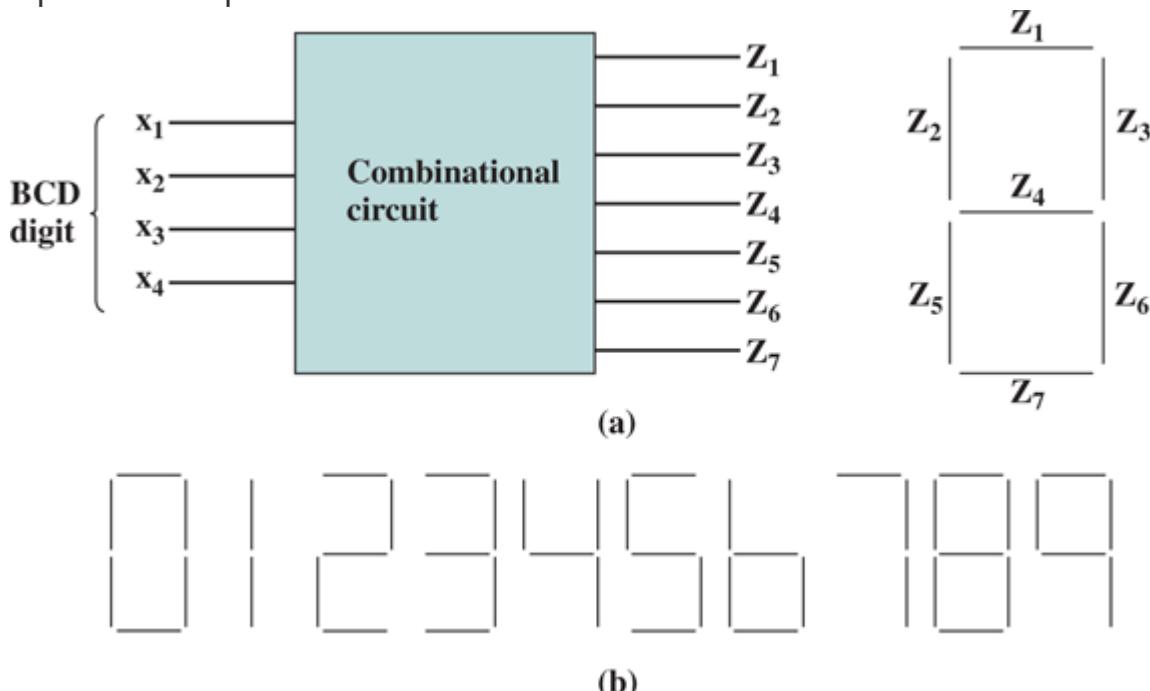

Figure 12.37 Seven-Segment LED Display Example

- Develop a truth table for this circuit.
- Express the truth table in SOP form.
- Express the truth table in POS form.
- Provide a simplified expression.

12.9 Design an 8-to-1 multiplexer.

12.10 Add an additional line to **Figure 12.17** so that it functions as a demultiplexer.

12.11 The Gray code is a binary code for integers. It differs from the ordinary binary representation in that there is just a single bit change between the representations of any two numbers. This is useful for applications such as counters or analog-to-digital converters where a sequence of numbers is generated. Because only one bit changes at a time, there is never any ambiguity due to slight timing differences. The first eight elements of the code are

Binary Code	Gray Code
000	000
001	001

010	011
011	010
100	110
101	111
110	101
111	100

Design a circuit that converts from binary to Gray code.

12.12 Design a 5×32 decoder using four 3×8 decoders (with enable inputs) and one 2×4 decoder.

12.13 Implement the full adder of [Figure 12.22](#) with just five gates. (*Hint:* Some of the gates are **XOR gates**.)

12.14 Consider [Figure 12.22](#). Assume that each gate produces a delay of 10 ns. Thus, the sum output is valid after 20 ns and the carry output after 20 ns. What is the total add time for a 32-bit adder

- a. Implemented without carry lookahead, as in [Figure 12.21](#) ?
- b. Implemented with carry lookahead and using 8-bit adders, as in [Figure 12.23](#) ?

12.15 An alternative form of the S–R latch has the same structure as [Figure 12.24](#) but uses NAND gates instead of NOR gates.

- a. Redo Table 12.11a and 12.11b for S–R latch implemented with NAND gates.
- b. Complete the following table, similar to Table 12.11c .

t	0	1	2	3	4	5	6	7	8	9
S	0	1	1	1	1	1	0	1	0	1
R	1	1	0	1	0	1	1	1	0	0

12.16 Consider the graphic symbol for the S–R flip-flop in [Figure 12.29](#) . Add additional lines to depict a D flip-flop wired from the S–R flip-flop.

12.17 Show the structure of a PLA with three inputs (C, B, A) and four outputs (O_0, O_1, O_2, O_3) with the outputs defined as follows:

$$\begin{aligned}O_0 &= \bar{A} BC + AB + ABC \\O_1 &= \bar{A} BC + ABC \\O_2 &= C \\O_3 &= AB + ABC\end{aligned}$$

12.18 An interesting application of a PLA is conversion from the old, obsolete punched card character codes to ASCII codes. The standard punched cards that were so popular with computers in the past had 12 rows and 80 columns where holes could be punched. Each

column corresponded to one character, so each character had a 12-bit code. However, only 96 characters were actually used. Consider an application that reads punched cards and converts the character codes to ASCII.

- a. Describe a PLA implementation of this application.
- b. Can this problem be solved with a ROM? Explain.

Learning Objectives

After studying this chapter, you should be able to:

- Present an overview of essential characteristics of machine instructions.

- Describe the types of operands used in typical machine instruction sets.
- Present an overview of x86 and ARM data types.
- Describe the types of operands supported by typical machine instruction sets.
- Present an overview of x86 and ARM operation types.
- Understand the differences among **big endian**, **little endian**, and **bi-endian**.

Much of what is discussed in this booktext is not readily apparent to the user or programmer of a computer. If a programmer is using a high-level language, such as Pascal or Ada, very little of the architecture of the underlying machine is visible.

One boundary where the computer designer and the computer programmer can view the same machine is the machine instruction set. From the designer's point of view, the machine instruction set provides the functional requirements for the processor: implementing the processor is a task that in large part involves implementing the machine instruction set. The user who chooses to program in machine language (actually, in assembly language; see [Chapter 15](#)) becomes aware of the register and memory structure, the types of data directly supported by the machine, and the functioning of the ALU.

A description of a computer's machine instruction set goes a long way toward explaining the computer's processor. Accordingly, we focus on machine instructions in this chapter and the next.

13.1 Machine Instruction Characteristics

The operation of the processor is determined by the instructions it executes, referred to as *machine instructions* or *computer instructions*. The collection of different instructions that the processor can execute is referred to as the processor's *instruction set*.

Elements of a Machine Instruction

Each instruction must contain the information required by the processor for execution. **Figure 13.1**, which repeats **Figure 3.6**, shows the steps involved in instruction execution and, by implication, defines the elements of a machine instruction. These elements are as follows:

- **Operation code:** Specifies the operation to be performed (e.g., ADD, I/O). The operation is specified by a binary code, known as the operation code, or **opcode**.
- **Source operand reference:** The operation may involve one or more source operands, that is, operands that are inputs for the operation.
- **Result operand reference:** The operation may produce a result.
- **Next instruction reference:** This tells the processor where to fetch the next instruction after the execution of this instruction is complete.

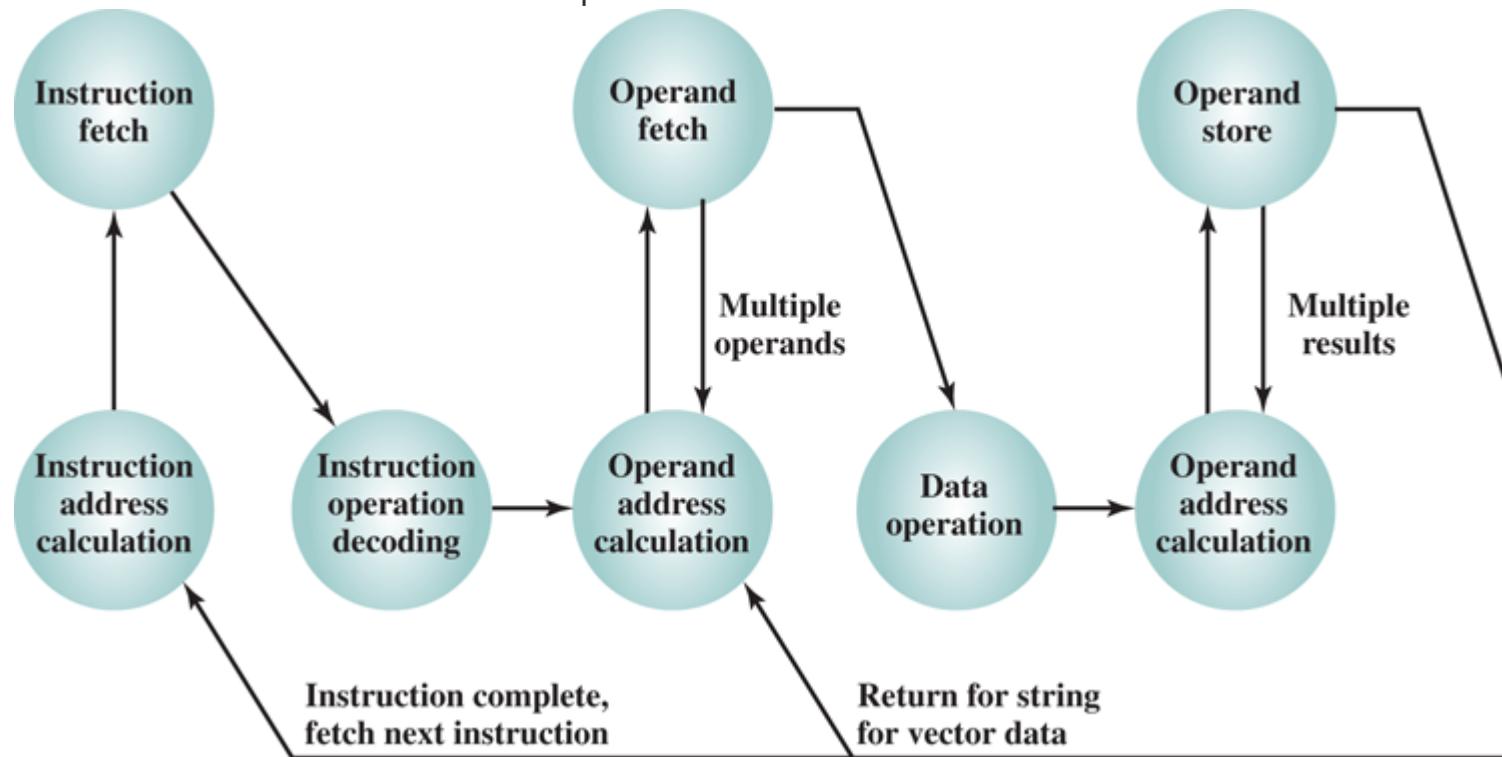

Figure 13.1 Instruction Cycle State Diagram

The address of the next instruction to be fetched could be either a real address or a virtual address, depending on the architecture. Generally, the distinction is transparent to the instruction set architecture. In most cases, the next instruction to be fetched immediately follows the current instruction. In those cases, there is no explicit reference to the next instruction. When an explicit reference is needed, the main memory or virtual memory address must be supplied. The form in which that address is supplied is discussed in **Chapter 14**.

Source and result operands can be in one of four areas:

- **Main or virtual memory:** As with next instruction references, the main or virtual memory address

must be supplied.

- **Processor register:** With rare exceptions, a processor contains one or more registers that may be referenced by machine instructions. If only one register exists, reference to it may be implicit. If more than one register exists, then each register is assigned a unique name or number, and the instruction must contain the number of the desired register.
- **Immediate:** The value of the operand is contained in a field in the instruction being executed.
- **I/O device:** The instruction must specify the I/O module and device for the operation. If memory-mapped I/O is used, this is just another main or virtual memory address.

Instruction Representation

Within the computer, each instruction is represented by a sequence of bits. The instruction is divided into fields, corresponding to the constituent elements of the instruction. A simple example of an instruction format is shown in [Figure 13.2](#). As another example, the IAS instruction format is shown in [Figure 1.7](#). With most instruction sets, more than one format is used. During instruction execution, an instruction is read into an instruction register (IR) in the processor. The processor must be able to extract the data from the various instruction fields to perform the required operation.

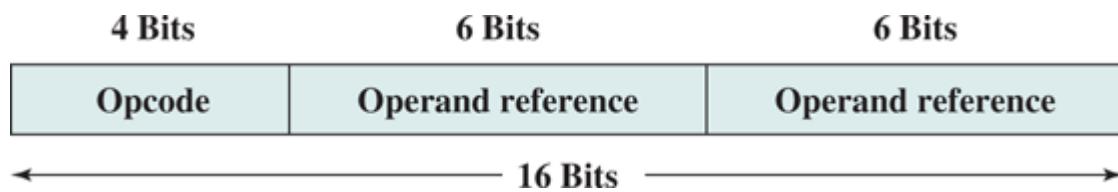

Figure 13.2 A Simple Instruction Format

It is difficult for both the programmer and the reader of textbooks to deal with binary representations of machine instructions. Thus, it has become common practice to use a *symbolic representation* of machine instructions. An example of this was used for the IAS instruction set, in [Table 1.1](#).

Opcodes are represented by abbreviations, called *mnenomics*, that indicate the operation. Common examples include

ADD	Add
SUB	Subtract
MUL	Multiply
DIV	Divide
LOAD	Load data from memory
STOR	Store data to memory

Operands are also represented symbolically. For example, the instruction

ADD R, Y

may mean add the value contained in data location Y to the contents of register R. In this example, Y

refers to the address of a location in memory, and R refers to a particular register. Note that the operation is performed on the contents of a location, not on its address.

Thus, it is possible to write a machine-language program in symbolic form. Each symbolic opcode has a fixed binary representation, and the programmer specifies the location of each symbolic operand. For example, the programmer might begin with a list of definitions:

$$\begin{aligned} X &= 513 \\ Y &= 514 \end{aligned}$$

and so on. A simple program would accept this symbolic input, convert opcodes and operand references to binary form, and construct binary machine instructions.

Machine-language programmers are rare to the point of nonexistence. Most programs today are written in a high-level language or, failing that, assembly language, which is discussed in Chapter 15. However, symbolic machine language remains a useful tool for describing machine instructions, and we will use it for that purpose.

Instruction Types

Consider a high-level language instruction that could be expressed in a language such as BASIC or FORTRAN. For example,

$$X = X + Y$$

This statement instructs the computer to add the value stored in Y to the value stored in X and put the result in X. How might this be accomplished with machine instructions? Let us assume that the variables X and Y correspond to locations 513 and 514. If we assume a simple set of machine instructions, this operation could be accomplished with three instructions:

1. Load a register with the contents of memory location 513.
2. Add the contents of memory location 514 to the register.
3. Store the contents of the register in memory location 513.

As can be seen, the single BASIC instruction may require three machine instructions. This is typical of the relationship between a high-level language and a machine language. A high-level language expresses operations in a concise algebraic form, using variables. A machine language expresses operations in a basic form involving the movement of data to or from registers.

With this simple example to guide us, let us consider the types of instructions that must be included in a practical computer. A computer should have a set of instructions that allows the user to formulate any data processing task. Another way to view it is to consider the capabilities of a high-level programming language. Any program written in a high-level language must be translated into machine language to be executed. Thus, the set of machine instructions must be sufficient to express any of the instructions from a high-level language. With this in mind we can categorize instruction types as follows:

- **Data processing:** Arithmetic and logic instructions.
- **Data storage:** Movement of data into or out of register and or memory locations.
- **Data movement:** I/O instructions.
- **Control:** Test and branch instructions.

Arithmetic instructions provide computational capabilities for processing numeric data. Logic (Boolean) instructions operate on the bits of a word as bits rather than as numbers; thus, they provide

capabilities for processing any other type of data the user may wish to employ. These operations are performed primarily on data in processor registers. Therefore, there must be *memory* instructions for moving data between memory and the registers. *I/O* instructions are needed to transfer programs and data into memory and the results of computations back out to the user. *Test* instructions are used to test the value of a data word or the status of a computation. *Branch* instructions are then used to branch to a different set of instructions depending on the decision made.

We will examine the various types of instructions in greater detail later in this chapter.

Number of Addresses

One of the traditional ways of describing processor architecture is in terms of the number of addresses contained in each instruction. This dimension has become less significant with the increasing complexity of processor design. Nevertheless, it is useful at this point to draw and analyze this distinction.

What is the maximum number of addresses one might need in an instruction? Evidently, arithmetic and logic instructions will require the most operands. Virtually all arithmetic and logic operations are either unary (one source operand) or binary (two source operands). Thus, we would need a maximum of two addresses to reference source operands. The result of an operation must be stored, suggesting a third address, which defines a destination operand. Finally, after completion of an instruction, the next instruction must be fetched, and its address is needed.

This line of reasoning suggests that an instruction could plausibly be required to contain four address references: two source operands, one destination operand, and the address of the next instruction. In most architectures, many instructions have one, two, or three operand addresses, with the address of the next instruction being implicit (obtained from the program counter). Most architectures also have a few special-purpose instructions with more operands. For example, the load and store multiple instructions of the ARM architecture, described in [Chapter 14](#), designate up to 17 register operands in a single instruction.

Figure 13.3 compares typical one-, two-, and three-address instructions that could be used to compute $Y = (A - B) / [C + (D \times E)]$. With three addresses, each instruction specifies two source operand locations and a destination operand location. Because we choose not to alter the value of any of the operand locations, a temporary location, T, is used to store some intermediate results. Note that there are four instructions and that the original expression had five operands.

<u>Instruction</u>	<u>Comment</u>
SUB Y, A, B	$Y \leftarrow A - B$
MPY T, D, E	$T \leftarrow D \times E$
ADD T, T, C	$T \leftarrow T + C$
DIV Y, Y, T	$Y \leftarrow Y \div T$

(a) Three-address instructions

<u>Instruction</u>	<u>Comment</u>
MOVE Y, A	$Y \leftarrow A$
SUB Y, B	$Y \leftarrow Y - B$
MOVE T, D	$T \leftarrow D$
MPY T, E	$T \leftarrow T \times E$
ADD T, C	$T \leftarrow T + C$
DIV Y, T	$Y \leftarrow Y \div T$

(b) Two-address instructions

<u>Instruction</u>	<u>Comment</u>
LOAD D	$AC \leftarrow D$
MPY E	$AC \leftarrow AC \times E$
ADD C	$AC \leftarrow AC + C$
STOR Y	$Y \leftarrow AC$
LOAD A	$AC \leftarrow A$
SUB B	$AC \leftarrow AC - B$
DIV Y	$AC \leftarrow AC \div Y$
STOR Y	$Y \leftarrow AC$

(c) One-address instructions

A – B

Figure 13.3 Programs to Execute $Y = C + (D \times E)$

Three-address instruction formats are not common because they require a relatively long instruction format to hold the three address references. With two-address instructions, and for binary operations, one address must do double duty as both an operand and a result. Thus, the instruction SUB Y, B carries out the calculation $Y - B$ and stores the result in Y. The two-address format reduces the space requirement but also introduces some awkwardness. To avoid altering the value of an operand, a MOVE instruction is used to move one of the values to a result or temporary location before performing the operation. Our sample program expands to six instructions.

Simpler yet is the one-address instruction. For this to work, a second address must be implicit. This was common in earlier machines, with the implied address being a processor register known as the **accumulator** (AC). The accumulator contains one of the operands and is used to store the result. In our example, eight instructions are needed to accomplish the task.

It is, in fact, possible to make do with zero addresses for some instructions. Zero-address instructions are applicable to a special memory organization called a **stack**. A stack is a last-in-first-out set of locations. The stack is in a known location and, often, at least the top two elements are in processor registers. Thus, zero-address instructions would reference the top two stack elements. Stacks are described in [Appendix E](#). Their use is explored further later in this chapter and in [Chapter 14](#).

Table 13.1 summarizes the interpretations to be placed on instructions with zero, one, two, or three addresses. In each case in the table, it is assumed that the address of the next instruction is implicit, and that one operation with two source operands and one result operand is to be performed.

Table 13.1 Utilization of Instruction Addresses (Nonbranching Instructions)

AC = accumulator

T = top of stack

(T – 1) = second element of stack

A , B , C = memory or register locations

Number of Addresses	Symbolic Representation	Interpretation
3	OP A, B, C	$A \leftarrow B \text{ OP } C$
2	OP A, B	$A \leftarrow A \text{ OP } B$
1	OP A	$AC \leftarrow AC \text{ OP } A$
0	OP	$T \leftarrow (T - 1) \text{ OP } T$

The number of addresses per instruction is a basic design decision. Fewer addresses per instruction result in instructions that are more primitive, requiring a less complex processor. It also results in instructions of shorter length. On the other hand, programs contain more total instructions, which in general results in longer execution times and longer, more complex programs. Also, there is an important threshold between one-address and multiple-address instructions. With one-address instructions, the programmer generally has available only one general-purpose register, the accumulator. With multiple-address instructions, it is common to have multiple general-purpose registers. This allows some operations to be performed solely on registers. Because register references are faster than memory references, this speeds up execution. For reasons of flexibility and ability to use multiple registers, most contemporary machines employ a mixture of two- and three-address instructions.

The design trade-offs involved in choosing the number of addresses per instruction are complicated by other factors. There is the issue of whether an address references a memory location or a register. Because there are fewer registers, fewer bits are needed for a register reference. Also, as we will see in [Chapter 14](#), a machine may offer a variety of addressing modes, and the specification of mode takes one or more bits. The result is that most processor designs involve a variety of instruction formats.

Instruction Set Design

One of the most interesting, and most analyzed, aspects of computer design is instruction set design. The design of an instruction set is very complex because it affects so many aspects of the computer system. The instruction set defines many of the functions performed by the processor and thus has a significant effect on the implementation of the processor. The instruction set is the programmer's means of controlling the processor. Thus, programmer requirements must be considered in designing the instruction set.

It may surprise you to know that some of the most fundamental issues relating to the design of instruction sets remain in dispute. Indeed, in recent years, the level of disagreement concerning these fundamentals has actually grown. The most important of these fundamental design issues include the following:

- **Operation repertoire:** How many and which operations to provide, and how complex operations should be.
- **Data types:** The various types of data upon which operations are performed.
- **Instruction format:** Instruction length (in bits), number of addresses, size of various fields, and so

on.

- **Registers:** Number of processor registers that can be referenced by instructions, and their use.
- **Addressing:** The mode or modes by which the address of an operand is specified.

These issues are highly interrelated and must be considered together in designing an instruction set. This booktext, of course, must consider them in some sequence, but an attempt is made to show the interrelationships.

Because of the importance of this topic, much of Part Three is devoted to instruction set design.

Following this overview section, this This chapter examines data types and operation repertoire.

Chapter 14 examines addressing modes (which includes a consideration of registers) and instruction formats. **Chapter 17** examines the reduced instruction set computer (RISC). RISC architecture calls into question many of the instruction set design decisions traditionally made in commercial computers.

13.2 Types of Operands

Machine instructions operate on data. The most important general categories of data are

- Addresses
- Numbers
- Characters
- Logical data

We shall see, in discussing addressing modes in [Chapter 14](#), that addresses are, in fact, a form of data. In many cases, some calculation must be performed on the operand reference in an instruction to determine the main or virtual memory address. In this context, addresses can be considered to be unsigned integers.

Other common data types are numbers, characters, and logical data, and each of these is briefly examined in this section. Beyond that, some machines define specialized data types or data structures. For example, there may be machine operations that operate directly on a list or a string of characters.

Numbers

All machine languages include numeric data types. Even in nonnumeric data processing, there is a need for numbers to act as counters, field widths, and so forth. An important distinction between numbers used in ordinary mathematics and numbers stored in a computer is that the latter are limited. This is true in two senses. First, there is a limit to the magnitude of numbers representable on a machine and second, in the case of floating-point numbers, a limit to their precision. Thus, the programmer is faced with understanding the consequences of rounding, overflow, and underflow.

Three types of numerical data are common in computers:

- Binary integer or binary fixed point
- Binary floating point
- Decimal

We examined the first two in some detail in [Chapter 10](#). It remains to say a few words about decimal numbers.

Although all internal computer operations are binary in nature, the human users of the system deal with decimal numbers. Thus, there is a necessity to convert from decimal to binary on input and from binary to decimal on output. For applications in which there is a great deal of I/O and comparatively little, comparatively simple computation, it is preferable to store and operate on the numbers in decimal form. The most common representation for this purpose is [packed decimal](#).¹

¹ Textbooks often refer to this as binary coded decimal (BCD). Strictly speaking, BCD refers to the encoding of each decimal digit by a unique 4-bit sequence. Packed decimal refers to the storage of BCD-encoded digits using one byte for each two digits.

With packed decimal, each decimal digit is represented by a 4-bit code, in the obvious way, with two digits stored per byte. Thus, 0 = 000, 1 = 0001, ..., 8 = 1000, and 9 = 1001. Note that this is a rather inefficient code because only 10 of 16 possible 4-bit values are used. To form numbers, 4-bit codes are strung together, usually in multiples of 8 bits. Thus, the code for 246 is 0000 0010 0100 0110. This

code is clearly less compact than a straight binary representation, but it avoids the conversion overhead. Negative numbers can be represented by including a 4-bit sign digit at either the left or right end of a string of packed decimal digits. Standard sign values are 1100 for positive (+) and 1101 for negative (-).

Many machines provide arithmetic instructions for performing operations directly on packed decimal numbers. The algorithms are quite similar to those described in [Section 10.3](#) but must take into account the decimal carry operation.

Characters

A common form of data is text or character strings. While textual data are most convenient for human beings, they cannot, in character form, be easily stored or transmitted by data processing and communications systems. Such systems are designed for binary data. Thus, a number of codes have been devised by which characters are represented by a sequence of bits. Perhaps the earliest common example of this is the Morse code. Today, the most commonly used character code is the International Reference Alphabet (IRA), referred to in the United States as the American Standard Code for Information Interchange (ASCII; see [Appendix D](#)). Each character in this code is represented by a unique 7-bit pattern; thus, 128 different characters can be represented. This is a larger number than is necessary to represent printable characters, and some of the patterns represent *control* characters. Some of these control characters have to do with controlling the printing of characters on a page. Others are concerned with communications procedures. IRA-encoded characters are almost always stored and transmitted using 8 bits per character. The eighth bit may be set to 0 or used as a parity bit for error detection. In the latter case, the bit is set such that the total number of binary 1s in each octet is always odd (odd parity) or always even (even parity).

Note in [Table D.1 \(Appendix D\)](#) that for the IRA bit pattern 011XXXX, the digits 0 through 9 are represented by their binary equivalents, 0000 through 1001, in the rightmost 4 bits. This is the same code as packed decimal. This facilitates conversion between 7-bit IRA and 4-bit packed decimal representation.

Another code used to encode characters is the Extended Binary Coded Decimal Interchange Code (EBCDIC). EBCDIC is used on IBM mainframes. It is an 8-bit code. As with IRA, EBCDIC is compatible with packed decimal. In the case of EBCDIC, the codes 11110000 through 11111001 represent the digits 0 through 9.

Logical Data

Normally, each word or other addressable unit (byte, halfword, and so on) is treated as a single unit of data. It is sometimes useful, however, to consider an n -bit unit as consisting of n 1-bit items of data, each item having the value 0 or 1. When data are viewed this way, they are considered to be *logical* data.

There are two advantages to the bit-oriented view. First, we may sometimes wish to store an array of Boolean or binary data items, in which each item can take on only the values 1 (true) and 0 (false). With logical data, memory can be used most efficiently for this storage. Second, there are occasions when we wish to manipulate the bits of a data item. For example, if floating-point operations are implemented in software, we need to be able to shift significant bits in some operations. Another example: To convert from IRA to packed decimal, we need to extract the rightmost 4 bits of each byte.

Note that, in the preceding examples, the same data are treated sometimes as logical and other times

as numerical or text. The “type” of a unit of data is determined by the operation being performed on it. While this is not normally the case in high-level languages, it is almost always the case with machine language.

13.3 Intel x86 and ARM Data Types

x86 Data Types

The x86 can deal with data types of 8 (byte), 16 (word), 32 (doubleword), 64 (quadword), and 128 (double quadword) bits in length. To allow maximum flexibility in data structures and efficient memory utilization, words need not be aligned at even-numbered addresses; doublewords need not be aligned at addresses evenly divisible by 4; quadwords need not be aligned at addresses evenly divisible by 8; and so on. However, when data are accessed across a 32-bit bus, data transfers take place in units of doublewords, beginning at addresses divisible by 4. The processor converts the request for misaligned values into a sequence of requests for the bus transfer. As with all of the Intel 80x86 machines, the x86 uses the little-endian style; that is, the least significant byte is stored in the lowest address (see [Appendix 13A](#) for a discussion of endianness).

The byte, word, doubleword, quadword, and double quadword are referred to as general data types. In addition, the x86 supports an impressive array of specific data types that are recognized and operated on by particular instructions. [Table 13.2](#) summarizes these types.

Table 13.2 x86 Data Types

Data Type	Description
General	Byte, word (16 bits), doubleword (32 bits), quadword (64 bits), and double quadword (128 bits) locations with arbitrary binary contents.
Integer	A signed binary value contained in a byte, word, or doubleword, using twos complement representation.
Ordinal	An unsigned integer contained in a byte, word, or doubleword.
Unpacked binary coded decimal (BCD)	A representation of a BCD digit in the range 0 through 9, with one digit in each byte.
Packed BCD	Packed byte representation of two BCD digits; value in the range 0 to 99.
Near pointer	A 16-bit, 32-bit, or 64-bit effective address that represents the offset within a segment. Used for all pointers in a nonsegmented memory and for references within a segment in a segmented memory.
Far pointer	A logical address consisting of a 16-bit segment selector and an offset of 16, 32, or 64 bits. Far pointers are used for memory references in a segmented memory model where the identity of a segment being accessed must be specified explicitly.
Bit field	A contiguous sequence of bits in which the position of each bit is considered as an

	independent unit. A bit string can begin at any bit position of any byte and can contain up to 32 bits.
Bit string	A contiguous sequence of bits, containing from zero to $2^{23} - 1$ bits.
Byte string	A contiguous sequence of bytes, words, or doublewords, containing from zero to $2^{23} - 1$ bytes.
Floating point	See Figure 13.4 .
Packed SIMD (single instruction, multiple data)	Packed 64-bit and 128-bit data types.

Figure 13.4 illustrates the x86 numerical data types. The signed integers are in twos complement representation and may be 16, 32, or 64 bits long. The floating-point type actually refers to a set of types that are used by the floating-point unit and operated on by floating-point instructions. The floating-point representations conform to the IEEE 754 standard.

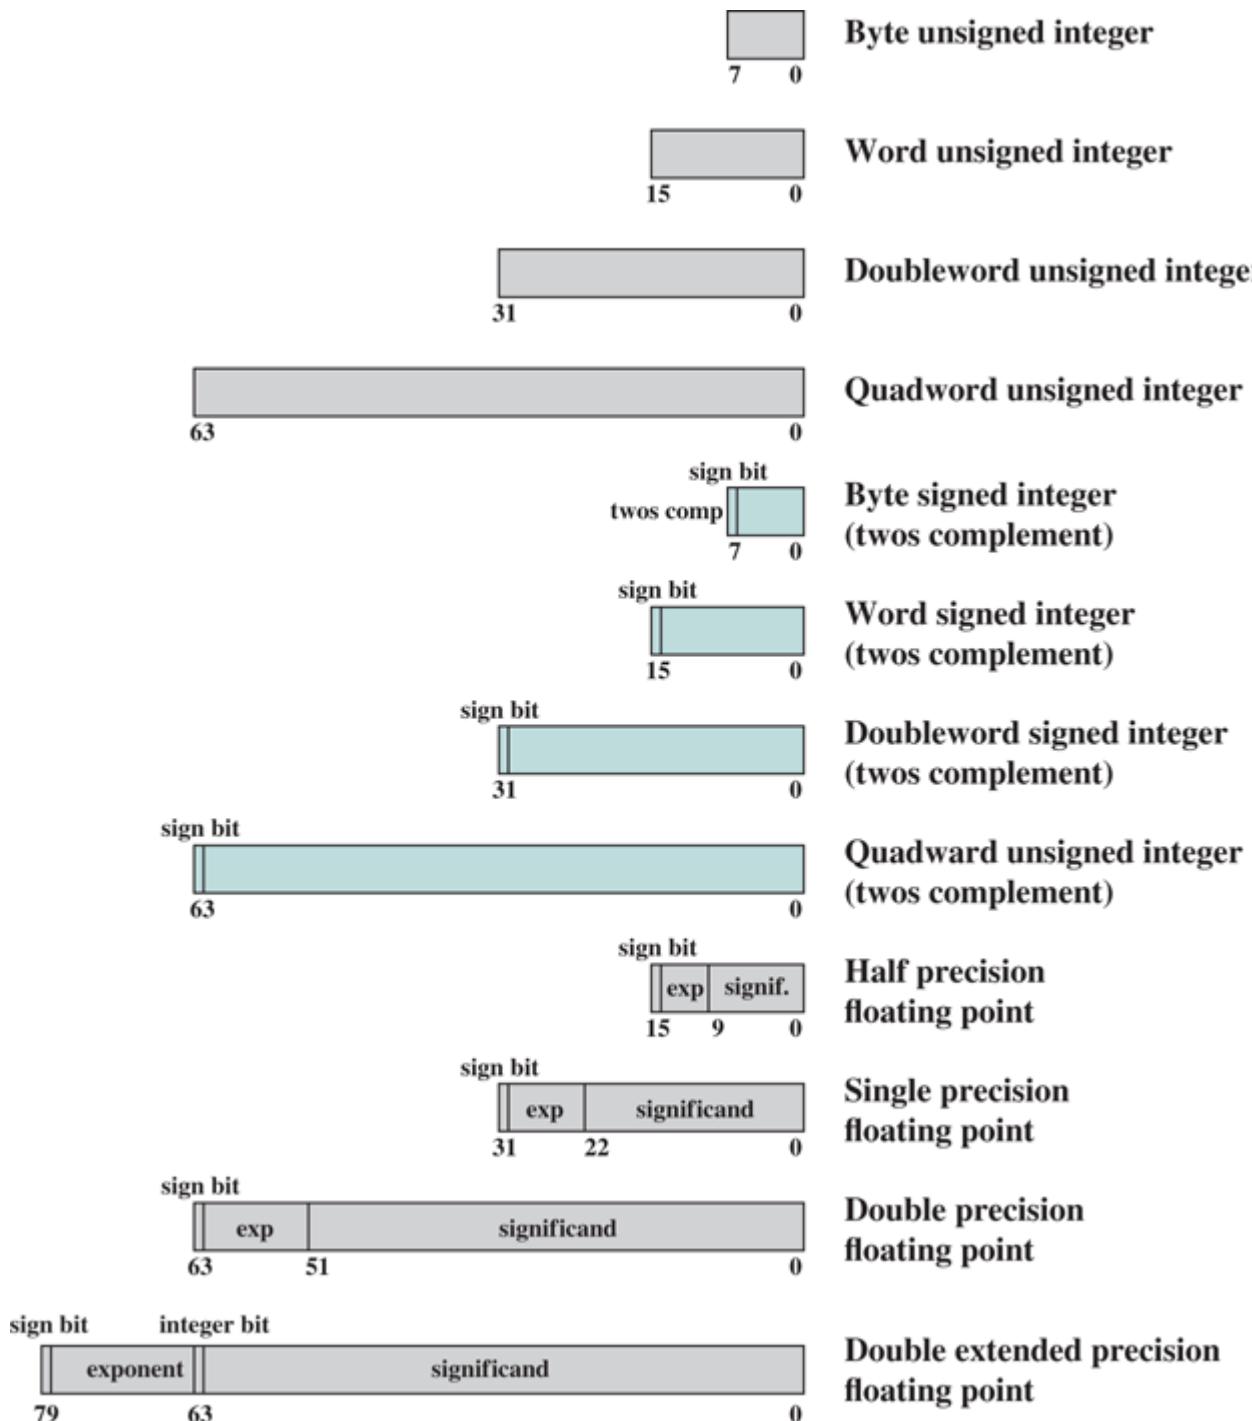

Figure 13.4 x86 Numeric Data Formats

The packed SIMD (single-instruction-multiple-data) data types were introduced to the x86 architecture as part of the extensions of the instruction set to optimize performance of multimedia applications. These extensions include MMX (multimedia extensions) and SSE (streaming SIMD extensions). The basic concept is that multiple operands are packed into a single referenced memory item and that these multiple operands are operated on in parallel. The data types are as follows:

- **Packed byte and packed byte integer:** Bytes packed into a 64-bit quadword or 128-bit double quadword, interpreted as a bit field or as an integer.
- **Packed word and packed word integer:** 16-bit words packed into a 64-bit quadword or 128-bit double quadword, interpreted as a bit field or as an integer.
- **Packed doubleword and packed doubleword integer:** 32-bit doublewords packed into a 64-bit quadword or 128-bit double quadword, interpreted as a bit field or as an integer.
- **Packed quadword and packed quadword integer:** Two 64-bit quadwords packed into a 128-bit

- double quadword, interpreted as a bit field or as an integer.
- **Packed single-precision floating-point and packed double-precision floatingpoint:** Four 32-bit floating-point or two 64-bit floating-point values packed into a 128-bit double quadword.

ARM Data Types

ARM processors support data types of 8 (byte), 16 (halfword), and 32 (word) bits in length. Normally, halfword access should be halfword aligned and word accesses should be word aligned. For nonaligned access attempts, the architecture supports three alternatives.

- Default case:
 - The address is treated as truncated, with address bits[1:0] treated as zero for word accesses, and address bit[0] treated as zero for halfword accesses.
 - Load single word ARM instructions are architecturally defined to rotate right the word-aligned data transferred by a non word-aligned address one, two, or three bytes depending on the value of the two least significant address bits.
- **Alignment checking:** When the appropriate control bit is set, a data abort signal indicates an alignment fault for attempting unaligned access.
- **Unaligned access:** When this option is enabled, the processor uses one or more memory accesses to generate the required transfer of adjacent bytes transparently to the programmer.

For all three data types (byte, halfword, and word) an unsigned interpretation is supported, in which the value represents an unsigned, nonnegative integer. All three data types can also be used for twos complement signed integers.

The majority of ARM processor implementations do not provide floating-point hardware, which saves power and area. If floating-point arithmetic is required in such processors, it must be implemented in software. ARM does support an optional floating-point coprocessor that supports the single- and double-precision floating point data types defined in IEEE 754.

ENDIAN SUPPORT

A state bit (E-bit) in the system control register is set and cleared under program control using the SETEND instruction. The E-bit determines which endian mode is used to load and store data. [Figure 13.5](#) illustrates the functionality associated with the E-bit for a word load or store operation. This mechanism enables efficient dynamic data load/store for system designers who know they need to access data structures in the opposite endianness to their OS/environment. Note that the address of each data byte is fixed in memory. However, the byte lane in a register is different.

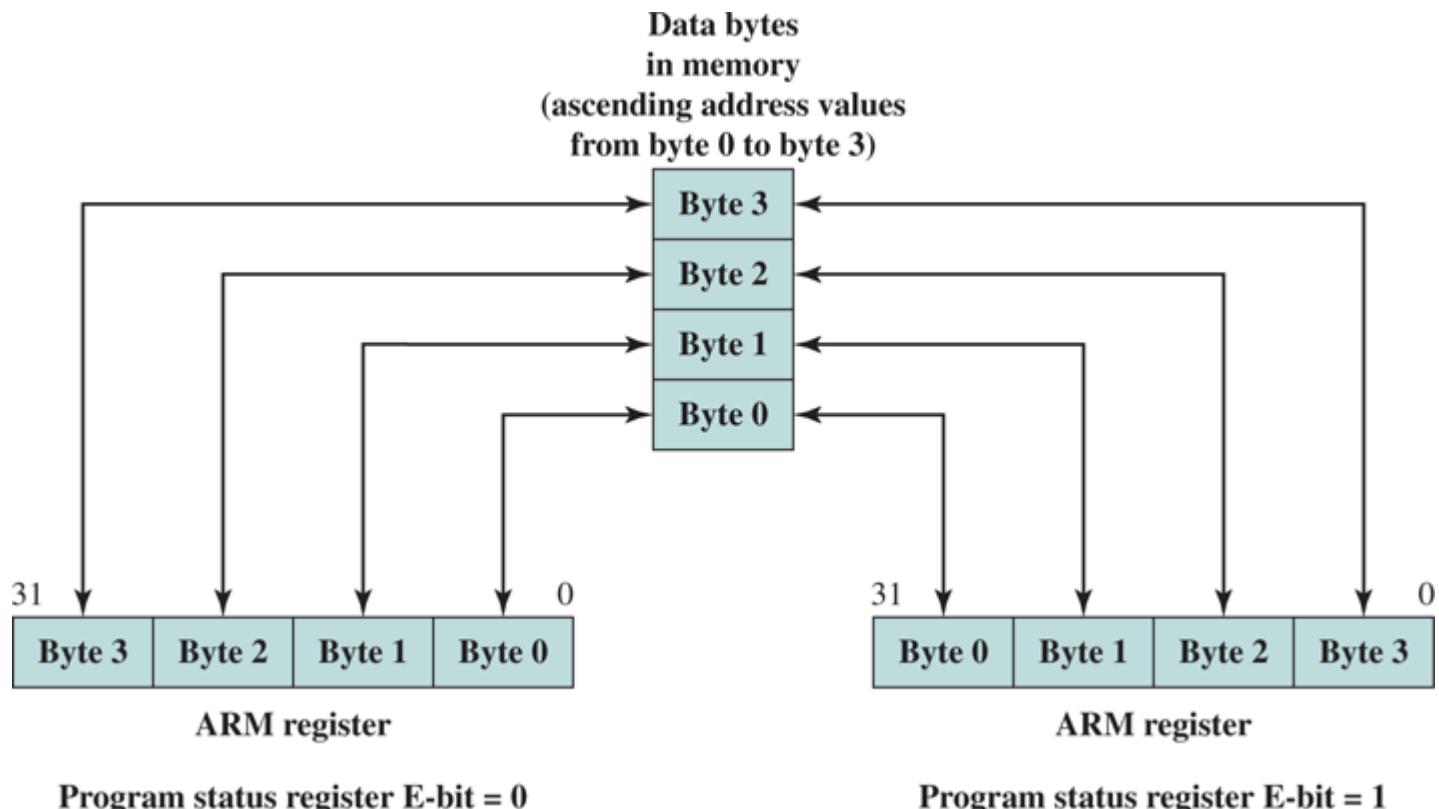

Figure 13.5 ARM Endian Support—Word Load/Store with E-Bit

13.4 Types of Operations

The number of different opcodes varies widely from machine to machine. However, the same general types of operations are found on all machines. A useful and typical categorization is the following:

- Data transfer
- Arithmetic
- Logical
- Conversion
- I/O
- System control
- Transfer of control

Table 13.3 lists common instruction types in each category. This section provides a brief survey of these various types of operations, together with a brief discussion of the actions taken by the processor to execute a particular type of operation (summarized in **Table 13.4**). The latter topic is examined in more detail in [Chapter 16](#).

Table 13.3 Common x86 Instruction Set Operations

(a) Data Transfer	
Operation Name	Description
MOV Dest, Source	Move data between registers or between register and memory or immediate to register.
XCHG Op1, Op2	Swap contents between two registers or register and memory.
PUSH Source	Decrements stack pointer (ESP register), then copies the source operand to the top of stack.
POP Dest	Copies top of stack to destination and increments ESP.
(b) Arithmetic	
ADD Dest, Source	Adds the destination and the source operand and stores the result in the destination. Destination can be register or memory. Source can be register, memory, or immediate.
SUB Dest, Source	Subtracts the source from the destination and stores the result in the destination.

MUL Op	Unsigned integer multiplication of the operand by the AL, AX, or EAX register and stores in the register. Opcode indicates size of register.
IMUL Op	Signed integer multiplication.
DIV Op	Divides unsigned the value in the AX, DX:AX, EDX:EAX, or RDX:RAX registers (dividend) by the source operand (divisor) and stores the result in the AX (AH:AL), DX:AX, EDX:EAX, or RDX:RAX registers.
IDIV Op	Signed integer division.
INC Op	Adds 1 to the destination operand, while preserving the state of the CF flag.
DEC Op	Subtracts 1 from the destination operand, while preserving the state of the CF flag.
NEG Op	Replaces the value of operand with $(0 - \text{operand})$, using twos complement representation.
CMP Op1, Op2	Compares the two operands by subtracting the second operand from the first operand and sets the status flags in the EFLAGS register according to the results.

(c) Shift and Rotate

SAL Op, Quantity	Shifts the source operand left by from 1 to 31 bit positions. Empty bit positions are cleared. The CF flag is loaded with the last bit shifted out of the operand.
SAR Op, Quantity	Shifts the source operand right by from 1 to 31 bit positions. Empty bit positions are cleared if the operand is positive and set if the operand is negative. The CF flag is loaded with the last bit shifted out of the operand.
SHR Op, Quantity	Shifts the source operand right by from 1 to 31 bit positions. Empty bit positions are cleared and the CF flag is loaded with the last bit shifted out of the operand.
ROL Op, Quantity	Rotate bits to the left, with wraparound. The CF flag is loaded with the last bit shifted out of the operand.
ROR Op, Quantity	Rotate bits to the right, with wraparound. The CF flag is loaded with the last bit shifted out of the operand.
RCL Op, Quantity	Rotate bits to the left, including the CF flag, with wraparound. This instruction treats the CF flag as a one-bit extension on the upper end of the operand.
RCR Op, Quantity	Rotate bits to the right, including the CF flag, with wraparound. This instruction treats the CF flag as a one-bit extension on the lower end of the operand.

(d) Logical

NOT Op	Inverts each bit of the operand.
AND Dest, Source	Performs a bitwise AND operation on the destination and source operands and stores the result in the destination operand.
OR Dest, Source	Performs a bitwise OR operation on the destination and source operands and stores the result in the destination operand.
XOR Dest, Source	Performs a bitwise XOR operation on the destination and source operands and stores the result in the destination operand.
TEST Op1, Op2	Performs a bitwise AND operation on the two operands and sets the S, Z, and P status flags. The operands are unchanged.

(e) Transfer of Control

CALL proc	Saves procedure linking information on the stack and branches to the called procedure specified using the operand. The operand specifies the address of the first instruction in the called procedure.
RET	Transfers program control to a return address located on the top of the stack. The return is made to the instruction that follows the CALL instruction.
JMP Dest	Transfers program control to a different point in the instruction stream without recording return information. The operand specifies the address of the instruction being jumped to.
Jcc Dest	Checks the state of one or more of the status flags in the EFLAGS register (CF, OF, PF, SF, and ZF) and, if the flags are in the specified state (condition), performs a jump to the target instruction specified by the destination operand. See Tables 13.8 and 13.9.
NOP	This instruction performs no operation. It is a one-byte or multi-byte NOP that takes up space in the instruction stream but does not impact machine context, except for the EIP register.
HLT	Stops instruction execution and places the processor in a HALT state. An enabled interrupt, a debug exception, the BINIT# signal, the INIT# signal, or the RESET# signal will resume execution.

WAIT	Causes the processor to repeatedly check for and handle pending, unmasked, floating-point exceptions before proceeding.
INT Nr	Interrupts current program, runs specified interrupt program
(f) Input/Output	
IN Dest, Source	Copies the data from the I/O port specified by the source operand to the destination operand, which is a register location.
INS Dest, Source	Copies the data from the I/O port specified by the source operand to the destination operand, which is a memory location.
OUT Dest, Source	Copies the byte, word, or doubleword value from the source register to the I/O port specified by the destination operand.
OUTS Dest, Source	Copies byte, word, or doubleword from the source operand to the I/O port specified with the destination operand. The source operand is a memory location.

Table 13.4 Processor Actions for Various Types of Operations

Data transfer	Transfer data from one location to another
	If memory is involved:
	Determine memory address
	Perform virtual-to-actual-memory address transformation
	Check cache
Arithmetic	Initiate memory read/write
	May involve data transfer, before and/or after
	Perform function in ALU
Logical	Set condition codes and flags
	Same as arithmetic
Conversion	Similar to arithmetic and logical. May involve special logic to perform conversion

Transfer of control	Update program counter. For subroutine call/return, manage parameter passing and linkage
I/O	Issue command to I/O module
	If memory-mapped I/O, determine memory-mapped address

Data Transfer

The most fundamental type of machine instruction is the data transfer instruction. The data transfer instruction must specify several things. First, the location of the source and destination operands must be specified. Each location could be memory, a register, or the top of the stack. Second, the length of data to be transferred must be indicated. Third, as with all instructions with operands, the mode of addressing for each operand must be specified. This latter point is discussed in [Chapter 14](#).

The choice of data transfer instructions to include in an instruction set exemplifies the kinds of trade-offs the designer must make. For example, the general location (memory or register) of an operand can be indicated in either the specification of the opcode or the operand. [Table 13.5](#) shows examples of the most common IBM EAS/390 data transfer instructions. Note that there are variants to indicate the amount of data to be transferred (8, 16, 32, or 64 bits). Also, there are different instructions for register to register, register to memory, memory to register, and memory to memory transfers. In contrast, the VAX has a move (MOV) instruction with variants for different amounts of data to be moved, but it specifies whether an operand is register or memory as part of the operand. The VAX approach is somewhat easier for the programmer, who has fewer mnemonics to deal with. However, it is also somewhat less compact than the IBM EAS/390 approach because the location (register versus memory) of each operand must be specified separately in the instruction. We will return to this distinction when we discuss instruction formats in [Chapter 14](#).

Table 13.5 Examples of IBM EAS/390 Data Transfer Operations

Operation Mnemonic	Name	Number of Bits Transferred	Description
L	Load	32	Transfer from memory to register
LH	Load Halfword	16	Transfer from memory to register
LR	Load	32	Transfer from register to register
LER	Load (short)	32	Transfer from floating-point register to floating-point register
LE	Load (short)	32	Transfer from memory to floating-point register
LDR	Load (long)	64	Transfer from floating-point register to

			floating-point register
LD	Load (long)	64	Transfer from memory to floating-point register
ST	Store	32	Transfer from register to memory
STH	Store Halfword	16	Transfer from register to memory
STC	Store Character	8	Transfer from register to memory
STE	Store (short)	32	Transfer from floating-point register to memory
STD	Store (long)	64	Transfer from floating-point register to memory

In terms of processor action, data transfer operations are perhaps the simplest type. If both source and destination are registers, then the processor simply causes data to be transferred from one register to another; this is an operation internal to the processor. If one or both operands are in memory, then the processor must perform some or all of the following actions:

1. Calculate the memory address, based on the address mode (discussed in [Chapter 14](#)).
2. If the address refers to virtual memory, translate from virtual to real memory address.
3. Determine whether the addressed item is in cache.
4. If not, issue a command to the memory module.

Arithmetic

Most machines provide the basic arithmetic operations of add, subtract, multiply, and divide. These are invariably provided for signed integer (fixed-point) numbers. Often they are also provided for floating-point and packed decimal numbers.

Other possible operations include a variety of single-operand instructions; for example,

- **Absolute:** Take the absolute value of the operand.
- **Negate:** Negate the operand.
- **Increment:** Add 1 to the operand.
- **Decrement:** Subtract 1 from the operand.

The execution of an arithmetic instruction may involve data transfer operations to position operands for input to the ALU, and to deliver the output of the ALU. [Figure 3.5](#) illustrates the movements involved in both data transfer and arithmetic operations. In addition, of course, the ALU portion of the processor performs the desired operation.

Logical

Most machines also provide a variety of operations for manipulating individual bits of a word or other addressable units, often referred to as “bit twiddling.” They are based upon Boolean operations (see [Chapter 12](#)).

Some of the basic logical operations that can be performed on Boolean or binary data are shown in [Table 13.5](#). The NOT operation inverts a bit. AND, OR, and Exclusive-OR (XOR) are the most common logical functions with two operands. EQUAL is a useful binary test.

These logical operations can be applied bitwise to n -bit logical data units. Thus, if two registers contain the data

$$\begin{aligned}(R1) &= 10100101 \\ (R2) &= 00001111\end{aligned}$$

then

$$(R1) \text{ AND } (R2) = 00000101$$

Table 13.6 Basic Logical Operations

P	Q	NOT P	P AND Q	P OR Q	P XOR Q	P=Q
0	0	1	0	0	0	1
0	1	1	0	1	1	0
1	0	0	0	1	1	0
1	1	0	1	1	0	1

where the notation (X) means the contents of location X. Thus, the AND operation can be used as a *mask* that selects certain bits in a word and zeros out the remaining bits. As another example, if two registers contain

$$\begin{aligned}(R1) &= 10100101 \\ (R2) &= 11111111\end{aligned}$$

then

$$(R1) \text{ XOR } (R2) = 01011010$$

With one word set to all 1s, the XOR operation inverts all of the bits in the other word (ones complement).

In addition to bitwise logical operations, most machines provide a variety of shifting and rotating functions (e.g., [Table 13.3c](#)). The most basic operations are illustrated in [Figure 13.6](#). With a **logical shift**, the bits of a word are shifted left or right. On one end, the bit shifted out is lost. On the other end, a 0 is shifted in. Logical shifts are useful primarily for isolating fields within a word. The 0s that are shifted into a word displace unwanted information that is shifted off the other end.

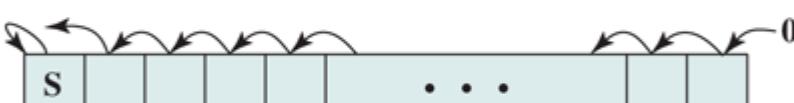

(a) Logical right shift

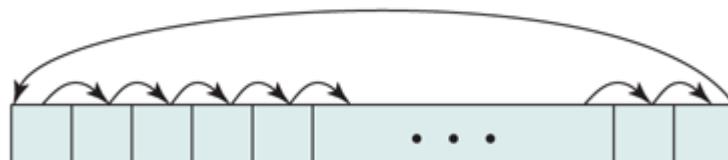

(b) Logical left shift

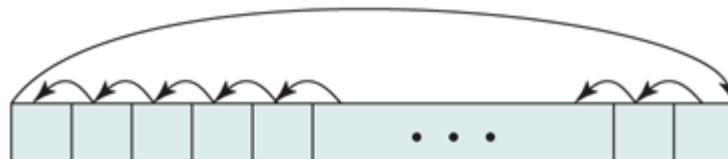

(c) Arithmetic right shift

(d) Arithmetic left shift

(e) Right rotate

(f) Left rotate

Figure 13.6 Shift and Rotate Operations

As an example, suppose we wish to transmit characters of data to an I/O device 1 character at a time. If each memory word is 16 bits in length and contains two characters, we must *unpack* the characters before they can be sent. To send the two characters in a word;

1. Load the word into a register.
2. Shift to the right eight times. This shifts the remaining character to the right half of the register.
3. Perform I/O. The I/O module reads the lower-order 8 bits from the data bus.

The preceding steps result in sending the left-hand character. To send the right-hand character;

1. Load the word again into the register.
2. AND with 0000000011111111. This masks out the character on the left.
3. Perform I/O.

The **arithmetic shift** operation treats the data as a signed integer and does not shift the sign bit. On a right arithmetic shift, the sign bit is replicated into the bit position to its right. On a left arithmetic shift, a logical left shift is performed on all bits but the sign bit, which is retained. These operations can speed up certain arithmetic operations. With numbers in twos complement notation, a right arithmetic shift corresponds to a division by 2, with truncation for odd numbers. Both an arithmetic left shift and a logical left shift correspond to a multiplication by 2 when there is no overflow. If overflow occurs, arithmetic and logical left shift operations produce different results, but the arithmetic left shift retains the sign of the number. Because of the potential for overflow, many processors do not include this instruction, including PowerPC and Itanium. Others, such as the IBM EAS/390, do offer the instruction. Curiously, the x86 architecture includes an arithmetic left shift but defines it to be identical to a logical left shift.

Rotate, or cyclic shift, operations preserve all of the bits being operated on. One use of a rotate is to bring each bit successively into the leftmost bit, where it can be identified by testing the sign of the data (treated as a number).

As with arithmetic operations, logical operations involve ALU activity and may involve data transfer operations. **Table 13.7** gives examples of all of the shift and rotate operations discussed in this subsection.

Table 13.7 Examples of Shift and Rotate Operations

Input	Operation	Result
10100110	Logical right shift (3 bits)	00010100
10100110	Logical left shift (3 bits)	00110000
10100110	Arithmetic right shift (3 bits)	11110100
10100110	Arithmetic left shift (3 bits)	10110000
10100110	Right rotate (3 bits)	11010100
10100110	Left rotate (3 bits)	00110101

Conversion

Conversion instructions are those that change the format or operate on the format of data. An example is converting from decimal to binary. An example of a more complex editing instruction is the EAS/390 Translate (TR) instruction. This instruction can be used to convert from one 8-bit code to another, and it takes three operands:

TR R1 (L), R2

The operand R2 contains the address of the start of a table of 8-bit codes. The L bytes starting at the address specified in R1 are translated, each byte being replaced by the contents of a table entry indexed by that byte. For example, to translate from EBCDIC to IRA, we first create a 256-byte table in storage locations, say, 1000-10FF hexadecimal. The table contains the characters of the IRA code in

the sequence of the binary representation of the EBCDIC code; that is, the IRA code is placed in the table at the relative location equal to the binary value of the EBCDIC code of the same character. Thus, locations 10F0 through 10F9 will contain the values 30 through 39, because F0 is the EBCDIC code for the digit 0, and 30 is the IRA code for the digit 0, and so on through digit 9. Now suppose we have the EBCDIC for the digits 1984 starting at location 2100 and we wish to translate to IRA. Assume the following:

- Locations 2100–2103 contain F1 F9 F8 F4.
- R1 contains 2100.
- R2 contains 1000.

Then, if we execute

TR R1 (4),R2

locations 2100–2103 will contain 31 39 38 34.

Input/Output

Input/output instructions were discussed in some detail in [Chapter 8](#). As we saw, there are a variety of approaches taken, including isolated programmed I/O, memory-mapped programmed I/O, DMA, and the use of an I/O processor. Many implementations provide only a few I/O instructions, with the specific actions specified by parameters, codes, or command words.

System Control

System control instructions are those that can be executed only while the processor is in a certain privileged state or is executing a program in a special privileged area of memory. Typically, these instructions are reserved for the use of the operating system.

Some examples of system control operations are as follows. A system control instruction may read or alter a control register; we discuss control registers in [Chapter 16](#). Another example is an instruction to read or modify a storage protection key, such as is used in the EAS/390 memory system. Yet another example is access to process control blocks in a multiprogramming system.

Transfer of Control

For all of the operation types discussed so far, the next instruction to be performed is the one that immediately follows, in memory, the current instruction. However, a significant fraction of the instructions in any program have as their function changing the sequence of instruction execution. For these instructions, the operation performed by the processor is to update the program counter to contain the address of some instruction in memory.

There are a number of reasons why transfer-of-control operations are required. Among the most important are the following:

1. In the practical use of computers, it is essential to be able to execute each instruction more than once and perhaps many thousands of times. It may require thousands or perhaps millions of instructions to implement an application. This would be unthinkable if each instruction had to be written out separately. If a table or a list of items is to be processed, a program loop is needed. One sequence of instructions is executed repeatedly to process all the data.
2. Virtually all programs involve some decision making. We would like the computer to do one thing if one condition holds, and another thing if another condition holds. For example, a

sequence of instructions computes the square root of a number. At the start of the sequence, the sign of the number is tested. If the number is negative, the computation is not performed, but an error condition is reported.

3. To compose correctly a large or even medium-size computer program is an exceedingly difficult task. It helps if there are mechanisms for breaking the task up into smaller pieces that can be worked on one at a time.

We now turn to a discussion of the most common transfer-of-control operations found in instruction sets: branch, **skip**, and **procedure call**.

BRANCH INSTRUCTIONS

A branch instruction, also called a jump instruction, has as one of its operands the address of the next instruction to be executed. Most often, the instruction is a **conditional branch** instruction. That is, the branch is made (update program counter to equal address specified in operand) only if a certain condition is met. Otherwise, the next instruction in sequence is executed (increment program counter as usual). A branch instruction in which the branch is always taken is an **unconditional branch**.

There are two common ways of generating the condition to be tested in a conditional branch instruction. First, most machines provide a 1-bit or multiple-bit condition code that is set as the result of some operations. This code can be thought of as a short user-visible register. As an example, an arithmetic operation (ADD, SUBTRACT, and so on) could set a 2-bit condition code with one of the following four values: 0, positive, negative, overflow. On such a machine, there could be four different conditional branch instructions:

BRP X	Branch to location X if result is positive.
BRN X	Branch to location X if result is negative.
BRZ X	Branch to location X if result is zero.
BRO X	Branch to location X if overflow occurs.

In all of these cases, the result referred to is the result of the most recent operation that set the condition code.

Another approach that can be used with a three-address instruction format is to perform a comparison and specify a branch in the same instruction. For example,

BRE R1 , R2 , X Branch to X if contents of R1 = contents of R2.

Figure 13.7 shows examples of these operations. Note that a branch can be either *forward* (an instruction with a higher address) or *backward* (lower address). The example shows how an unconditional and a conditional branch can be used to create a repeating loop of instructions. The instructions in locations 202 through 210 will be executed repeatedly until the result of subtracting Y from X is 0.

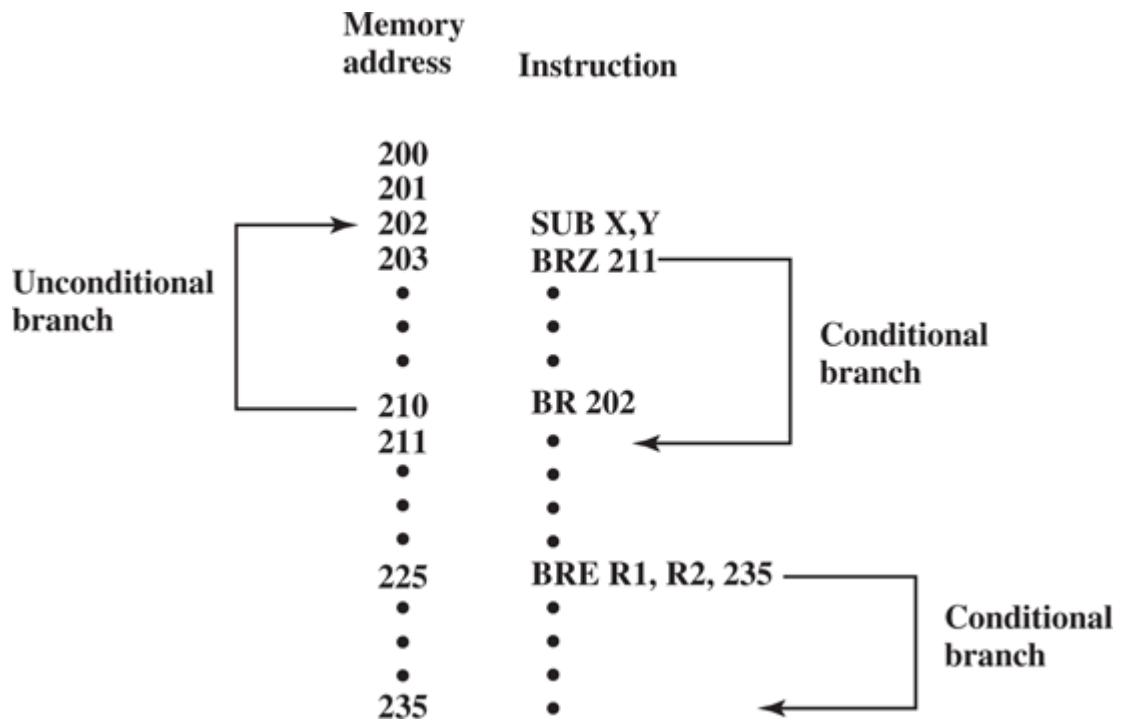

Figure 13.7 Branch Instructions

SKIP INSTRUCTIONS

Another form of transfer-of-control instruction is the skip instruction. The skip instruction includes an implied address. Typically, the skip implies that one instruction be skipped; thus, the implied address equals the address of the next instruction plus one instruction length. Because the skip instruction does not require a destination address field, it is free to do other things. A typical example is the increment-and-skip-if-zero (ISZ) instruction. Consider the following program fragment:

```

301
:
309 ISZ R1
310 BR 301
311

```

In this fragment, the two transfer-of-control instructions are used to implement an iterative loop. R1 is set with the negative of the number of iterations to be performed. At the end of the loop, R1 is incremented. If it is not 0, the program branches back to the beginning of the loop. Otherwise, the branch is skipped, and the program continues with the next instruction after the end of the loop.

PROCEDURE CALL INSTRUCTIONS

Perhaps the most important innovation in the development of programming languages is the *procedure*. A procedure is a self-contained computer program that is incorporated into a larger program. At any point in the program the procedure may be invoked, or *called*. The processor is instructed to go and execute the entire procedure and then return to the point from which the call took place.

The two principal reasons for the use of procedures are economy and modularity. A procedure allows the same piece of code to be used many times. This is important for economy in programming effort and for making the most efficient use of storage space in the system (the program must be stored). Procedures also allow large programming tasks to be subdivided into smaller units. This use of *modularity* greatly eases the programming task.

The procedure mechanism involves two basic instructions: a call instruction that branches from the present location to the procedure, and a return instruction that returns from the procedure to the place from which it was called. Both of these are forms of branching instructions.

Figure 13.8a illustrates the use of procedures to construct a program. In this example, there is a main program starting at location 4000. This program includes a call to procedure PROC1, starting at location 4500. When this call instruction is encountered, the processor suspends execution of the main program and begins execution of PROC1 by fetching the next instruction from location 4500. Within PROC1, there are two calls to PROC2 at location 4800. In each case, the execution of PROC1 is suspended and PROC2 is executed. The RETURN statement causes the processor to go back to the calling program and continue execution at the instruction after the corresponding CALL instruction. This behavior is illustrated in **Figure 13.8b**.

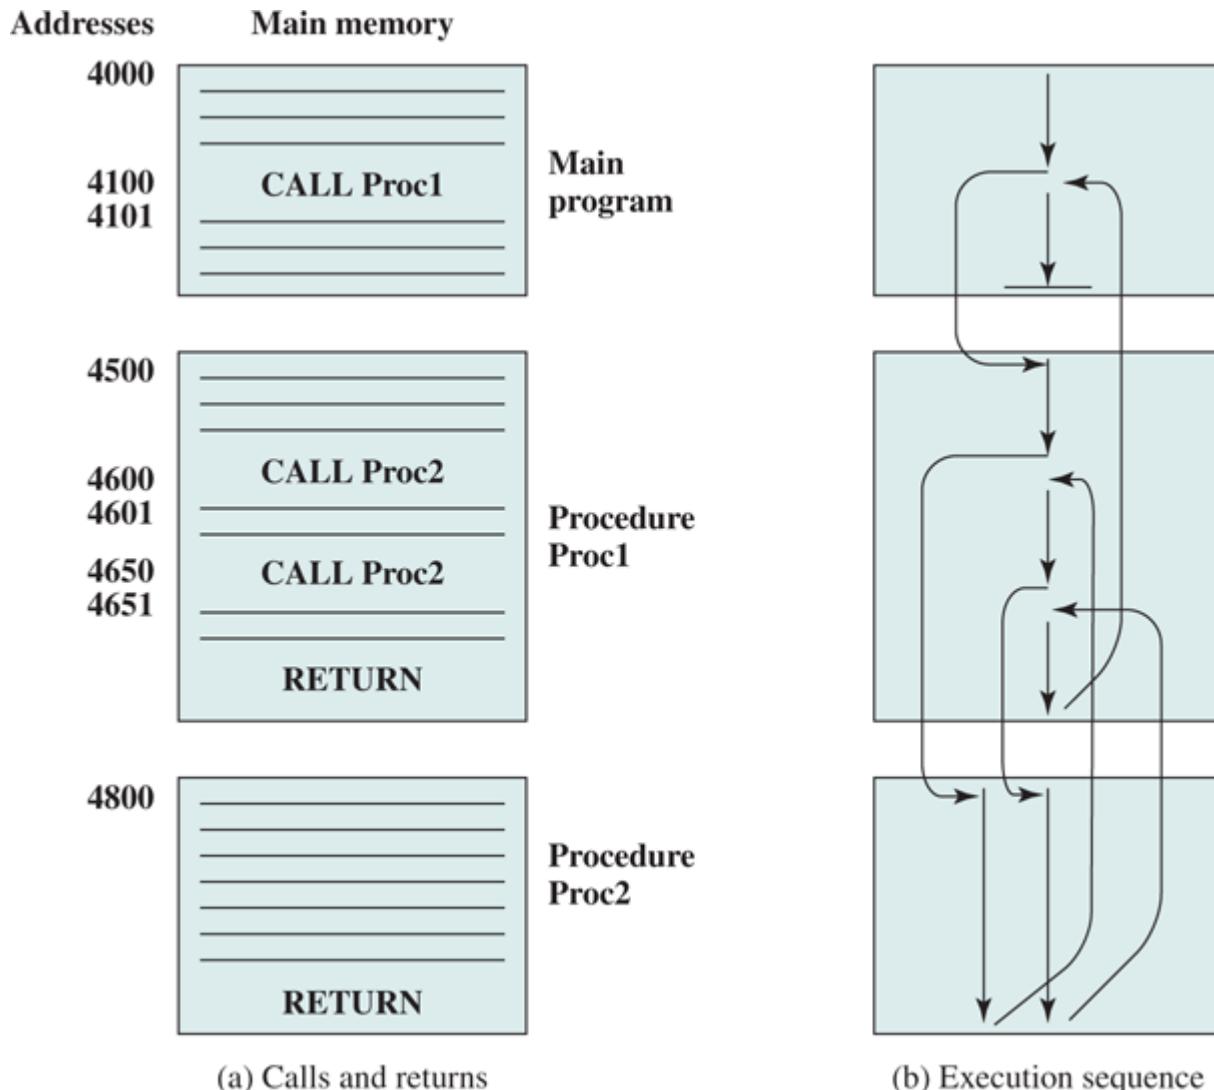

Figure 13.8 Nested Procedures

Three points are worth noting:

1. A procedure can be called from more than one location.
2. A procedure call can appear in a procedure. This allows the *nesting* of procedures to an arbitrary depth.
3. Each procedure call is matched by a return in the called program.

Because we would like to be able to call a procedure from a variety of points, the processor must somehow save the return address so that the return can take place appropriately. There are three

common places for storing the return address:

- Register
- Start of called procedure
- Top of stack

Consider a machine-language instruction CALL X, which stands for *call procedure at location X*. If the register approach is used, CALL X causes the following actions:

$$\begin{aligned} RN &\leftarrow PC + \Delta \\ PC &\leftarrow X \end{aligned}$$

where RN is a register that is always used for this purpose, PC is the program counter, and Δ is the instruction length. The called procedure can now save the contents of RN to be used for the later return.

A second possibility is to store the return address at the start of the procedure. In this case, CALL X causes

$$\begin{aligned} X &\leftarrow PC + \Delta \\ PC &\leftarrow X + 1 \end{aligned}$$

This is quite handy. The return address has been stored safely away.

Both of the preceding approaches work and have been used. The only limitation of these approaches is that they complicate the use of *reentrant* procedures. A **reentrant procedure** is one in which it is possible to have several calls open to it at the same time. A recursive procedure (one that calls itself) is an example of the use of this feature (see [Appendix F](#)). If parameters are passed via registers or memory for a reentrant procedure, some code must be responsible for saving the parameters so that the registers or memory space are available for other procedure calls.

A more general and powerful approach is to use a stack (see [Appendix E](#) for a discussion of stacks). When the processor executes a call, it places the return address on the stack. When it executes a return, it uses the address on the stack. [Figure 13.9](#) illustrates the use of the stack.

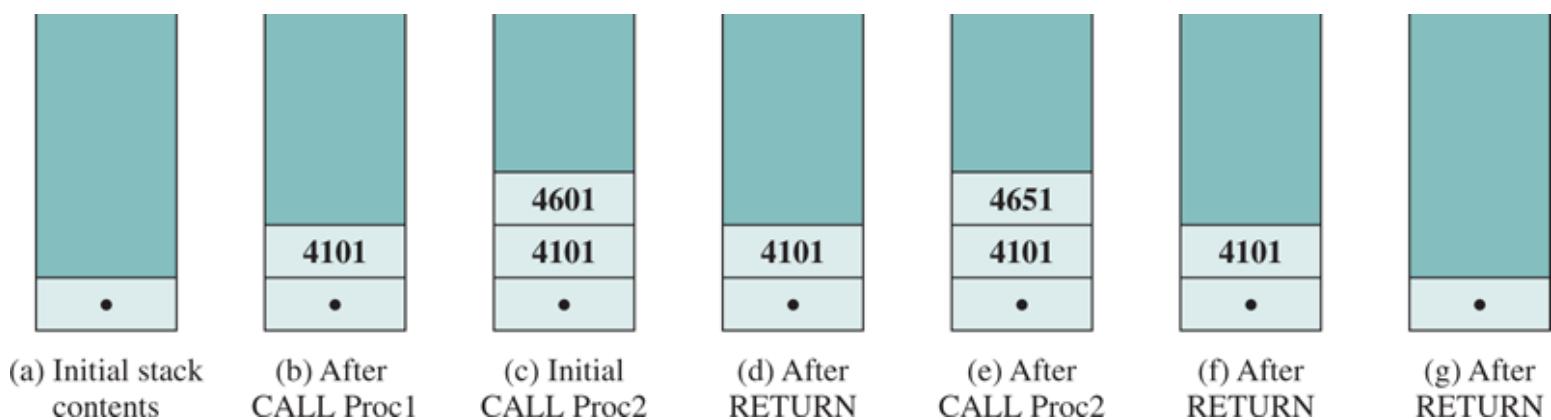

Figure 13.9 Use of Stack to Implement Nested Subroutines of [Figure 13.8](#)

In addition to providing a return address, it is also often necessary to pass parameters with a procedure call. These can be passed in registers. Another possibility is to store the parameters in memory just after the CALL instruction. In this case, the return must be to the location following the parameters. Again, both of these approaches have drawbacks. If registers are used, the called

program and the calling program must be written to assure that the registers are used properly. The storing of parameters in memory makes it difficult to exchange a variable number of parameters. Both approaches prevent the use of reentrant procedures.

A more flexible approach to parameter passing is the stack. When the processor executes a call, it not only stacks the return address, it stacks parameters to be passed to the called procedure. The called procedure can access the parameters from the stack. Upon return, return parameters can also be placed on the stack. The entire set of parameters, including return address, that is stored for a procedure invocation is referred to as a *stack frame*.

An example is provided in **Figure 13.10**. The example refers to procedure P in which the local variables x_1 and x_2 are declared, and procedure Q, which P can call and in which the local variables y_1 and y_2 are declared. In this figure, the return point for each procedure is the first item stored in the corresponding stack frame. Next is stored a pointer to the beginning of the previous frame. This is needed if the number or length of parameters to be stacked is variable.

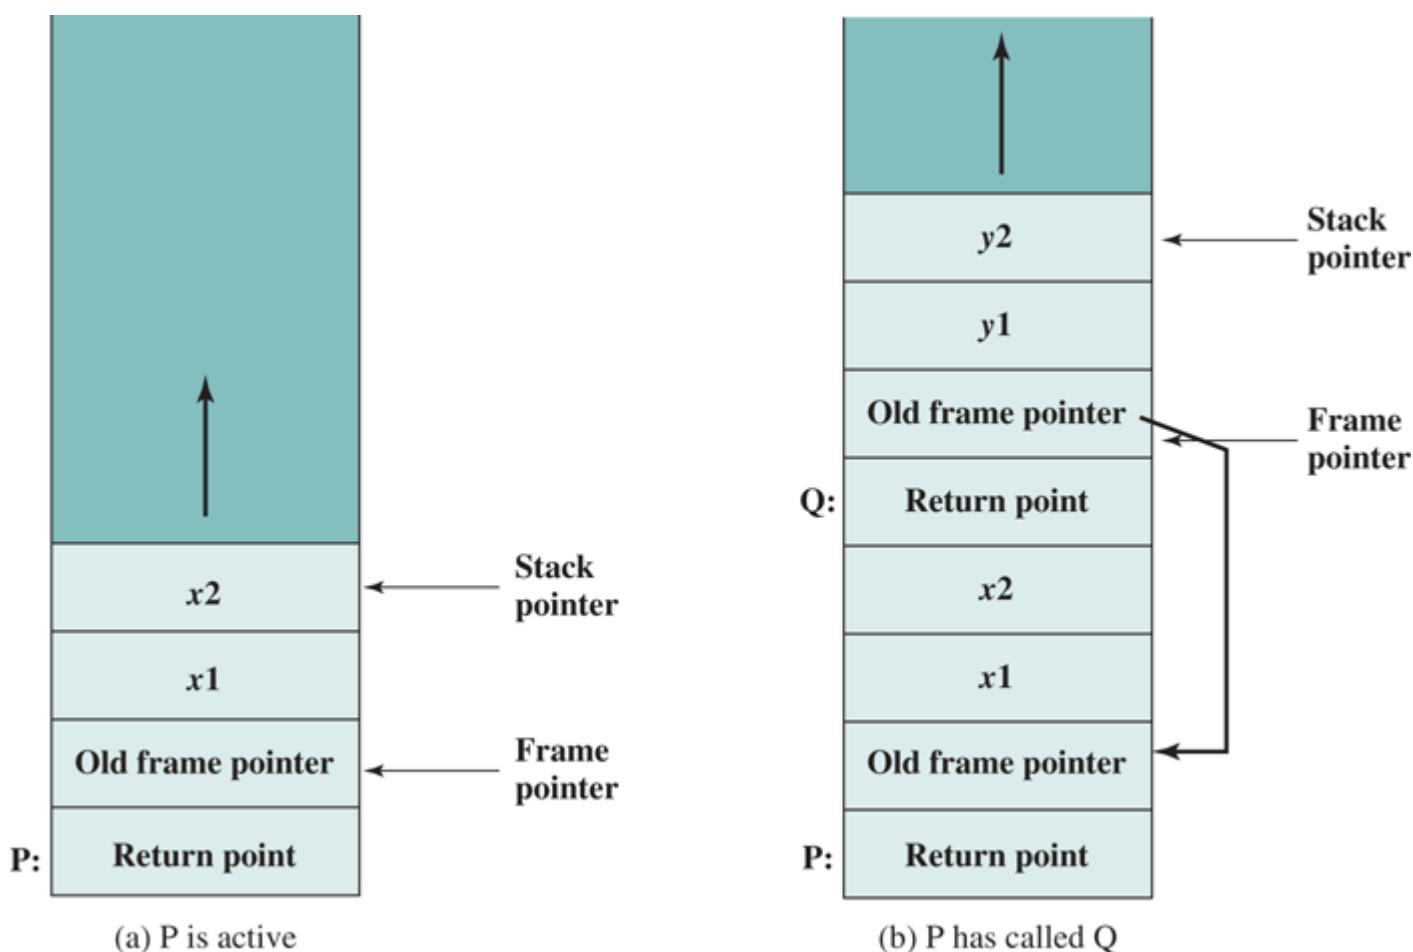

Figure 13.10 Stack Frame Growth Using Sample Procedures P and Q

13.5 Intel x86 and ARM Operation Types

x86 Operation Types

The x86 provides a complex array of operation types, including a number of specialized instructions. The intent was to provide tools for the compiler writer to produce optimized machine language translation of high-level language programs. Most of these are the conventional instructions found in most machine instruction sets, but several types of instructions are tailored to the x86 architecture and are of particular interest. [Appendix A](#) of [CART06] lists the x86 instructions, together with the operands for each and the effect of the instruction on the condition codes. [Appendix B](#) of the NASM assembly language manual [NASM17] provides a more detailed description of each x86 instruction. Both documents are available at box.com/COA11e.

CALL/RETURN INSTRUCTIONS

The x86 provides four instructions to support procedure call/return: CALL, ENTER, LEAVE, RETURN. It will be instructive to look at the support provided by these instructions. Recall from [Figure 13.10](#) that a common means of implementing the procedure call/return mechanism is via the use of stack frames. When a new procedure is called, the following must be performed upon entry to the new procedure:

- **Push** the return point on the stack.
- Push the current frame pointer on the stack.
- Copy the stack pointer as the new value of the frame pointer.
- Adjust the stack pointer to allocate a frame.

The CALL instruction pushes the current instruction pointer value onto the stack and causes a jump to the entry point of the procedure by placing the address of the entry point in the instruction pointer. In the 8088 and 8086 machines, the typical procedure began with the sequence

PUSH	EBP
MOV	EBP, ESP
SUB	ESP, space_for_locals

where EBP is the frame pointer and ESP is the stack pointer. In the 80286 and later machines, the ENTER instruction performs all the aforementioned operations in a single instruction.

The ENTER instruction was added to the instruction set to provide direct support for the compiler. The instruction also includes a feature for support of what are called nested procedures in languages such as Pascal, COBOL, and Ada (not found in C or FORTRAN). It turns out that there are better ways of handling nested procedure calls for these languages. Furthermore, although the ENTER instruction saves a few bytes of memory compared with the PUSH, MOV, SUB sequence (4 bytes versus 6 bytes), it actually takes longer to execute (10 clock cycles versus 6 clock cycles). Thus, although it may have seemed a good idea to the instruction set designers to add this feature, it complicates the implementation of the processor while providing little or no benefit. We will see that, in contrast, a RISC approach to processor design would avoid complex instructions such as ENTER and might

produce a more efficient implementation with a sequence of simpler instructions.

MEMORY MANAGEMENT

Another set of specialized instructions deals with memory segmentation. These are privileged instructions that can only be executed from the operating system. They allow local and global segment tables (called descriptor tables) to be loaded and read, and for the privilege level of a segment to be checked and altered.

The special instructions for dealing with the on-chip cache were discussed in [Chapter 5](#).

STATUS FLAGS AND CONDITION CODES

Status flags are bits in special registers that may be set by certain operations and used in conditional branch instructions. The term *condition code* refers to the settings of one or more status flags. In the x86 and many other architectures, status flags are set by arithmetic and compare operations. The compare operation in most languages subtracts two operands, as does a subtract operation. The difference is that a compare operation only sets status flags, whereas a subtract operation also stores the result of the subtraction in the destination operand. Some architectures also set status flags for data transfer instructions.

Table 13.8 lists the status flags used on the x86. Each flag, or combinations of these flags, can be tested for a conditional jump. **Table 13.9** shows the condition codes (combinations of status flag values) for which conditional jump opcodes have been defined.

Table 13.8 x86 Status Flags

Status Bit	Name	Description
C	Carry	Indicates carrying or borrowing out of the left-most bit position following an arithmetic operation. Also modified by some of the shift and rotate operations.
P	Parity	Parity of the least-significant byte of the result of an arithmetic or logic operation. 1 indicates even parity; 0 indicates odd parity.
A	Auxiliary Carry	Represents carrying or borrowing between half-bytes of an 8-bit arithmetic or logic operation. Used in binary-coded decimal arithmetic.
Z	Zero	Indicates that the result of an arithmetic or logic operation is 0.
S	Sign	Indicates the sign of the result of an arithmetic or logic operation.
O	Overflow	Indicates an arithmetic overflow after an addition or subtraction for twos complement arithmetic.

Table 13.9 x86 Condition Codes for Conditional Jump and SETcc Instructions

Symbol	Condition Tested	Comment
--------	------------------	---------

A, NBE	$C = 0 \text{ AND } Z = 0$	Above; Not below or equal (greater than, unsigned)
AE, NB, NC	$C = 0$	Above or equal; Not below (greater than or equal, unsigned); Not carry
B, NAE, C	$C = 1$	Below; Not above or equal (less than, unsigned); Carry set
BE, NA	$C = 1 \text{ OR } Z = 1$	Below or equal; Not above (less than or equal, unsigned)
E, Z	$Z = 1$	Equal; Zero (signed or unsigned)
G, NLE	$[(S = 1 \text{ AND } O = 1) \text{ OR } (S = 0 \text{ AND } O = 0)] \text{ AND } [Z = 0]$	Greater than; Not less than or equal (signed)
GE, NL	$(S = 1 \text{ AND } O = 1) \text{ OR } (S = 0 \text{ AND } O = 0)$	Greater than or equal; Not less than (signed)
L, NGE	$(S = 1 \text{ AND } O = 0) \text{ OR } (S = 0 \text{ AND } O = 0)$	Less than; Not greater than or equal (signed)
LE, NG	$(S = 1 \text{ AND } O = 0) \text{ OR } (S = 0 \text{ AND } O = 1) \text{ OR } (Z = 1)$	Less than or equal; Not greater than (signed)
NE, NZ	$Z = 0$	Not equal; Not zero (signed or unsigned)
NO	$O = 0$	No overflow
NS	$S = 0$	Not sign (not negative)
NP, PO	$P = 0$	Not parity; Parity odd
O	$O = 1$	Overflow
P	$P = 1$	Parity; Parity even
S	$S = 1$	Sign (negative)

Several interesting observations can be made about this list. First, we may wish to test two operands to determine if one number is bigger than another. But this will depend on whether the numbers are signed or unsigned. For example, the 8-bit number 11111111 is bigger than 00000000 if the two numbers are interpreted as unsigned integers ($255 > 0$), but is less if they are considered as 8-bit twos complement numbers ($-1 < 0$). Many assembly languages therefore introduce two sets of terms to distinguish the two cases: If we are comparing two numbers as signed integers, we use the terms *less than* and *greater than*; if we are comparing them as unsigned integers, we use the terms *below* and *above*.

A second observation concerns the complexity of comparing signed integers. A signed result is greater than or equal to zero if (1) the sign bit is zero and there is no overflow ($S = 0 \text{ AND } O = 0$), or (2) the sign bit is one and there is an overflow. A study of [Figure 11.4](#) should convince you that the conditions tested for the various signed operations are appropriate.

X86 SIMD INSTRUCTIONS

In 1996, Intel introduced MMX technology into its Pentium product line. MMX is a set of highly optimized instructions for multimedia tasks. There are 57 new instructions that treat data in a SIMD (single-instruction, multiple-data) fashion, which makes it possible to perform the same operation, such as addition or multiplication, on multiple data elements at once. Each instruction typically takes a single clock cycle to execute. For the proper application, these fast parallel operations can yield a speedup of two to eight times over comparable algorithms that do not use the MMX instructions [ATKI96]. With the introduction of 64-bit x86 architecture, Intel has expanded this extension to include double quadword (128 bits) operands and floating-point operations. In this subsection, we describe the MMX features.

The focus of MMX is multimedia programming. Video and audio data are typically composed of large arrays of small data types, such as 8 or 16 bits, whereas conventional instructions are tailored to operate on 32- or 64-bit data. Here are some examples: In graphics and video, a single scene consists of an array of pixels,² and there are 8 bits for each pixel or 8 bits for each pixel color component (red, green, blue). Typical audio samples are quantized using 16 bits. For some 3D graphics algorithms, 32 bits are common for basic data types. To provide for parallel operation on these data lengths, three new data types are defined in MMX. Each data type is 64 bits in length and consists of multiple smaller data fields, each of which holds a fixed-point integer. The types are as follows:

² A pixel, or picture element, is the smallest element of a digital image that can be assigned a gray level.

Equivalently, a pixel is an individual dot in a dot-matrix representation of a picture.

- **Packed byte:** Eight bytes packed into one 64-bit quantity.
- **Packed word:** Four 16-bit words packed into 64 bits.
- **Packed doubleword:** Two 32-bit doublewords packed into 64 bits.

[Table 13.10](#) lists the MMX instruction set. Most of the instructions involve parallel operation on bytes, words, or doublewords. For example, the PSLLW instruction performs a left logical shift separately on each of the four words in the packed word operand; the PADDB instruction takes packed byte operands as input and performs parallel additions on each byte position independently to produce a packed byte output.

Table 13.10 MMX Instruction Set

Note: If an instruction supports multiple data types [byte (B), word (W), doubleword (D), quadword

(Q)], the data types are indicated in brackets.

Category	Instruction	Description
Arithmetic	PADD [B, W, D]	Parallel add of packed eight bytes, four 16-bit words, or two 32-bit doublewords, with wraparound.
	PADDS [B, W]	Add with saturation.
	PADDUS [B, W]	Add unsigned with saturation.
	PSUB [B, W, D]	Subtract with wraparound.
	PSUBS [B, W]	Subtract with saturation.
	PSUBUS [B, W]	Subtract unsigned with saturation.
	PMULHW	Parallel multiply of four signed 16-bit words, with high-order 16 bits of 32-bit result chosen.
	PMULLW	Parallel multiply of four signed 16-bit words, with low-order 16 bits of 32-bit result chosen.
	PMADDWD	Parallel multiply of four signed 16-bit words; add together adjacent pairs of 32-bit results.
Comparison	PCMPEQ [B, W, D]	Parallel compare for equality; result is mask of 1s if true or 0s if false.
	PCMPGT [B, W, D]	Parallel compare for greater than; result is mask of 1s if true or 0s if false.
Conversion	PACKUSWB	Pack words into bytes with unsigned saturation.
	PACKSS [WB, DW]	Pack words into bytes, or doublewords into words, with signed saturation.
	PUNPCKH [BW, WD, DQ]	Parallel unpack (interleaved merge) high-order bytes, words, or doublewords from MMX register.

	PUNPCKL [BW, WD, DQ]	Parallel unpack (interleaved merge) low-order bytes, words, or doublewords from MMX register.
Logical	PAND	64-bit bitwise logical AND
	PNDN	64-bit bitwise logical AND NOT
	POR	64-bit bitwise logical OR
	PXOR	64-bit bitwise logical XOR
Shift	PSLL [W, D, Q]	Parallel logical left shift of packed words, doublewords, or quadword by amount specified in MMX register or immediate value.
	PSRL [W, D, Q]	Parallel logical right shift of packed words, doublewords, or quadword.
	PSRA [W, D]	Parallel arithmetic right shift of packed words, doublewords, or quadword.
Data transfer	MOV [D, Q]	Move doubleword or quadword to/from MMX register.
Statemgmt	EMMS	Empty MMX state (empty FP registers tag bits).

One unusual feature of the new instruction set is the introduction of **saturation arithmetic** for byte and 16-bit word operands. With ordinary unsigned arithmetic, when an operation overflows (i.e., a carry out of the most significant bit), the extra bit is truncated. This is referred to as wraparound, because the effect of the truncation can be, for example, to produce an addition result that is smaller than the two input operands. Consider the addition of the two words, in hexadecimal, F000h and 3000h. The sum would be expressed as

$$\begin{aligned}
 F000h &= 1111000000000000 \\
 +3000h &= 0011000000000000 \\
 10010\ 0000\ 0000\ 0000 &= 2000h
 \end{aligned}$$

If the two numbers represented image intensity, then the result of the addition is to make the combination of two dark shades turn out to be lighter. This is typically not what is intended. With saturation arithmetic, if addition results in overflow or subtraction results in underflow, the result is set to the largest or smallest value representable. For the preceding example, with saturation arithmetic, we have

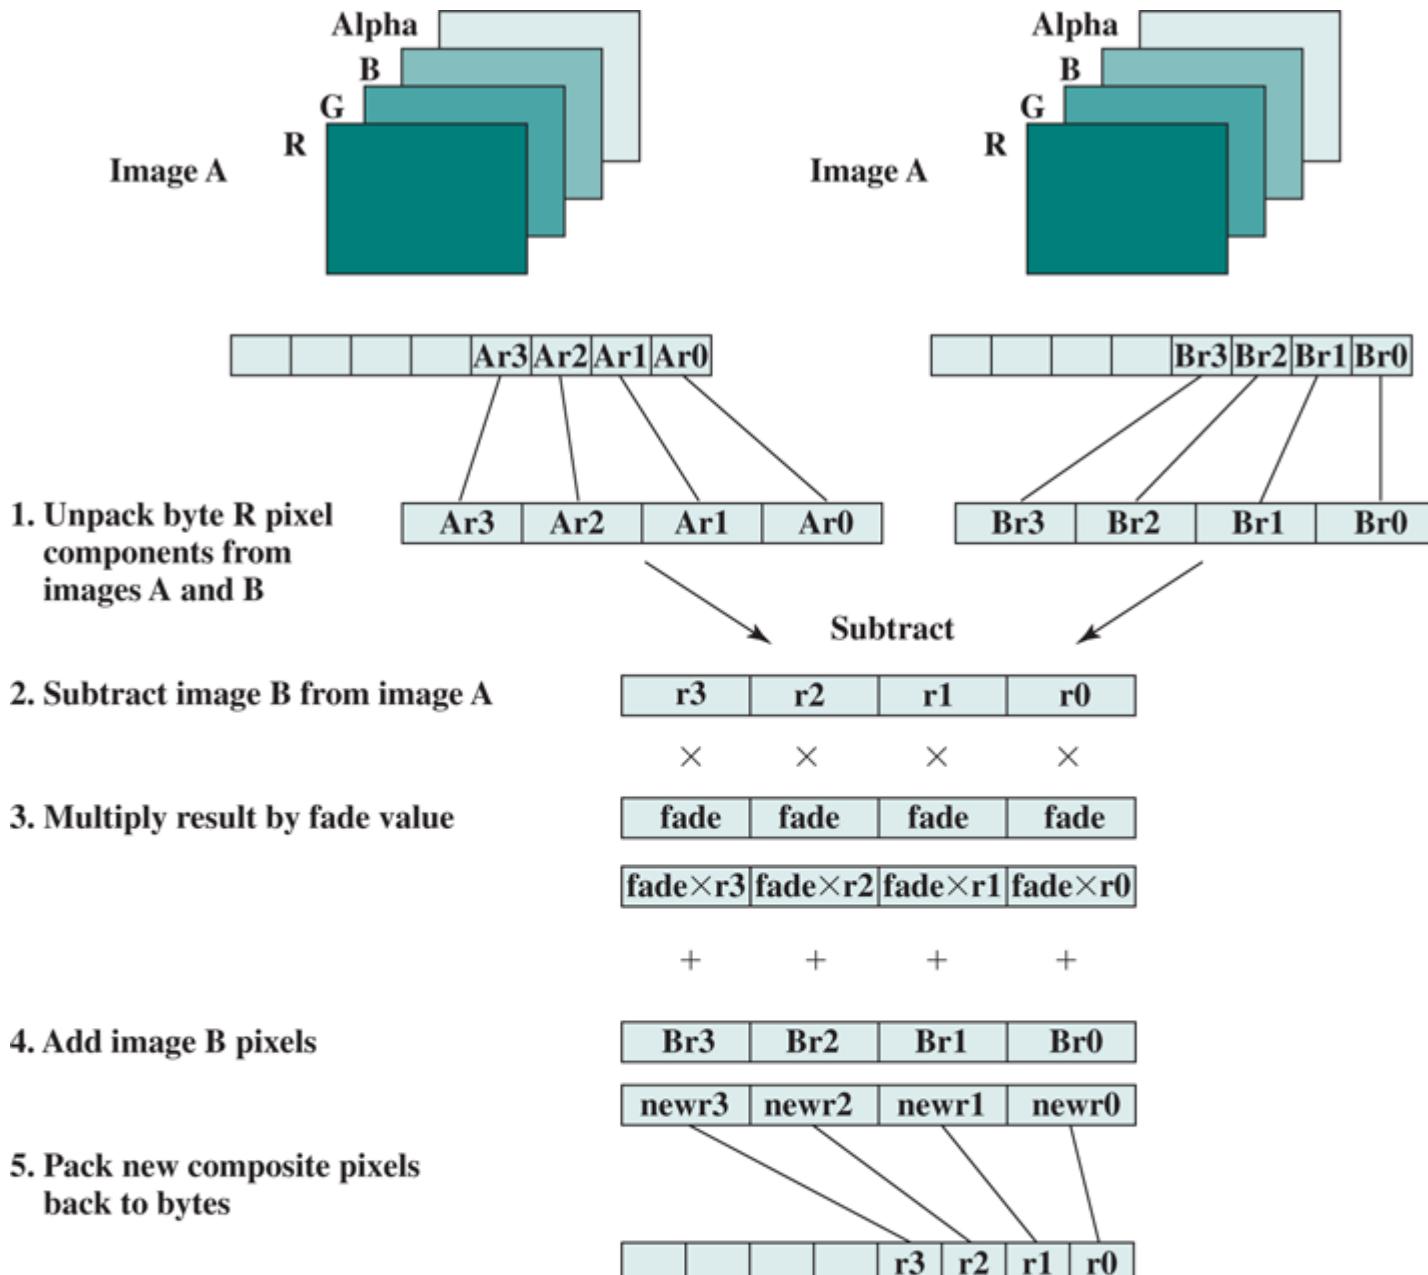

$$\begin{aligned}
 F0001 &= 1111000000000000 \\
 +3000h &= 0011000000000000 \\
 10010\ 0000\ 0000\ 0000 &= \bar{0} \\
 1111\ 1111\ 1111\ 1111 &= FFFFh
 \end{aligned}$$

To provide a feel for the use of MMX instructions, we look at an example, taken from [PELE97]. A common video application is the fade-out, fade-in effect, in which one scene gradually dissolves into another. Two images are combined with a weighted average:

$$\text{Result_pixel} = \text{A_pixel} \times \text{fade} + \text{B_pixel} \times (1 - \text{fade})$$

This calculation is performed on each pixel position in A and B. If a series of video frames is produced while gradually changing the fade value from 1 to 0 (scaled appropriately for an 8-bit integer), the result is to fade from image A to image B.

Figure 13.11 shows the sequence of steps required for one set of pixels. The 8-bit pixel components are converted to 16-bit elements to accommodate the MMX 16-bit multiply capability. If these images use 640×480 resolution, and the dissolve technique uses all 255 possible values of the fade value, then the total number of instructions executed using MMX is 535 million. The same calculation, performed without the MMX instructions, requires 1.4 billion instruction executions [INTE98].

MMX code sequence performing this operation:

```

pxor      mm7, mm7    ;zero out mm7
movq      mm3, fad_val ;load fade value replicated 4 times
movd      mm0, imageA  ;load 4 red pixel components from image A
movd      mm1, imageB  ;load 4 red pixel components from image B
punpckblw mm0, mm7    ;unpack 4 pixels to 16 bits
punpckblw mm1, mm7    ;unpack 4 pixels to 16 bits
psubw    mm0, mm1    ;subtract image B from image A
pmulhw   mm0, mm3    ;multiply the subtract result by fade values
padddw   mm0, mm1    ;add result to image B
packuswb mm0, mm7    ;pack 16-bit results back to bytes

```

Figure 13.11 Image Compositing on Color Plane Representation

ARM Operation Types

The ARM architecture provides a large collection of operation types. The following are the principal categories:

- **Load and store instructions:** In the ARM architecture, only load and store instructions access memory locations; arithmetic and logical instructions are performed only on registers and immediate values encoded in the instruction. This limitation is characteristic of RISC design and it is explored further in [Chapter 17](#). The ARM architecture supports two broad types of instruction that load or store the value of a single register, or a pair of registers, from or to memory: (1) load or store a 32-bit word or an 8-bit unsigned byte, and (2) load or store a 16-bit unsigned halfword, and load and sign extend a 16-bit halfword or an 8-bit byte.
- **Branch instructions:** ARM supports a branch instruction that allows a conditional branch forwards or backwards up to 32 MB. A subroutine call can be performed by a variant of the standard branch instruction. As well as allowing a branch forward or backward up to 32 MB, the Branch with Link (BL) instruction preserves the address of the instruction after the branch (the return address) in the LR (R14). Branches are determined by a 4-bit condition field in the instruction.
- **Data-processing instructions:** This category includes logical instructions (AND, OR, XOR), add and subtract instructions, and test and compare instructions.
- **Multiply instructions:** The integer multiply instructions operate on word or halfword operands and can produce normal or long results. For example, there is a multiply instruction that takes two 32-bit operands and produces a 64-bit result.
- **Parallel addition and subtraction instructions:** In addition to the normal data processing and multiply instructions, there are a set of parallel addition and subtraction instructions, in which portions of two operands are operated on in parallel. For example, ADD16 adds the top halfwords of two registers to form the top halfword of the result and adds the bottom halfwords of the same two registers to form the bottom halfword of the result. These instructions are useful in image processing applications, similar to the x86 MMX instructions.
- **Extend instructions:** There are several instructions for unpacking data by sign or zero extending bytes to halfwords or words, and halfwords to words.
- **Status register access instructions:** ARM provides the ability to read and also to write portions of the status register.

CONDITION CODES

The ARM architecture defines four condition flags that are stored in the program status register: N, Z, C, and V (Negative, Zero, Carry and oVerflow), with meanings essentially the same as the S, Z, C, and V flags in the x86 architecture. These four flags constitute a condition code in ARM. [Table 13.11](#) shows the combination of conditions for which conditional execution is defined.

Table 13.11 ARM Conditions for Conditional Instruction Execution

Code	Symbol	Condition Tested	Comment
0000	EQ	Z = 1	Equal
0001	NE	Z = 0	Not equal
0010	CS/HS	C = 1	Carry set/unsigned higher or same
0011	CC/LO	C = 0	Carry clear/unsigned lower
0100	MI	N = 1	Minus/negative
0101	PL	N = 0	Plus/positive or zero
		V = 1	

0110	VS		Overflow
0111	VC	$V = 0$	No overflow
1000	HI	$C = 1 \text{ AND } Z = 0$	Unsigned higher
1001	LS	$C = 0 \text{ OR } Z = 1$	Unsigned lower or same
1010	GE	$N = V$ [$(N = 1 \text{ AND } V = 1)$ $\text{OR } (N = 0 \text{ AND } V = 0)$]	Signed greater than or equal
1011	LT	$N \neq V$ [$(N = 1 \text{ AND } V = 0)$ $\text{OR } (N = 0 \text{ AND } V = 1)$]	Signed less than
1100	GT	$(Z = 0) \text{ AND } (N = V)$	Signed greater than
1101	LE	$(Z = 1) \text{ OR } (N \neq V)$	Signed less than or equal
1110	AL	—	Always (unconditional)
1111	—	—	This instruction can only be executed unconditionally

There are two unusual aspects to the use of condition codes in ARM:

1. All instructions, not just branch instructions, include a condition code field, which means that virtually all instructions may be conditionally executed. Any combination of flag settings except 1110 or 1111 in an instruction's condition code field signifies that the instruction will be executed only if the condition is met.
2. All data processing instructions (arithmetic, logical) include an S bit that signifies whether the instruction updates the condition flags.

The use of conditional execution and conditional setting of the condition flags helps in the design of shorter programs that use less memory. On the other hand, all instructions include 4 bits for the condition code, so there is a trade-off in that fewer bits in the 32-bit instruction are available for opcode and operands. Because the ARM is a RISC design that relies heavily on register addressing, this seems to be a reasonable trade-off.

13.6 Key Terms, Review Questions, and Problems

Key Terms

accumulator
address
arithmetic shift
bi-endian
big endian
branch
conditional branch
instruction set
jump
little endian
logical shift
machine instruction
operand
operation
packed decimal
pop
procedure call
procedure return
push
reentrant procedure
rotate
skip
stack

Review Questions

- 13.1 What are the typical elements of a machine instruction?
- 13.2 What types of locations can hold source and destination operands?
- 13.3 If an instruction contains four addresses, what might be the purpose of each address?
- 13.4 List and briefly explain five important instruction set design issues.
- 13.5 What types of operands are typical in machine instruction sets?
- 13.6 What is the relationship between the IRA character code and the packed decimal representation?

- 13.7 What is the difference between an arithmetic shift and a logical shift?
- 13.8 Why are transfer of control instructions needed?
- 13.9 List and briefly explain two common ways of generating the condition to be tested in a conditional branch instruction.
- 13.10 What is meant by the term *nesting of procedures*?
- 13.11 List three possible places for storing the return address for a **procedure return**.
- 13.12 What is a reentrant procedure?
- 13.13 What is **reverse Polish notation**?
- 13.14 What is the difference between big endian and little endian?

Problems

- 13.1 Show in hex notation:
- The packed decimal format for 23.
 - The ASCII characters 23.
- 13.2 For each of the following packed decimal numbers, show the decimal value:
- 0111 0011 0000 1001
 - 0101 1000 0010
 - 0100 1010 0110
- 13.3 A given microprocessor has words of 1 byte. What is the smallest and largest integer that can be represented in the following representations?
- Unsigned.
 - Sign-magnitude.
 - Ones complement.
 - Twos complement.
 - Unsigned packed decimal.
 - Signed packed decimal.
- 13.4 Many processors provide logic for performing arithmetic on packed decimal numbers. Although the rules for decimal arithmetic are similar to those for binary operations, the decimal results may require some corrections to the individual digits if binary logic is used. Consider the decimal addition of two unsigned numbers. If each number consists of N digits, then there are $4N$ bits in each number. The two numbers are to be added using a binary adder. Suggest a simple rule for correcting the result. Perform addition in this fashion on the numbers 1698 and 1786.
- 13.5 The tens complement of the decimal number X is defined to be $10^N - X$, where N is the number of decimal digits in the number. Describe the use of ten's complement representation to perform decimal subtraction. Illustrate the procedure by subtracting $(0326)_{10}$ from $(0736)_{10}$.
- 13.6 Compare zero-, one-, two-, and three-address machines by writing programs to compute

for each of the four machines. The instructions available for use are as follows:

0 Address	1 Address	2 Address	3 Address
PUSH M	LOAD M	MOVE (X \leftarrow Y)	MOVE (X \leftarrow Y)
POP M	STORE M	ADD (X \leftarrow X + Y)	ADD (X \leftarrow Y + Z)

ADD	ADD M	SUB ($X \leftarrow X - Y$)	SUB ($X \leftarrow Y - Z$)
SUB	SUB M	MUL ($X \leftarrow X \times Y$)	MUL ($X \leftarrow Y \times Z$)
MUL	MUL M	DIV ($X \leftarrow X / Y$)	DIV ($X \leftarrow Y / Z$)
DIV	DIV M		

13.7 Consider a hypothetical computer with an instruction set of only two n -bit instructions. The first bit specifies the opcode, and the remaining bits specify one of the 2^{n-1} n -bit words of main memory. The two instructions are as follows:

SUBS X	Subtract the contents of location X from the accumulator, and store the result in location X and the accumulator.
JUMP X	Place address X in the program counter.

A word in main memory may contain either an instruction or a binary number in two's complement notation. Demonstrate that this instruction repertoire is reasonably complete by specifying how the following operations can be programmed:

- Data transfer: Location X to accumulator, accumulator to location X.
- Addition: Add contents of location X to accumulator.
- Conditional branch.
- Logical OR.
- I/O Operations.

13.8 Many instruction sets contain the instruction NOOP, meaning no operation, which has no effect on the processor state other than incrementing the program counter. Suggest some uses of this instruction.

13.9 In [Section 13.4](#), it was stated that both an arithmetic left shift and a logical left shift correspond to a multiplication by 2 when there is no overflow, and if overflow occurs, arithmetic and logical left shift operations produce different results, but the arithmetic left shift retains the sign of the number. Demonstrate that these statements are true for 5-bit two's complement integers.

13.10 In what way are numbers rounded using arithmetic right shift (e.g., round toward $+\infty$, round toward $-\infty$, toward zero, away from 0)?

13.11 Suppose a stack is to be used by the processor to manage procedure calls and returns. Can the program counter be eliminated by using the top of the stack as a program counter?

13.12 The x86 architecture includes an instruction called Decimal Adjust after Addition (DAA). DAA performs the following sequence of instructions:

```

if ((AL AND 0FH) >9) OR (AF = 1) then
    AL ← AL + 6;
    AF ← 1;
else

```

```

        AF d 0;
endif;
if (AL > 9FH) OR (CF = 1) then
    AL ← AL + 60H;
    CF ← 1;
else
    CF ← 0;
endif.

```

"H" indicates hexadecimal. AL is an 8-bit register that holds the result of addition of two unsigned 8-bit integers. AF is a flag set if there is a carry from bit 3 to bit 4 in the result of an addition. CF is a flag set if there is a carry from bit 7 to bit 8. Explain the function performed by the DAA instruction.

13.13 The x86 Compare instruction (CMP) subtracts the source operand from the destination operand; it updates the status flags (C, P, A, Z, S, O) but does not alter either of the operands. The CMP instruction can be used to determine if the destination operand is greater than, equal to, or less than the source operand.

- Suppose the two operands are treated as unsigned integers. Show which status flags are relevant to determine the relative size of the two integers and what values of the flags correspond to greater than, equal to, or less than.
- Suppose the two operands are treated as two's complement signed integers. Show which status flags are relevant to determine the relative size of the two integers and what values of the flags correspond to greater than, equal to, or less than.
- The CMP instruction may be followed by a conditional Jump (Jcc) or Set Condition (SETcc) instruction, where cc refers to one of the 16 conditions listed in [Table 13.11](#). Demonstrate that the conditions tested for a signed number comparison are correct.

13.14 Suppose we wished to apply the x86 CMP instruction to 32-bit operands that contained numbers in a floating-point format. For correct results, what requirements have to be met in the following areas?

- The relative position of the significand, sign, and exponent fields.
- The representation of the value zero.
- The representation of the exponent.
- Does the IEEE format meet these requirements? Explain.

13.15 Many microprocessor instruction sets include an instruction that tests a condition and sets a destination operand if the condition is true. Examples include the SETcc on the x86, the Scc on the Motorola MC68000, and the Scond on the National NS32000.

- There are a few differences among these instructions:
 - SETcc and Scc operate only on a byte, whereas Scond operates on byte, word, and doubleword operands.
 - SETcc and Scond set the operand to integer one if true and to zero if false. Scc sets the byte to all binary ones if true and all zeros if false. What are the relative advantages and disadvantages of these differences?
- None of these instructions set any of the condition code flags, and thus an explicit test of the result of the instruction is required to determine its value. Discuss whether condition codes should be set as a result of this instruction.
- A simple IF statement such as IF $a > b$ THEN can be implemented using a numerical representation method, that is, making the Boolean value manifest, as opposed to a *flow of control* method, which represents the value of a Boolean expression by a point reached in the program. A compiler might implement IF $a > ssb$ THEN with the following

x86 code:

	SUB	CX, CX	;set register CX to 0
	MOV	AX, B	;move contents of location B to register AX
	CMP	AX, A	;compare contents of register AX and location A
	JLE	TEST	;jump if $A \leq B$
	INC	CX	;add 1 to contents of register CX
TEST	JCXZ	OUT	;jump if contents of CX equal 0
THEN		OUT	

The result of $(A > B)$ is a Boolean value held in a register and available later on, outside the context of the flow of code just shown. It is convenient to use register CX for this, because many of the branch and loop opcodes have a built-in test for CX.

Show an alternative implementation using the SETcc instruction that saves memory and execution time. (*Hint:* No additional new x86 instructions are needed, other than the SETcc.)

- d. Now consider the high-level language statement $A \text{ AND } (B > C) \text{ OR } (D = F)$

A compiler might generate the following code:

	MOV	EAX, B	;move contents of location B to register EAX
	CMP	EAX, C	;compare contents of register EAX and location C
	MOV	BL, 0	;0 represents false
	JLE	N1	;jump if $(B \leq C)$
	MOV	BL, 1	;1 represents false
N1	MOV	EAX, D	
	CMP	EAX, F	
	MOV	BH, 0	
	JNE	N2	
	MOV	BH, 1	
N2	OR	BL, BH	

Show an alternative implementation using the SETcc instruction that saves memory and execution time.

13.16 Suppose that two registers contain the following hexadecimal values: AB0890C2, 4598EE50. What is the result of adding them using MMX instructions:

- a. packed byte.
- b. packed word.

Assume saturation arithmetic is not used.

13.17 [Appendix E](#) points out that there are no stack-oriented instructions in an instruction set if the stack is to be used only by the processor for such purposes as procedure handling.

How can the processor use a stack for any purpose without stack-oriented instructions?

13.18 Mathematical formulas are usually expressed in what is known as infix notation, in which a binary operator appears between the operands. An alternative technique is known as reverse Polish, or postfix, notation, in which the operator follows its two operands. See [Appendix E](#) for more details. Convert the following formulas from reverse Polish to infix:

- a. AB + C + D ×
- b. AB / CD / +
- c. ABCDE + × × /
- d. ABCDE + F / + G - H / × +

13.19 Convert the following formulas from infix to reverse Polish:

- a. A + B + C + D + E
- b. (A + B) × (C + D) + E
- c. (A × B) + (C × D) + E
- d. (A - B) × ((C - D × E) / F) / G) × H

13.20 Convert the expression $A + B - C$ to postfix notation using Dijkstra's algorithm. Show the steps involved. Is the result equivalent to $(A + B) - C$ or $A + (B - C)$? Does it matter?

13.21 Using the algorithm for converting infix to postfix defined in [Appendix E](#), show the steps involved in converting the expression of [Figure E.3](#) into postfix. Use a presentation similar to [Figure E.5](#).

13.22 Show the calculation of the expression in [Figure E.5](#), using a presentation similar to [Figure E.4](#).

13.23 Redraw the little-endian layout in [Figure 13.13](#) so that the bytes appear as numbered in the big-endian layout. That is, show memory in 64-bit rows, with the bytes listed left to right, top to bottom.

```

struct{
    int      a;      //0x1112_1314          word
    int      pad;    //
    double   b;      //0x2122_2324_2526_2728    doubleword
    char*   c;      //0x3132_3334          word
    char    d[7];  //''A','B','C','D','E','F','G' byte array
    short   e;      //0x5152            halfword
    int      f;      //0x6162_6364        word
} s;

```

Big-endian address mapping										Little-endian address mapping											
Byte address	11	12	13	14							11	12	13	14							Byte address
00	00	01	02	03	04	05	06	07			07	06	05	04	03	02	01	00		00	
	21	22	23	24	25	26	27	28			21	22	23	24	25	26	27	28

13.24 For the following data structures, draw the big-endian and little-endian layouts, using the format of [Figure 13.13](#), and comment on the results.

a.

```
struct {
    double i;           //0x1112131415161718
} s1;
```

b.

```
struct {
    int i;             //0x11121314
    int j;             //0x15161718
} s2;
```

c.

```
struct {
    short i;           //0x1112
    short j;           //0x1314
    short k;           //0x1516
    short l;           //0x1718
} s3;
```

13.25 The IBM Power architecture specification does not dictate how a processor should

implement little-endian mode. It specifies only the view of memory a processor must have when operating in little-endian mode. When converting a data structure from big endian to little endian, processors are free to implement a true byte-swapping mechanism or to use some sort of an address modification mechanism. Current Power processors are all default big-endian machines and use address modification to treat data as little-endian.

Consider the structure `s` defined in [Figure 13.13](#). The layout in the lower-right portion of the figure shows the structure `s` as seen by the processor. In fact, if structures is compiled in little-endian mode, its layout in memory is shown in [Figure 13.13](#). Explain the mapping that is involved, describe an easy way to implement the mapping, and discuss the effectiveness of this approach.

Figure 13.12 Power Architecture Little-Endian Structures in Memory

13.26 Write a small program to determine the endianness of a machine and report the results. Run the program on a computer available to you and turn in the output.

13.27 The MIPS processor can be set to operate in either big-endian or little-endian mode. Consider the Load Byte Unsigned (LBU) instruction, which loads a byte from memory into the low-order 8 bits of a register and fills the high-order 24 bits of the register with zeros. The description of LBU is given in the MIPS reference manual using a register-transfer language as

```

mem ← LoadMemory(…)
byte ← VirtualAddress1..0
if CONDITION then
    GPR[rt] ← 024 | mem31 - 8 × byte .. 24 - 8 × byte
else
    GPR[rt] ← 024 | mem7 + 8 × byte .. 8 × byte
endif

```

where `byte` refers to the two low-order bits of the effective address and `mem` refers to the value loaded from memory. In the manual, instead of the word CONDITION, one of the following two words is used: BigEndian, LittleEndian. Which word is used?

13.28 Most, but not all, processors use big- or little-endian bit ordering within a byte that is consistent with big- or little-endian ordering of bytes within a multibyte scalar. Let us consider the Motorola 68030, which uses big-endian byte ordering. The documentation of the 68030 concerning formats is confusing. The user's manual explains that the bit ordering of bit fields is the opposite of bit ordering of integers. Most bit field operations operate with one endian

ordering, but a few bit field operations require the opposite ordering. The following description from the user's manual describes most of the bit field operations:

A bit operand is specified by a base address that selects one byte in memory (the base byte), and a bit number that selects the one bit in this byte. The most significant bit is bit seven. A bit field operand is specified by: **(1)** a base address that selects one byte in memory; **(2)** a bit field offset that indicates the leftmost (base) bit of the bit field in relation to the most significant bit of the base byte; and **(3)** a bit field width that determines how many bits to the right of the base byte are in the bit field. The most significant bit of the base byte is bit field offset 0, the least significant bit of the base byte is bit field offset 7.

Do these instructions use big-endian or little-endian bit ordering?

Appendix 13A Little-, Big-, and Bi-Endian

An annoying and curious phenomenon relates to how the bytes within a word and the bits within a byte are both referenced and represented. We look first at the problem of byte ordering and then consider that of bits.

Byte Ordering

The concept of endianness was first discussed in the literature by Cohen [COHE81]. With respect to bytes, endianness has to do with the byte ordering of multibyte scalar values. The issue is best introduced with an example. Suppose we have the 32-bit hexadecimal value 12345678, and that it is stored in a 32-bit word in byte-addressable memory at byte location 184. The value consists of 4 bytes, with the least significant byte containing the value 78 and the most significant byte containing the value 13. There are two obvious ways to store this value:

Address	Value	Address	Value
184	12	184	78
185	34	185	56
186	56	186	34
187	78	187	12

The mapping on the left stores the most significant byte in the lowest numerical byte address; this is known as **big endian** and is equivalent to the left-to-right order of writing in Western culture languages. The mapping on the right stores the least significant byte in the lowest numerical byte address; this is known as **little endian** and is reminiscent of the right-to-left order of arithmetic operations in arithmetic units.³ For a given multibyte scalar value, big endian and little endian are byte-reversed mappings of each other.

³ The terms *big endian* and *little endian* come from [Part I, Chapter 4](#) of Jonathan Swift's *Gulliver's Travels*. They refer to a religious war between two groups, one that breaks eggs at the big end and the other that breaks eggs at the little end.

The concept of endianness arises when it is necessary to treat a multiple-byte entity as a single data item with a single address, even though it is composed of smaller addressable units. Some machines, such as the Intel 80x86, x86, VAX, and Alpha, are little-endian machines, whereas others, such as the IBM System 370/390, the Motorola 680x0, Sun SPARC, and most RISC machines, are big endian. This presents problems when data are transferred from a machine of one endian type to the other, and when a programmer attempts to manipulate individual bytes or bits within a multibyte scalar.

The property of endianness does not extend beyond an individual data unit. In any machine, aggregates such as files, data structures, and arrays are composed of multiple data units, each with endianness. Thus, conversion of a block of memory from one style of endianness to the other requires knowledge of the data structure.

Figure 13.13 illustrates how endianness determines addressing and byte order. The C structure at the top contains a number of data types. The memory layout in the lower left results from compilation of that structure for a big-endian machine, and that in the lower right for a little-endian machine. In each case, memory is depicted as a series of 64-bit rows. For the big-endian case, memory typically is viewed left to right, top to bottom, whereas for the little-endian case, memory typically is viewed as right to left, top to bottom. Note that these layouts are arbitrary. Either scheme could use either left to right or right to left within a row; this is a matter of depiction, not memory assignment. In fact, in looking at programmer manuals for a variety of machines, a bewildering collection of depictions is to be found, even within the same manual.

```
struct{
    int a; //0x1112_1314           word
    int pad; //
    double b; //0x2122_2324_2526_2728   doubleword
    char* c; //0x3132_3334           word
    char d[7]; //'A','B','C','D','E','F','G' byte array
    short e; //0x5152                halfword
    int f; //0x6162_6364           word
} s;
```

We can make several observations about this data structure:

- Each data item has the same address in both schemes. For example, the address of the doubleword with hexadecimal value 2122232425262728 is 08.
- Within any given multibyte scalar value, the ordering of bytes in the little-endian structure is the reverse of that for the big-endian structure.
- Endianness does not affect the ordering of data items within a structure. Thus, the four-character word c exhibits byte reversal, but the seven-character byte array d does not. Hence, the address of each individual element of d is the same in both structures.

(b) Little endian

Figure 13.14 Another View of Figure 13.13

The effect of endianness is perhaps more clearly demonstrated when we view memory as a vertical array of bytes, as shown in [Figure 13.14](#).

There is no general consensus as to which is the superior style of endianness.⁴ The following points favor the big-endian style:

⁴ The prophet revered by both groups in the Endian Wars of *Gulliver's Travels* had this to say. "All true Believers shall break their Eggs at the convenient End." Not much help!

- **Character-string sorting:** A big-endian processor is faster in comparing integer-aligned character strings; the integer ALU can compare multiple bytes in parallel.

- **Decimal/IRA dumps:** All values can be printed left to right without causing confusion.
- **Consistent order:** Big-endian processors store their integers and character strings in the same order (most significant byte comes first).

The following points favor the little-endian style:

- A big-endian processor has to perform addition when it converts a 32-bit integer address to a 16-bit integer address, to use the least significant bytes.
- It is easier to perform higher-precision arithmetic with the little-endian style; you don't have to find the least-significant byte and move backward.

The differences are minor and the choice of endian style is often more a matter of accommodating previous machines than anything else.

The PowerPC is a bi-endian processor that supports both big-endian and little-endian modes. The bi-endian architecture enables software developers to choose either mode when migrating operating systems and applications from other machines. The operating system establishes the endian mode in which processes execute. Once a mode is selected, all subsequent memory loads and stores are determined by the memory-addressing model of that mode. To support this hardware feature, 2 bits are maintained in the machine state register (MSR) maintained by the operating system as part of the process state. One bit specifies the endian mode in which the kernel runs; the other specifies the processor's current operating mode. Thus, mode can be changed on a per-process basis.

Bit Ordering

In ordering the bits within a byte, we are immediately faced with two questions:

1. Do you count the first bit as bit zero, or as bit one?
2. Do you assign the lowest bit number to the byte's least significant bit (little endian), or to the bytes, most significant bit (big endian)?

These questions are not answered in the same way on all machines. Indeed, on some machines, the answers are different in different circumstances. Furthermore, the choice of big- or little-endian bit ordering within a byte is not always consistent with big- or little-endian ordering of bytes within a multibyte scalar. The programmer needs to be concerned with these issues when manipulating individual bits.

Another area of concern is when data are transmitted over a bit-serial line. When an individual byte is transmitted, does the system transmit the most significant bit first, or the least significant bit first? The designer must make certain that incoming bits are handled properly. For a discussion of this issue, see [JAME90].

Learning Objectives

After studying this chapter, you should be able to:

- Describe the various types of addressing modes common in instruction sets.
- Present an overview of x86 and ARM addressing modes.
- Summarize the issues and trade-offs involved in designing an **instruction format** .
- Present an overview of x86 and ARM instruction formats.
- Understand the distinction between machine language and assembly language.

In **Chapter 13**, we focused on what an instruction set does. Specifically, we examined the types of operands and operations that may be specified by machine instructions. This chapter turns to the question of how to specify the operands and operations of instructions. Two issues arise. First, how is the address of an operand specified, and second, how are the bits of an instruction organized to define the operand addresses and operation of that instruction?

14.1 Addressing Modes

The address field or fields in a typical instruction format are relatively small. We would like to be able to reference a large range of locations in main memory or, for some systems, virtual memory. To achieve this objective, a variety of addressing techniques has been employed. They all involve some trade-off between address range and/or addressing flexibility, on the one hand, and the number of memory references in the instruction and/or the complexity of address calculation, on the other. In this section, we examine the most common addressing techniques, or modes:

- Immediate
- Direct
- Indirect
- Register
- Register indirect
- Displacement
- Stack

These modes are illustrated in **Figure 14.1**. In this section, we use the following notation:

A = contents of an address field in the instruction

R = contents of an address field in the instruction that refers to a register

EA = actual (effective) address of the location containing the referenced operand

(X) = contents of memory location X or register X

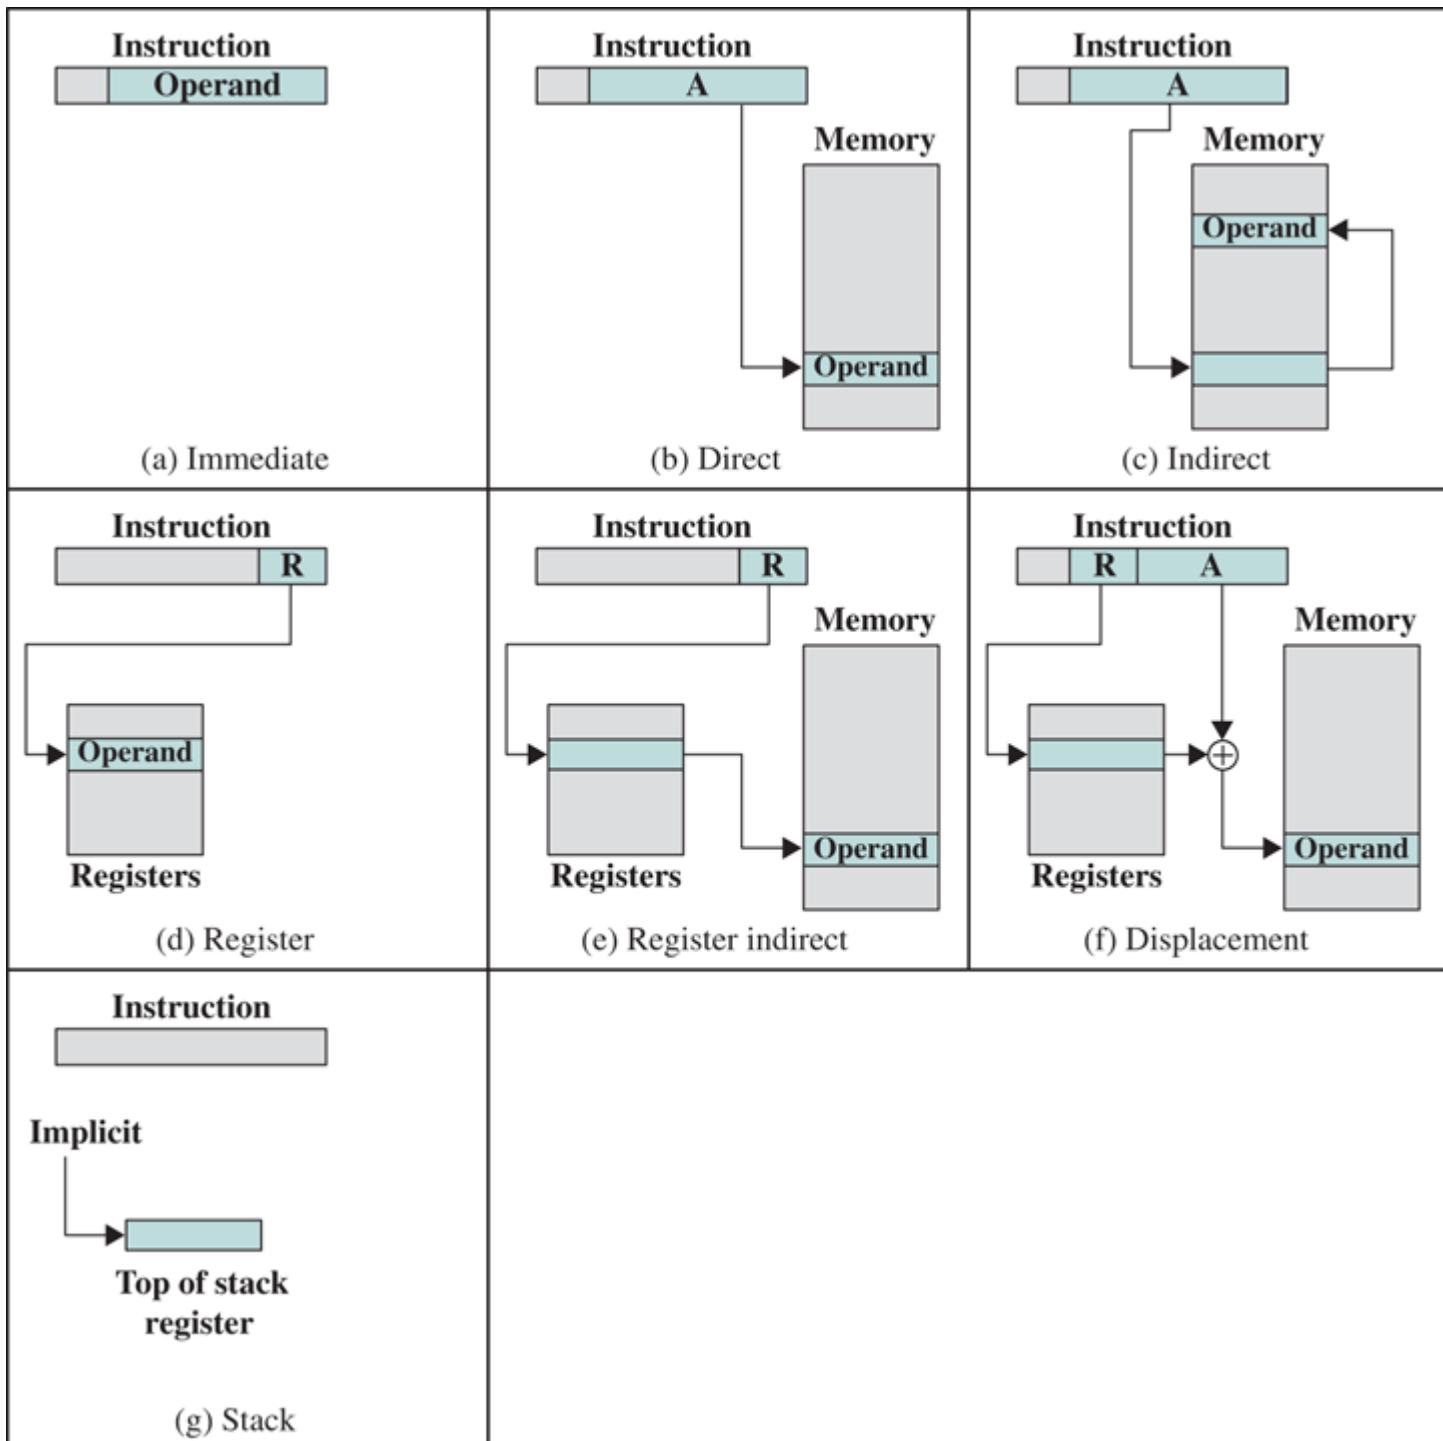

Figure 14.1 Addressing Modes

Table 14.1 indicates the address calculation performed for each addressing mode.

Table 14.1 Basic Addressing Modes

Mode	Algorithm	Principal Advantage	Principal Disadvantage
Immediate	$\text{Operand} = \text{A}$	No memory reference	Limited operand magnitude
Direct	$\text{EA} = \text{A}$	Simple	Limited address space
Indirect	$\text{EA} = (\text{A})$	Large address space	Multiple memory references
	$\text{EA} = \text{R}$		

Register		No memory reference	Limited address space
Register indirect	$EA = (R)$	Large address space	Extra memory reference
Displacement	$EA = A + (R)$	Flexibility	Complexity
Stack	$EA = \text{top of stack}$	No memory reference	Limited applicability

Before beginning this discussion, two comments need to be made. First, virtually all computer architectures provide more than one of these addressing modes. The question arises as to how the processor can determine which address mode is being used in a particular instruction. Several approaches are taken. Often, different opcodes will use different addressing modes. Also, one or more bits in the instruction format can be used as a *mode field*. The value of the mode field determines which addressing mode is to be used.

The second comment concerns the interpretation of the effective address (EA). In a system without virtual memory, the **effective address** will be either a main memory address or a register. In a virtual memory system, the effective address is a virtual address or a register. The actual mapping to a physical address is a function of the memory management unit (MMU) and is invisible to the programmer.

Immediate Addressing

The simplest form of addressing is **immediate addressing**, in which the operand value is present in the instruction

$$\text{Operand} = A$$

This mode can be used to define and use constants or set initial values of variables. Typically, the number will be stored in two's complement form; the leftmost bit of the operand field is used as a sign bit. When the operand is loaded into a data register, the sign bit is extended to the left to the full data **word** size. In some cases, the immediate binary value is interpreted as an unsigned nonnegative integer.

The advantage of immediate addressing is that no memory reference other than the instruction fetch is required to obtain the operand, thus saving one memory or cache cycle in the instruction cycle. The disadvantage is that the size of the number is restricted to the size of the address field, which, in most instruction sets, is small compared with the word length.

Direct Addressing

A very simple form of addressing is direct addressing, in which the address field contains the effective address of the operand:

$$EA = A$$

The technique was common in earlier generations of computers, but is not common on contemporary architectures. It requires only one memory reference and no special calculation. The obvious limitation is that it provides only a limited address space.

Indirect Addressing

With direct addressing, the length of the address field is usually less than the word length, thus limiting the address range. One solution is to have the address field refer to the address of a word in memory, which in turn contains a full-length address of the operand. This is known as **indirect addressing** :

$$EA = (A)$$

As defined earlier, the parentheses are to be interpreted as meaning *contents of* N . The obvious advantage of this approach is that for a word length of N , an address space of 2^N is now available. The disadvantage is that instruction execution requires two memory references to fetch the operand: one to get its address and a second to get its value.

Although the number of words that can be addressed is now equal to 2^N , the number of different effective addresses that may be referenced at any one time is limited to 2^K , where K is the length of the address field. Typically, this is not a burdensome restriction, and it can be an asset. In a virtual memory environment, all the effective address locations can be confined to page 0 of any process. Because the address field of an instruction is small, it will naturally produce low-numbered direct addresses, which would appear in page 0. (The only restriction is that the page size must be greater than or equal to 2^K .) When a process is active, there will be repeated references to page 0, causing it to remain in real memory. Thus, an indirect memory reference will involve, at most, one page fault rather than two.

A rarely used variant of indirect addressing is multilevel or cascaded indirect addressing:

$$EA = (\dots (A) \dots)$$

In this case, one bit of a full-word address is an indirect flag (I). If the I bit is 0, then the word contains the EA. If the I bit is 1, then another level of indirection is invoked. There does not appear to be any particular advantage to this approach, and its disadvantage is that three or more memory references could be required to fetch an operand.

Register Addressing

Register addressing is similar to direct addressing. The only difference is that the address field refers to a register rather than a main memory address:

$$EA = R$$

To clarify, if the contents of a register address field in an instruction is 5, then register R5 is the intended address, and the operand value is contained in R5. Typically, an address field that references registers will have from 3 to 5 bits, so that a total of from 8 to 32 general-purpose registers can be referenced.

The advantages of register addressing are that (1) only a small address field is needed in the instruction, and (2) no time-consuming memory references are required. As was discussed in [Chapter 5](#), the memory access time for a register internal to the processor is much less than that for a main memory address. The disadvantage of register addressing is that the address space is very limited.

If register addressing is heavily used in an instruction set, this implies that the processor registers will be heavily used. Because of the severely limited number of registers (compared with main memory locations), their use in this fashion makes sense only if they are employed efficiently. If every operand

is brought into a register from main memory, operated on once, and then returned to main memory, then a wasteful intermediate step has been added. If, instead, the operand in a register remains in use for multiple operations, then a real savings is achieved. An example is the intermediate result in a calculation. In particular, suppose that the algorithm for two's complement multiplication were to be implemented in software. The location labeled A in the flowchart ([Figure 11.12](#)) is referenced many times and should be implemented in a register rather than a main memory location.

It is up to the programmer or compiler to decide which values should remain in registers, and which should be stored in main memory. Most modern processors employ multiple general-purpose registers, placing a burden for efficient execution on the assembly-language programmer (e.g., compiler writer).

Register Indirect Addressing

Just as register addressing is analogous to direct addressing, **register indirect addressing** is analogous to indirect addressing. In both cases, the only difference is whether the address field refers to a memory location or a register. Thus, for register indirect address,

$$EA = (R)$$

The advantages and limitations of register indirect addressing are basically the same as for indirect addressing. In both cases, the address space limitation (limited range of addresses) of the address field is overcome by having that field refer to a word-length location containing an address. In addition, register indirect addressing uses one less memory reference than indirect addressing.

Displacement Addressing

A very powerful mode of addressing combines the capabilities of direct addressing and register indirect addressing. It is known by a variety of names depending on the context of its use, but the basic mechanism is the same. We will refer to this as **displacement addressing**:

$$EA = A + (R)$$

Displacement addressing requires that the instruction have two address fields, at least one of which is explicit. The value contained in one address field ($value = A$) is used directly. The other address field, or an implicit reference based on opcode, refers to a register whose contents are added to A to produce the effective address.

We will describe three of the most common uses of displacement addressing:

- Relative addressing
- Base-register addressing
- Indexing

Relative Addressing

For relative addressing, also called PC-relative addressing, the implicitly referenced register is the program counter (PC). That is, the next instruction address is added to the address field to produce the EA. Typically, the address field is treated as a two's complement number for this operation. Thus, the effective address is a displacement relative to the address of the instruction.

Relative addressing exploits the concept of locality that was discussed in [Chapters 4 and 9](#). If most

memory references are relatively near to the instruction being executed, then the use of relative addressing saves address bits in the instruction.

Base-Register Addressing

For **base-register addressing**, the interpretation is the following: The referenced register contains a main memory address, and the address field contains a displacement (usually an unsigned integer representation) from that address. The register reference may be explicit or implicit.

Base-register addressing also exploits the locality of memory references. It is a convenient means of implementing segmentation, which was discussed in [Chapter 9](#). In some implementations, a single segment-base register is employed and is used implicitly. In others, the programmer may choose a register to hold the base address of a segment, and the instruction must reference it explicitly. In this latter case, if the length of the address field is K and the number of possible registers is N , then one instruction can reference any one of N areas of 2^K words.

Indexing

For indexing, the interpretation is typically the following: The address field references a main memory address, and the referenced register contains a positive displacement from that address. Note that this usage is just the opposite of the interpretation for base-register addressing. Of course, it is more than just a matter of user interpretation. Because the address field is considered to be a memory address in indexing, it generally contains more bits than an address field in a comparable base-register instruction. Also, we will see that there are some refinements to indexing that would not be as useful in the base-register context. Nevertheless, the method of calculating the EA is the same for both base-register addressing and indexing, and in both cases the register reference is sometimes explicit and sometimes implicit (for different processor types).

An important use of indexing is to provide an efficient mechanism for performing iterative operations. Consider, for example, a list of numbers stored starting at location A. Suppose that we would like to add 1 to each element on the list. We need to fetch each value, add 1 to it, and store it back. The sequence of effective addresses that we need is $A, A + 1, A + 2, \dots$, up to the last location on the list. With indexing, this is easily done. The value A is stored in the instruction's address field, and the chosen register, called an *index register*, is initialized to 0. After each operation, the index register is incremented by 1.

Because index registers are commonly used for such iterative tasks, it is typical that there is a need to increment or decrement the index register after each reference to it. Because this is such a common operation, some systems will automatically do this as part of the same instruction cycle. This is known as **autoindexing**. If certain registers are devoted exclusively to indexing, then autoindexing can be invoked implicitly and automatically. If general-purpose registers are used, the autoindex operation may need to be signaled by a bit in the instruction. Autoindexing using increment can be depicted as follows.

$$\begin{aligned} EA &= A + (R) \\ (R) &\leftarrow (R) + 1 \end{aligned}$$

In some machines, both indirect addressing and indexing are provided, and it is possible to employ both in the same instruction. There are two possibilities: the indexing is performed either before or after the indirection.

If indexing is performed after the indirection, it is termed **postindexing**:

$$EA = (A) + (R)$$

First, the contents of the address field are used to access a memory location containing a direct address. This address is then indexed by the register value. This technique is useful for accessing one of a number of blocks of data of a fixed format. For example, it was described in [Chapter 9](#) that the operating system needs to employ a process control block for each process. The operations performed are the same regardless of which block is being manipulated. Thus, the addresses in the instructions that reference the block could point to a location (value = A) containing a variable pointer to the start of a process control block. The index register contains the displacement within the block.

With **preindexing**, the indexing is performed before the indirection:

$$EA = (A + (R))$$

An address is calculated as with simple indexing. In this case, however, the calculated address contains not the operand, but the address of the operand. An example of the use of this technique is to construct a multiway branch table. At a particular point in a program, there may be a branch to one of a number of locations depending on conditions. A table of addresses can be set up starting at location A. By indexing into this table, the required location can be found.

Typically, an instruction set will not include both preindexing and postindexing.

Stack Addressing

The final addressing mode that we consider is stack addressing. As defined in Appendix E, a stack is a linear array of locations. It is sometimes referred to as a *pushdown list* or *last-in-first-out queue*. The stack is a reserved block of locations. Items are appended to the top of the stack so that, at any given time, the block is partially filled. Associated with the stack is a pointer whose value is the address of the top of the stack. Alternatively, the top two elements of the stack may be in processor registers, in which case the stack pointer references the third element of the stack. The stack pointer is maintained in a register. Thus, references to stack locations in memory are in fact register indirect addresses.

The stack mode of addressing is a form of implied addressing. The machine instructions need not include a memory reference, but implicitly operate on the top of the stack.

14.2 x86 and ARM Addressing Modes

x86 Addressing Modes

Recall from [Figure 9.21](#) that the x86 address translation mechanism produces an address, called a virtual or effective address, that is an offset into a segment. The sum of the starting address of the segment and the effective address produces a linear address. If paging is being used, this linear address must pass through a page-translation mechanism to produce a physical address. In what follows, we ignore this last step because it is transparent to the instruction set and to the programmer.

The x86 is equipped with a variety of addressing modes intended to allow the efficient execution of high-level languages. [Figure 14.2](#) indicates the logic involved. The segment register determines the segment that is the subject of the reference. There are six segment registers; the one being used for a particular reference depends on the context of execution and the instruction. Each segment register holds an index into the segment descriptor table ([Figure 9.20](#)), which holds the starting address of the corresponding segments. Associated with each user-visible segment register is a segment descriptor register (not programmer visible), which records the access rights for the segment as well as the starting address and limit (length) of the segment. In addition, there are two registers that may be used in constructing an address: the base register and the index register.

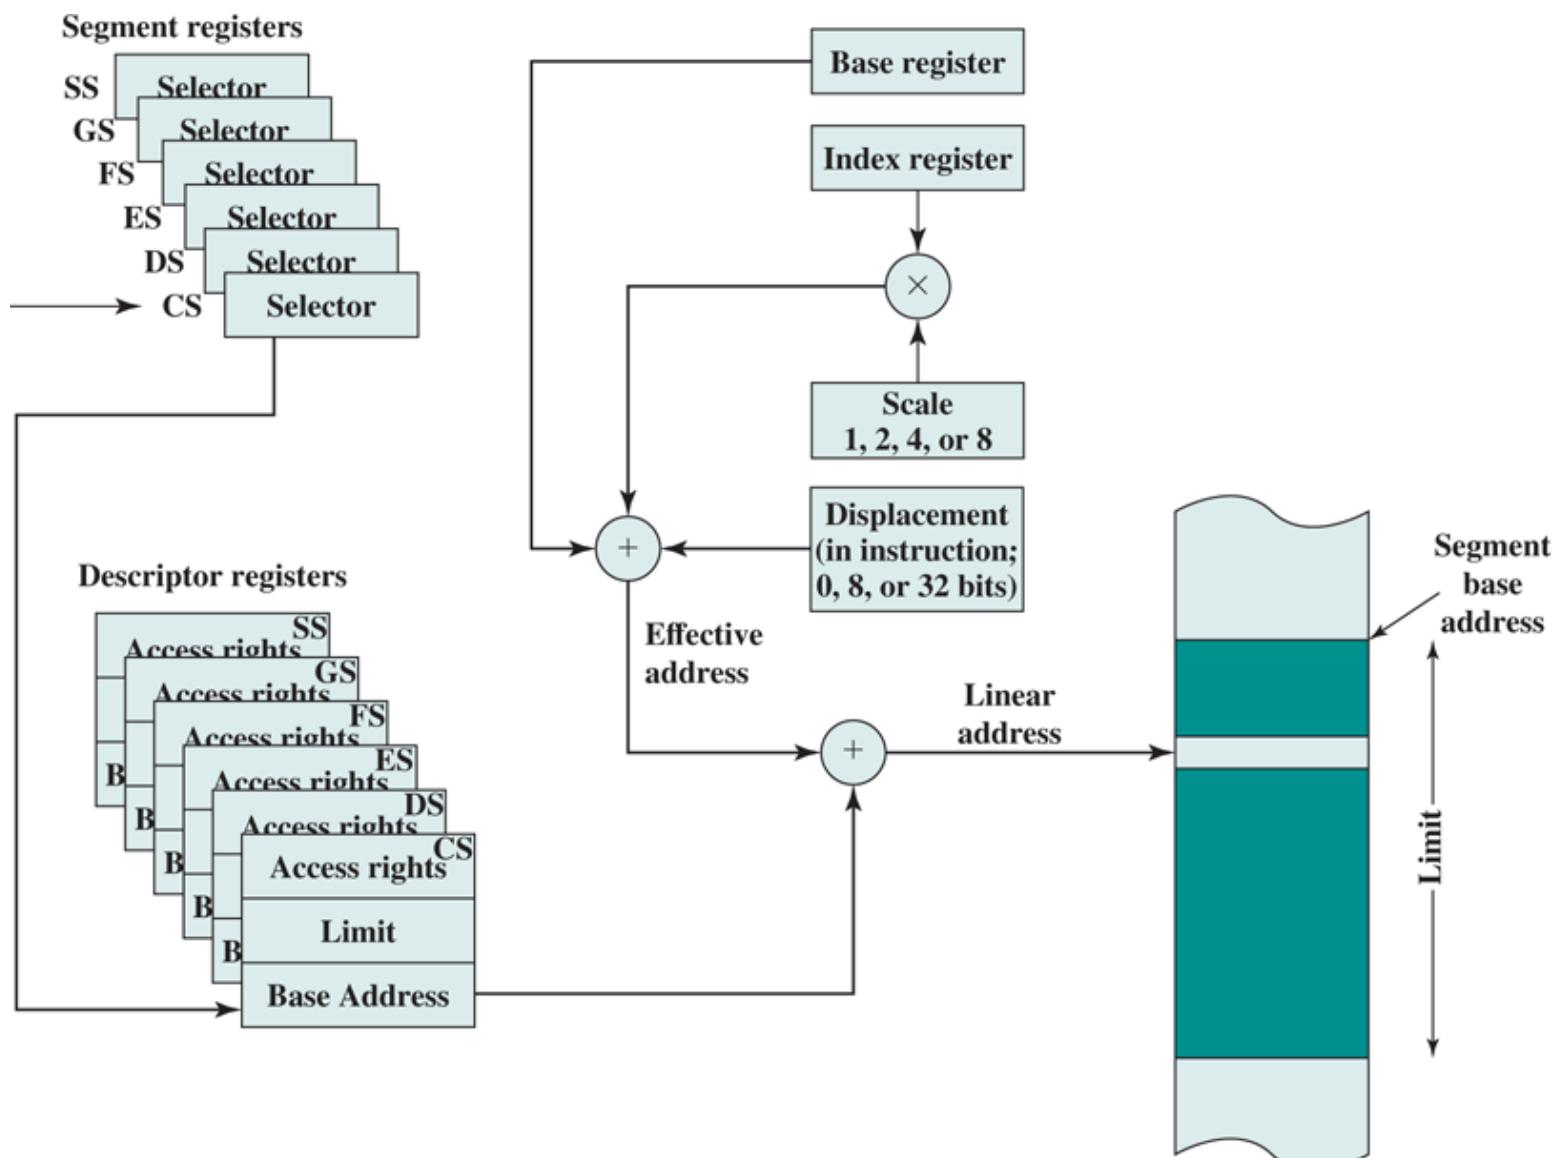

Figure 14.2 x86 Addressing Mode Calculation

Table 14.2 lists the x86 addressing modes. Let us consider each of these in turn.

Table 14.2 x86 Addressing Modes

LA = linear address

(X) = contents of X

SR = segment register

PC = program counter

A = contents of an address field in the instruction

R = register

B = base register

I = index register

S = scaling factor

Mode	Algorithm
Immediate	Operand = A
Register Operand	LA = R
Displacement	LA = (SR) + A
Base	LA = (SR) + (B)
Base with Displacement	LA = (SR) + (B) + A
Scaled Index with Displacement	LA = (SR) + (I) × S + A
Base with Index and Displacement	LA = (SR) + (B) + (I) + A
Base with Scaled Index and Displacement	LA = (SR) + (I) × S + (B) + A
Relative	LA = (PC) + A

For the **immediate mode**, the operand is included in the instruction. The operand can be a byte, word, or doubleword of data.

For **register operand mode**, the operand is located in a register. For general instructions, such as data transfer, arithmetic, and logical instructions, the operand can be one of the 32-bit general registers (EAX, EBX, ECX, EDX, ESI, EDI, ESP, EBP), one of the 16-bit general registers (AX, BX, CX, DX, SI, DI, SP, BP), or one of the 8-bit general registers (AH, BH, CH, DH, AL, BL, CL, DL). There are also some instructions that reference the segment selector registers (CS, DS, ES, SS, FS, GS).

The remaining addressing modes reference locations in memory. The memory location must be specified in terms of the segment containing the location and the offset from the beginning of the

segment. In some cases, a segment is specified explicitly; in others, the segment is specified by simple rules that assign a segment by default.

In the **displacement mode**, the operand's offset (the effective address of [Figure 14.2](#)) is contained as part of the instruction as an 8-, 16-, or 32-bit displacement. With segmentation, all addresses in instructions refer merely to an offset in a segment. The displacement addressing mode is found on few machines because, as mentioned earlier, it leads to long instructions. In the case of the x86, the displacement value can be as long as 32 bits, making for a 6-byte instruction. Displacement addressing can be useful for referencing global variables.

The remaining addressing modes are indirect, in the sense that the address portion of the instruction tells the processor where to look to find the address. The **base mode** specifies that one of the 8-, 16-, or 32-bit registers contains the effective address. This is equivalent to what we have referred to as register indirect addressing.

In the **base with displacement mode**, the instruction includes a displacement to be added to a base register, which may be any of the general-purpose registers. Examples of uses of this mode are as follows:

- Used by a compiler to point to the start of a local variable area. For example, the base register could point to the beginning of a stack frame, which contains the local variables for the corresponding procedure.
- Used to index into an array when the element size is not 1, 2, 4, or 8 bytes and which therefore cannot be indexed using an index register. In this case, the displacement points to the beginning of the array, and the base register holds the results of a calculation to determine the offset to a specific element within the array.
- Used to access a field of a record. The base register points to the beginning of the record, while the displacement is an offset to the field.

In the **scaled index with displacement mode**, the instruction includes a displacement to be added to a register, in this case called an index register. The index register may be any of the general-purpose registers except the one called ESP, which is generally used for stack processing. In calculating the effective address, the contents of the index register are multiplied by a scaling factor of 1, 2, 4, or 8, and then added to a displacement. This mode is very convenient for indexing arrays. A scaling factor of 2 can be used for an array of 16-bit integers. A scaling factor of 4 can be used for 32-bit integers or floating-point numbers. Finally, a scaling factor of 8 can be used for an array of double-precision floating-point numbers.

The **base with index and displacement mode** sums the contents of the base register, the index register, and a displacement to form the effective address. Again, the base register can be any general-purpose register and the index register can be any general-purpose register except ESP. As an example, this addressing mode could be used for accessing a local array on a stack frame. This mode can also be used to support a two-dimensional array; in this case, the displacement points to the beginning of the array, and each register handles one dimension of the array.

The **based scaled index with displacement mode** sums the contents of the index register multiplied by a scaling factor, the contents of the base register, and the displacement. This is useful if an array is stored in a stack frame; in this case, the array elements would be 2, 4, or 8 bytes each in length. This mode also provides efficient indexing of a two-dimensional array when the array elements are 2, 4, or 8 bytes in length.

Finally, **relative addressing** can be used in transfer-of-control instructions. A displacement is added to the value of the program counter, which points to the next instruction. In this case, the displacement is treated as a signed byte, word, or doubleword value, and that value either increases or decreases

the address in the program counter.

ARM Addressing Modes

Typically, a RISC machine, unlike a CISC machine, uses a simple and relatively straightforward set of addressing modes. The ARM architecture departs somewhat from this tradition by providing a relatively rich set of addressing modes. These modes are most conveniently classified with respect to the type of instruction.¹

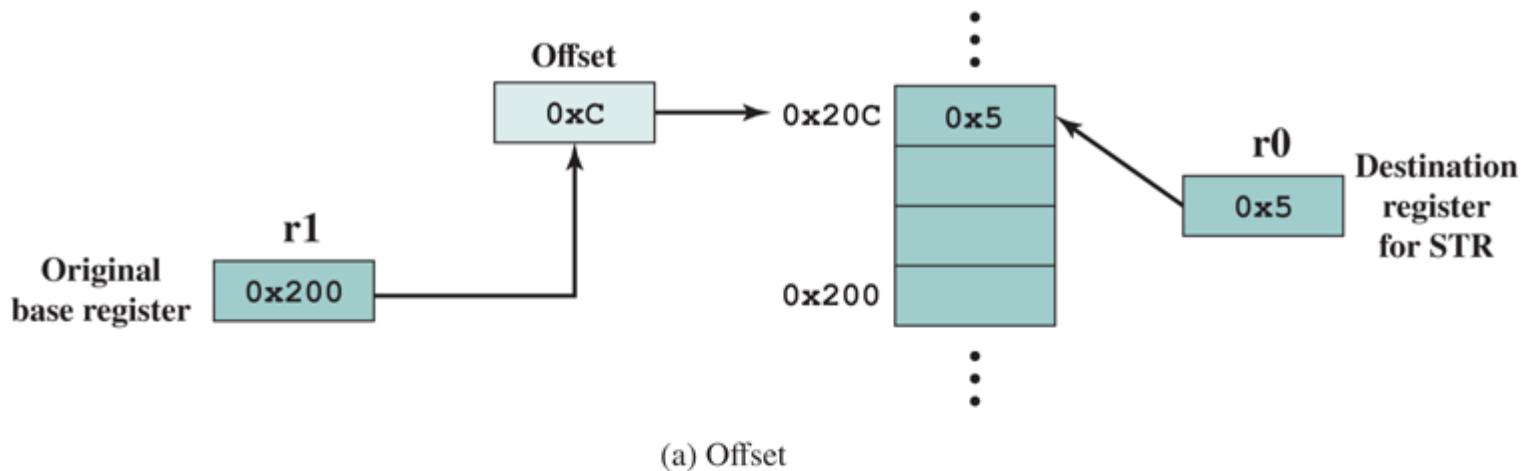

¹ As with our discussion of x86 addressing, we ignore the translation from virtual to physical address in the following discussion.

LOAD/STORE ADDRESSING

Load and store instructions are the only instructions that reference memory. This is always done indirectly through a base register plus offset. There are three alternatives with respect to indexing ([Figure 14.3](#)):

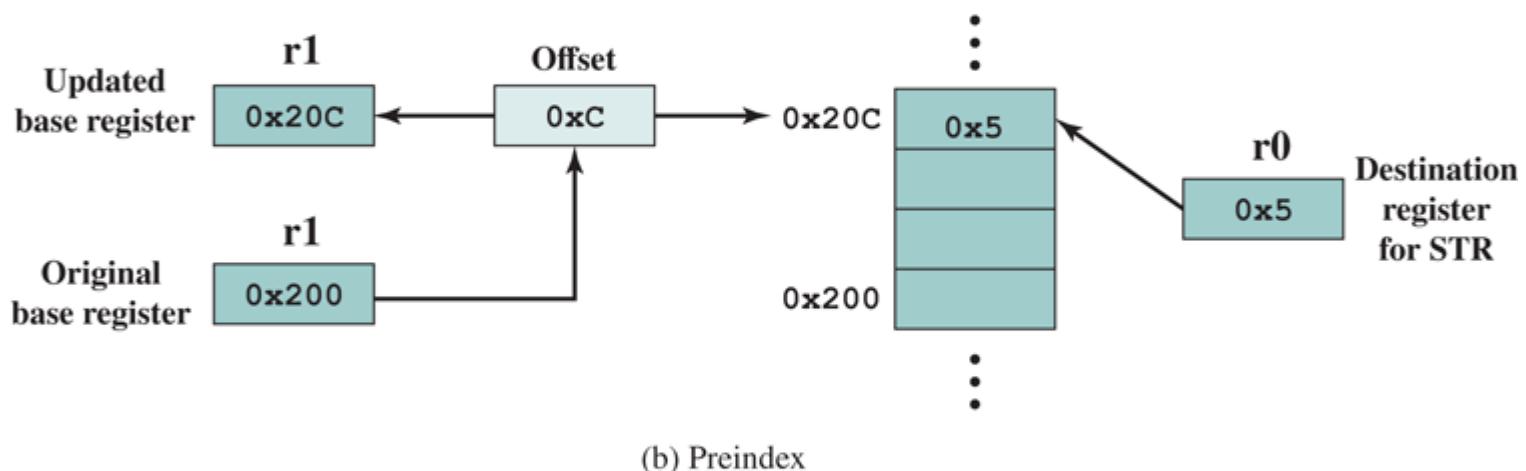

- **Offset:** For this addressing method, **indexing** is not used. An offset value is added to or subtracted from the value in the base register to form the memory address. As an example, [Figure 14.3a](#) illustrates this method with the assembly language instruction `STRB r0, [r1, #12]!`. This is the store byte instruction. In this case the base address is in register r1 and the displacement is an immediate value of decimal 12. The resulting address (base plus offset) is the location where the least significant byte from r0 is to be stored.
- **Preindex:** The memory address is formed in the same way as for offset addressing. The memory address is also written back to the base register. In other words, the base register value is incremented or decremented by the offset value. [Figure 14.3b](#) illustrates this method with the assembly language instruction `STRB r0, [r1, #12]!`. The exclamation point signifies preindexing.
- **Postindex:** The memory address is the base register value. An offset is added to or subtracted from the base register value and the result is written back to the base register. [Figure 14.3c](#) illustrates this method with the assembly language instruction `STRB r0, [r1], #12`.

STRB r0, [r1, #12]

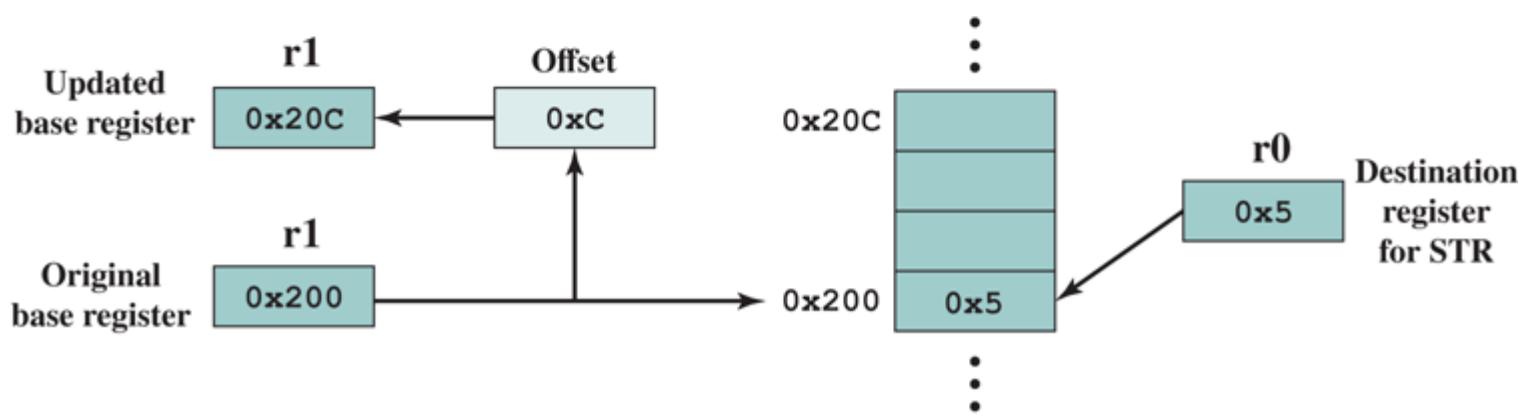

(a) Offset

STRB r0, [r1, #12]!

(b) Preindex

STRB r0, [r1], #12

(c) Postindex

Figure 14.3 ARM Indexing Methods

Note that what ARM refers to as a base register acts as an index register for preindex and postindex addressing. The offset value can either be an immediate value stored in the instruction, or it can be in another register. If the offset value is in a register, another useful feature is available: scaled register addressing. The value in the offset register is scaled by one of the shift operators: Logical Shift Left, Logical Shift Right, Arithmetic Shift Right, Rotate Right, or Rotate Right Extended (which includes the

carry bit in the rotation). The amount of the shift is specified as an immediate value in the instruction.

DATA PROCESSING INSTRUCTION ADDRESSING

Data processing instructions use either register addressing or a mixture of register and immediate addressing. For register addressing, the value in one of the register operands may be scaled using one of the five shift operators defined in the preceding paragraph.

BRANCH INSTRUCTIONS

The only form of addressing for branch instructions is immediate addressing. The branch instruction contains a 24-bit value. For address calculation, this value is shifted left 2 bits, so that the address is on a word boundary. Thus the effective address range is $\pm 32\text{MB}$ from the program counter.

LOAD/STORE MULTIPLE ADDRESSING

Load Multiple instructions load a subset (possibly all) of the general-purpose registers from memory. Store Multiple instructions store a subset (possibly all) of the general-purpose registers to memory. The list of registers for the load or store is specified in a 16-bit field in the instruction, with each bit corresponding to one of the 16 registers. Load and Store Multiple addressing modes produce a sequential range of memory addresses. The lowest-numbered register is stored at the lowest memory address and the highest-numbered register at the highest memory address. Four addressing modes are used (**Figure 14.4**): increment after, increment before, decrement after, and decrement before. A base register specifies a main memory address where register values are stored in or loaded from in ascending (increment) or descending (decrement) word locations. Incrementing or decrementing starts either before or after the first memory access.

```
LDMxx r10, {r0, r1, r4}  
STMxx r10, {r0, r1, r4}
```

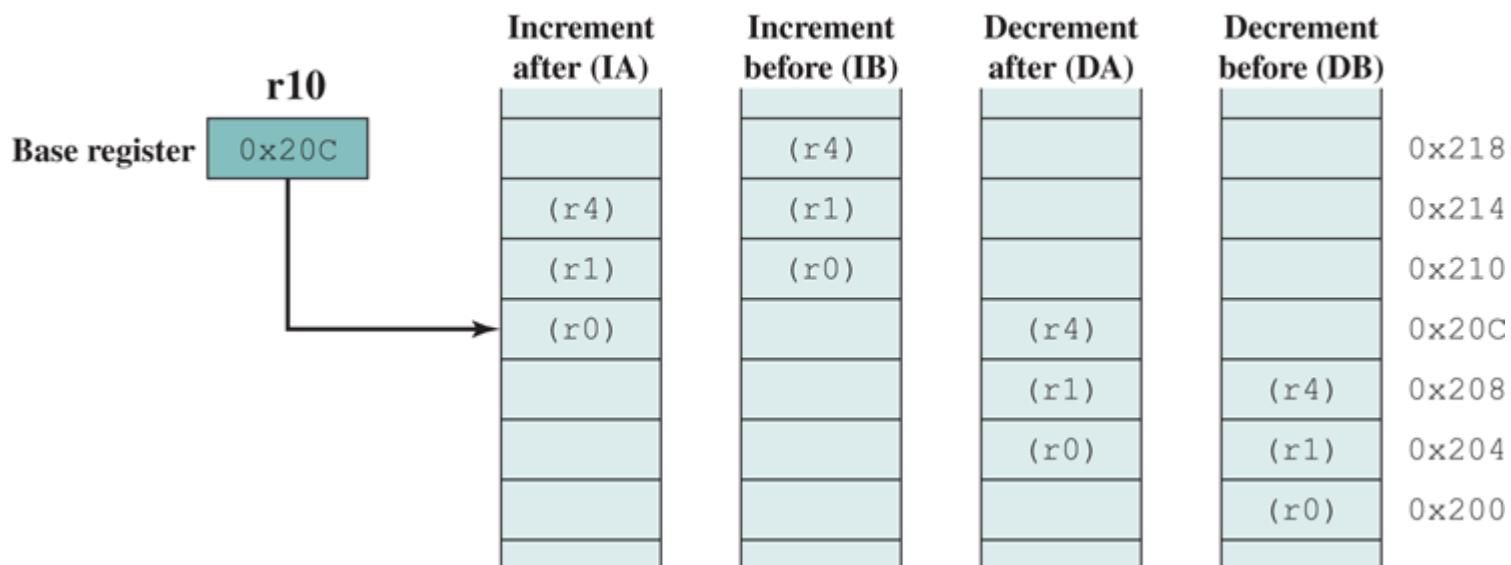

Figure 14.4 ARM Load/Store Multiple Addressing

These instructions are useful for block loads or stores, stack operations, and procedure exit sequences.

14.3 Instruction Formats

An instruction format defines the layout of the bits of an instruction, in terms of its constituent fields. An instruction format must include an opcode and, implicitly or explicitly, zero or more operands. Each explicit operand is referenced using one of the addressing modes described in [Section 14.1](#). The format must, implicitly or explicitly, indicate the addressing mode for each operand. For most instruction sets, more than one instruction format is used.

The design of an instruction format is a complex art, and an amazing variety of designs have been implemented. We examine the key design issues, looking briefly at some designs to illustrate points, and then we examine the x86 and ARM solutions in detail.

Instruction Length

The most basic design issue to be faced is the instruction format length. This decision affects, and is affected by, memory size, memory organization, bus structure, processor complexity, and processor speed. This decision determines the richness and flexibility of the machine as seen by the assembly-language programmer.

The most obvious trade-off here is between the desire for a powerful instruction repertoire and a need to save space. Programmers want more opcodes, more operands, more addressing modes, and greater address range. More opcodes and more operands make life easier for the programmer, because shorter programs can be written to accomplish given tasks. Similarly, more addressing modes give the programmer greater flexibility in implementing certain functions, such as table manipulations and multiple-way branching. And, of course, with the increase in main memory size and the increasing use of virtual memory, programmers want to be able to address larger memory ranges. All of these things (opcodes, operands, addressing modes, address range) require bits and push in the direction of longer instruction lengths. But longer instruction length may be wasteful. A 64-bit instruction occupies twice the space of a 32-bit instruction, but is probably less than twice as useful.

Beyond this basic trade-off, there are other considerations. Either the instruction length should be equal to the memory-transfer length (in a bus system, databus length) or one should be a multiple of the other. Otherwise, we will not get an integral number of instructions during a fetch cycle. A related consideration is the memory transfer rate. This rate has not kept up with increases in processor speed. Accordingly, memory can become a bottleneck if the processor can execute instructions faster than it can fetch them. One solution to this problem is to use cache memory (see [Section 4.3](#)); another is to use shorter instructions. Thus, 16-bit instructions can be fetched at twice the rate of 32-bit instructions, but probably can be executed less than twice as rapidly.

A seemingly mundane but nevertheless important feature is that the instruction length should be a multiple of the character length, which is usually 8 bits, and of the length of fixed-point numbers. To see this, we need to make use of that unfortunately ill-defined word, *word* [FRAI83]. The word length of memory is, in some sense, the “natural” unit of organization. The size of a word usually determines the size of fixed-point numbers (usually the two are equal). Word size is also typically equal to, or at least integrally related to, the memory transfer size. Because a common form of data is character data, we would like a word to store an integral number of characters. Otherwise, there are wasted bits in each word when storing multiple characters, or a character will have to straddle a word boundary. The importance of this point is such that IBM, when it introduced the System/360 and wanted to employ 8-bit characters, made the wrenching decision to move from the 36-bit architecture of the scientific members of the 700/7000 series to a 32-bit architecture.

Allocation of Bits

We've looked at some of the factors that go into deciding the length of the instruction format. An equally difficult issue is how to allocate the bits in that format. The trade-offs here are complex.

For a given instruction length, there is clearly a trade-off between the number of opcodes and the power of the addressing capability. More opcodes obviously mean more bits in the opcode field. For an instruction format of a given length, this reduces the number of bits available for addressing. There is one interesting refinement to this trade-off, and that is the use of variable-length opcodes. In this approach, there is a minimum opcode length but, for some opcodes, additional operations may be specified by using additional bits in the instruction. For a fixed-length instruction, this leaves fewer bits for addressing. Thus, this feature is used for those instructions that require fewer operands and/or less powerful addressing.

The following interrelated factors go into determining the use of the addressing bits.

- **Number of addressing modes:** Sometimes an addressing mode can be indicated implicitly. For example, certain opcodes might always call for indexing. In other cases, the addressing modes must be explicit, and one or more mode bits will be needed.
- **Number of operands:** We have seen that fewer addresses can make for longer, more awkward programs (e.g., [Figure 13.3](#)). Typical instruction formats on today's machines include two operands. Each operand address in the instruction might require its own mode indicator, or the use of a mode indicator could be limited to just one of the address fields.
- **Register versus memory:** A machine must have registers so that data can be brought into the processor for processing. With a single user-visible register (usually called the accumulator), one operand address is implicit and consumes no instruction bits. However, single-register programming is awkward and requires many instructions. Even with multiple registers, only a few bits are needed to specify the register. The more that registers can be used for operand references, the fewer bits are needed. A number of studies indicate that a total of 8 to 32 user-visible registers is desirable [LUND77, HUCK83]. Most contemporary architectures have at least 32 registers.
- **Number of register sets:** Most contemporary machines have one set of general-purpose registers, with typically 32 or more registers in the set. These registers can be used to store data and can be used to store addresses for displacement addressing. Some architectures, including that of the x86, have a collection of two or more specialized sets (such as data and displacement). One advantage of this latter approach is that, for a fixed number of registers, a functional split requires fewer bits to be used in the instruction. For example, with two sets of eight registers, only 3 bits are required to identify a register; the opcode or mode register will determine which set of registers is being referenced.
- **Address range:** For addresses that reference memory, the range of addresses that can be referenced is related to the number of address bits. Because this imposes a severe limitation, direct addressing is rarely used. With displacement addressing, the range is opened up to the length of the address register. Even so, it is still convenient to allow rather large displacements from the register address, which requires a relatively large number of address bits in the instruction.
- **Address granularity:** For addresses that reference memory rather than registers, another factor is the granularity of addressing. In a system with 16- or 32-bit words, an address can reference a word or a byte at the designer's choice. Byte addressing is convenient for character manipulation but requires, for a fixed-size memory, more address bits.

Thus, the designer is faced with a host of factors to consider and balance. How critical the various choices are is not clear. As an example, we cite one study [CRAG79] that compared various instruction format approaches, including the use of a stack, general-purpose registers, an

accumulator, and only memory-to-register approaches. Using a consistent set of assumptions, no significant difference in code space or execution time was observed.

Let us briefly look at how two historical machine designs balance these various factors.

PDP-8

One of the simplest instruction designs for a general-purpose computer was for the PDP-8 [BELL78b]. The PDP-8 uses 12-bit instructions and operates on 12-bit words. There is a single general-purpose register, the accumulator.

Despite the limitations of this design, the addressing is quite flexible. Each memory reference consists of 7 bits plus two 1-bit modifiers. The memory is divided into fixed-length pages of $2^7 = 128$ words each. Address calculation is based on references to page 0 or the current page (page containing this instruction) as determined by the page bit. The second modifier bit indicates whether direct or indirect addressing is to be used. These two modes can be used in combination, so that an indirect address is a 12-bit address contained in a word of page 0 or the current page. In addition, 8 dedicated words on page 0 are autoindex “registers.” When an indirect reference is made to one of these locations, preindexing occurs.

Figure 14.5 shows the PDP-8 instruction format. There are a 3-bit opcode and three types of instructions. For opcodes 0 through 5, the format is a single-address memory reference instruction including a page bit and an indirect bit. Thus, there are only six basic operations. To enlarge the group of operations, opcode 7 defines a register reference or *microinstruction*. In this format, the remaining bits are used to encode additional operations. In general, each bit defines a specific operation (e.g., clear accumulator), and these bits can be combined in a single instruction. The microinstruction strategy was used as far back as the PDP-1 by DEC and is, in a sense, a forerunner of today’s microprogrammed machines, to be discussed in Part Four. Opcode 6 is the I/O operation; 6 bits are used to select one of 64 devices, and 3 bits specify a particular I/O command.

Memory reference instructions												
Opcode		D/I	Z/C	Displacement								
0	2	3	4	5	11							
Input/output instructions												
1	1	0			Device				Opcode			
0		2	3		8	9		11

0	1	2	3	4	5	6	7	8	9	10	11	

D/I = Direct/Indirect address
 Z/C = Page 0 or Current page
 CLA = Clear Accumulator
 CLL = Clear Link
 CMA = CoMplement Accumulator
 CML = CoMplement Link
 RAR = Rotate Accumulator Right
 RAL = Rotate Accumulator Left
 BSW = Byte SWap

IAC = Increment ACcumulator
 SMA = Skip on Minus Accumulator
 SZA = Skip on Zero Accumulator
 SNL = Skip on Nonzero Link
 RSS = Reverse Skip Sense
 OSR = Or with Switch Register
 HLT = HaLT
 MQA = Multiplier Quotient into Accumulator
 MQL = Multiplier Quotient Load

Figure 14.5 PDP-8 Instruction Formats

The PDP-8 instruction format is remarkably efficient. It supports indirect addressing, displacement addressing, and indexing. With the use of the opcode extension, it supports a total of approximately 35 instructions. Given the constraints of a 12-bit instruction length, the designers could hardly have done better.

PDP-10

A sharp contrast to the instruction set of the PDP-8 is that of the PDP-10. The PDP-10 was designed to be a large-scale time-shared system, with an emphasis on making the system easy to program, even if additional hardware expense was involved.

Among the design principles employed in designing the instruction set were the following [BELL78c]:

- **Orthogonality:** Orthogonality is a principle by which two variables are independent of each other. In the context of an instruction set, the term indicates that other elements of an instruction are independent of (not determined by) the opcode. The PDP-10 designers use the term to describe the fact that an address is always computed in the same way, independent of the opcode. This is in contrast to many machines, where the address mode sometimes depends implicitly on the operator being used.
- **Completeness:** Each arithmetic data type (integer, fixed-point, floating-point) should have a complete and identical set of operations.
- **Direct addressing:** Base plus displacement addressing, which places a memory organization

burden on the programmer, was avoided in favor of direct addressing. Each of these principles advances the main goal of ease of programming.

The PDP-10 has a 36-bit word length and a 36-bit instruction length. The fixed instruction format is shown in [Figure 14.6](#). The opcode occupies 9 bits, allowing up to 512 operations. In fact, a total of 365 different instructions are defined. Most instructions have two addresses, one of which is one of 16 general-purpose registers. Thus, this operand reference occupies 4 bits. The other operand reference starts with an 18-bit memory address field. This can be used as an immediate operand or a memory address. In the latter usage, both indexing and indirect addressing are allowed. The same general-purpose registers are also used as index registers.

Opcode	Register	I	Index register	Memory address
0	8 9	12	14	17 18 35

I = indirect bit

Figure 14.6 PDP-10 Instruction Format

A 36-bit instruction length is a true luxury. There is no need to do clever things to get more opcodes; a 9-bit opcode field is more than adequate. Addressing is also straightforward. An 18-bit address field makes direct addressing desirable. For memory sizes greater than 2^{18} , indirection is provided. For the ease of the programmer, indexing is provided for table manipulation and iterative programs. Also, with an 18-bit operand field, immediate addressing becomes attractive.

The PDP-10 instruction set design does accomplish the objectives listed earlier [LUND77]. It eases the task of the programmer or compiler at the expense of an inefficient utilization of space. This was a conscious choice made by the designers and therefore cannot be faulted as poor design.

Variable-Length Instructions

The examples we have looked at so far have used a single fixed instruction length, and we have implicitly discussed trade-offs in that context. But the designer may choose instead to provide a variety of instruction formats of different lengths. This tactic makes it easy to provide a large repertoire of opcodes, with different opcode lengths. Addressing can be more flexible, with various combinations of register and memory references plus addressing modes. With variable-length instructions, these many variations can be provided efficiently and compactly.

The principal price to pay for variable-length instructions is an increase in the complexity of the processor. Falling hardware prices, the use of microprogramming (discussed in Part Four), and a general increase in understanding of the principles of processor design have all contributed to making this a small price to pay. However, we will see that RISC and superscalar machines can exploit the use of fixed-length instructions to provide improved performance.

The use of variable-length instructions does not remove the desirability of making all of the instruction lengths integrally related to the word length. Because the processor does not know the length of the next instruction to be fetched, a typical strategy is to fetch a number of bytes or words equal to at least the longest possible instruction. This means that sometimes multiple instructions are fetched. However, as we shall see in [Chapter 16](#), this is a good strategy to follow in any case.

16-bit minicomputer [BELL70].

The PDP-11 employs a set of eight 16-bit general-purpose registers. Two of these registers have additional significance: one is used as a stack pointer for special-purpose stack operations, and one is used as the program counter, which contains the address of the next instruction.

Figure 14.7 shows the PDP-11 instruction formats. Thirteen different formats are used, encompassing zero-, one-, and two-address instruction types. The opcode can vary from 4 to 16 bits in length. Register references are 6 bits in length. Three bits identify the register, and the remaining 3 bits identify the addressing mode. The PDP-11 is endowed with a rich set of addressing modes. One advantage of linking the addressing mode to the operand rather than the opcode, as is sometimes done, is that any addressing mode can be used with any opcode. As was mentioned, this independence is referred to as *orthogonality*.

1	Opcode 4	Source 6	Destination 6	2	Opcode 7	R 3	Source 6	3	Opcode 8	Offset 8
4	Opcode 8	FP 2	Destination 6	5	Opcode 10		Destination 6	6	Opcode 12	CC 4
7	Opcode 13		R 3	8	Opcode 16					
9	Opcode 4	Source 6	Destination 6		Memory Address 16					
10	Opcode 7	R 3	Source 6		Memory Address 16					
11	Opcode 8	FP 2	Source 6		Memory Address 16					
12	Opcode 10		Destination 6		Memory Address 16					
13	Opcode 4	Source 6	Destination 6		Memory Address 1 16		Memory Address 2 16			

Numbers below fields indicate bit length.

Source and destination each contain a 3-bit addressing mode field and a 3-bit register number.

FP indicates one of four floating-point registers.

R indicates one of the general-purpose registers.

CC is the condition code field.

Figure 14.7 Instruction Formats for the PDP-11

PDP-11 instructions are usually one word (16 bits) long. For some instructions, one or two memory addresses are appended, so that 32-bit and 48-bit instructions are part of the repertoire. This provides for further flexibility in addressing.

The PDP-11 instruction set and addressing capability are complex. This increases both hardware cost and programming complexity. The advantage is that more efficient or compact programs can be developed.

VAX

Most architectures provide a relatively small number of fixed instruction formats. This can cause two problems for the programmer. First, addressing mode and opcode are not orthogonal. For example, for a given operation, one operand must come from a register and another from memory, or both from registers, and so on. Second, only a limited number of operands can be accommodated: typically up to two or three. Because some operations inherently require more operands, various strategies must be used to achieve the desired result using two or more instructions.

To avoid these problems, two criteria were used in designing the VAX instruction format [STRE78]:

1. All instructions should have the “natural” number of operands.
2. All operands should have the same generality in specification.

The result is a highly variable instruction format. An instruction consists of a 1- or 2-byte opcode followed by from zero to six operand specifiers, depending on the opcode. The minimal instruction length is 1 byte, and instructions up to 37 bytes can be constructed. [Figure 14.8](#) gives a few examples.

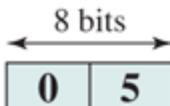

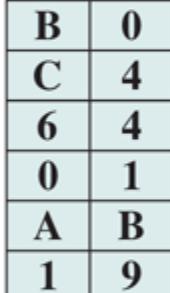

Hexadecimal Format	Explanation	Assembler Notation and Description
	Opcode for RSB	RSB Return from subroutine
	Opcode for CLRL Register R9	CLRL R9 Clear register R9
	Opcode for MOVW Word displacement mode, Register R4 356 in hexadecimal Byte displacement mode, Register R11 25 in hexadecimal	MOVW 356(R4), 25(R11) Move a word from address that is 356 plus contents of R4 to address that is 25 plus contents of R11
	Opcode for ADDL3 Short literal 5 Register mode R0 Index prefix R2 Indirect word relative (displacement from PC) Amount of displacement from PC relative to location A	ADDL3 #5, R0, @A[R2] Add 5 to a 32-bit integer in R0 and store the result in location whose address is sum of A and 4 times the contents of R2

Figure 14.8 Example of VAX Instructions

The VAX instruction begins with a 1-byte opcode. This suffices to handle most VAX instructions. However, as there are over 300 different instructions, 8 bits are not enough. The hexadecimal codes FD and FF indicate an extended opcode, with the actual opcode being specified in the second byte.

The remainder of the instruction consists of up to six operand specifiers. An operand specifier is, at minimum, a 1-byte format in which the leftmost 4 bits are the address mode specifier. The only exception to this rule is the literal mode, which is signaled by the pattern 00 in the leftmost 2 bits, leaving space for a 6-bit literal. Because of this exception, a total of 12 different addressing modes can be specified.

An operand specifier often consists of just one byte, with the rightmost 4 bits specifying one of 16 general-purpose registers. The length of the operand specifier can be extended in one of two ways. First, a constant value of one or more bytes may immediately follow the first byte of the operand specifier. An example of this is the displacement mode, in which an 8-, 16-, or 32-bit displacement is

used. Second, an index mode of addressing may be used. In this case, the first byte of the operand specifier consists of the 4-bit addressing mode code of 0100 and a 4-bit index register identifier. The remainder of the operand specifier consists of the base address specifier, which may itself be one or more bytes in length.

The reader may be wondering, as the author did, what kind of instruction requires six operands. Surprisingly, the VAX has a number of such instructions. Consider

ADDP6 OP1, OP2, OP3, OP4, OP5, OP6

This instruction adds two packed decimal numbers. OP1 and OP2 specify the length and starting address of one decimal string; OP3 and OP4 specify a second string. These two strings are added and the result is stored in the decimal string whose length and starting location are specified by OP5 and OP6.

The VAX instruction set provides for a wide variety of operations and addressing modes. This gives a programmer, such as a compiler writer, a very powerful and flexible tool for developing programs. In theory, this should lead to efficient machine-language compilations of high-level language programs and, in general, to effective and efficient use of processor resources. The penalty to be paid for these benefits is the increased complexity of the processor compared with a processor with a simpler instruction set and format.

We return to these matters in [Chapter 17](#), where we examine the case for very simple instruction sets.

14.4 x86 and ARM Instruction Formats

x86 Instruction Formats

The x86 is equipped with a variety of instruction formats. Of the elements described in this subsection, only the opcode field is always present. **Figure 14.9** illustrates the general instruction format. Instructions are made up of from zero to four optional instruction prefixes, a 1- or 2-byte opcode, an optional address specifier (which consists of the ModR/M byte and the Scale Index Base byte) an optional displacement, and an optional immediate field.

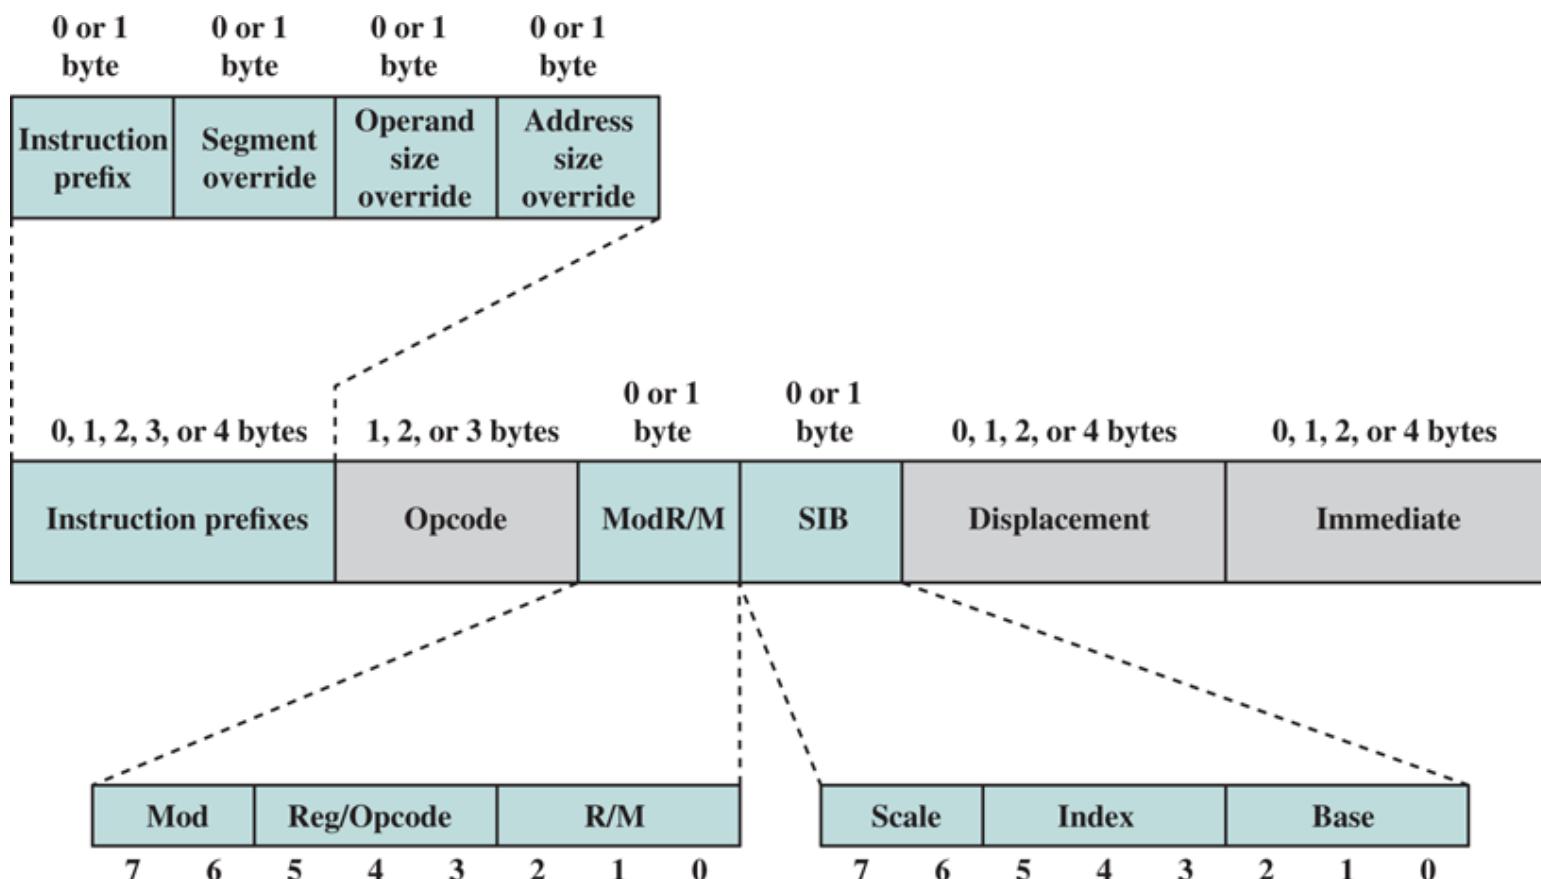

Figure 14.9 x86 Instruction Format

Let us first consider the prefix bytes:

- **Instruction prefixes:** The instruction prefix, if present, consists of the LOCK prefix or one of the repeat prefixes. The LOCK prefix is used to ensure exclusive use of shared memory in multiprocessor environments. The repeat prefixes specify repeated operation of a string, which enables the x86 to process strings much faster than with a regular software loop. There are five different repeat prefixes: REP, REPE, REPZ, REPNE, and REPNZ. When the absolute REP prefix is present, the operation specified in the instruction is executed repeatedly on successive elements of the string; the number of repetitions is specified in register CX. The conditional REP prefix causes the instruction to repeat until the count in CX goes to zero, or until the condition is met.
- **Segment override:** Explicitly specifies which segment register an instruction should use, overriding the default segment-register selection generated by the x86 for that instruction.
- **Operand size:** An instruction has a default operand size of 16 or 32 bits, and the operand prefix switches between 32-bit and 16-bit operands.
- **Address size:** The processor can address memory using either 16- or 32-bit addresses. The

address size determines the displacement size in instructions and the size of address offsets generated during effective address calculation. One of these sizes is designated as default, and the address size prefix switches between 32-bit and 16-bit address generation.

The instruction itself includes the following fields:

- **Opcode:** The opcode field is 1, 2, or 3 bytes in length. The opcode may also include bits that specify if data is byte- or full-size (16 or 32 bits depending on context), direction of data operation (to or from memory), and whether an immediate data field must be sign extended.
- **ModR/M:** This byte, and the next, provide addressing information. The ModR/M byte specifies whether an operand is in a register or in memory; if it is in memory, then fields within the byte specify the addressing mode to be used. The ModR/M byte consists of three fields: The Mod field (2 bits) combines with the R/M field to form 32 possible values: 8 registers and 24 indexing modes; the Reg/Opcode field (3 bits) specifies either a register number or three more bits of opcode information; the R/M field (3 bits) can specify a register as the location of an operand, or it can form part of the addressing-mode encoding in combination with the Mod field.
- **SIB:** Certain encoding of the ModR/M byte specifies the inclusion of the SIB byte to specify fully the addressing mode. The SIB byte consists of three fields: The Scale field (2 bits) specifies the scale factor for scaled indexing; the Index field (3 bits) specifies the index register; the Base field (3 bits) specifies the base register.
- **Displacement:** When the addressing-mode specifier indicates that a displacement is used, an 8-, 16-, or 32-bit signed integer displacement field is added.
- **Immediate:** Provides the value of an 8-, 16-, or 32-bit operand.

Several comparisons may be useful here. In the x86 format, the addressing mode is provided as part of the opcode sequence rather than with each operand. Because only one operand can have address-mode information, only one memory operand can be referenced in an instruction. In contrast, the VAX carries the address-mode information with each operand, allowing memory-to-memory operations. The x86 instructions are therefore more compact. However, if a memory-to-memory operation is required, the VAX can accomplish this in a single instruction.

The x86 format allows the use of not only 1-byte, but also 2-byte and 4-byte offsets for indexing. Although the use of the larger index offsets results in longer instructions, this feature provides needed flexibility. For example, it is useful in addressing large arrays or large stack frames. In contrast, the IBM S/370 instruction format allows offsets no greater than 4 Kbytes (12 bits of offset information), and the offset must be positive. When a location is not in reach of this offset, the compiler must generate extra code to generate the needed address. This problem is especially apparent in dealing with stack frames that have local variables occupying in excess of 4 Kbytes. As [DEWA90] puts it, “generating code for the 370 is so painful as a result of that restriction that there have even been compilers for the 370 that simply chose to limit the size of the stack frame to 4 Kbytes.”

As can be seen, the encoding of the x86 instruction set is very complex. This has to do partly with the need to be backward compatible with the 8086 machine and partly with a desire on the part of the designers to provide every possible assistance to the compiler writer in producing efficient code. It is a matter of some debate whether an instruction set as complex as this is preferable to the opposite extreme of the RISC instruction sets.

ARM Instruction Formats

All instructions in the ARM architecture are 32 bits long and follow a regular format ([Figure 14.10](#)). The first four bits of an instruction are the condition code. As discussed in [Chapter 13](#), virtually Virtually all ARM instructions can be conditionally executed. The next three bits specify the general type of instruction. For most instructions other than branch instructions, the next five bits constitute an opcode and/or modifier bits for the operation. The remaining 20 bits are for operand addressing. The

regular structure of the instruction formats eases the job of the instruction decode units.

	31 30 29 28 27 26 25 24 23 22 21 20 19 18 17 16 15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0													
Data processing immediate shift	cond	0 0 0	opcode	S	Rn	Rd	shift amount	shift	0	Rm				
Data processing register shift	cond	0 0 0	opcode	S	Rn	Rd	Rs	0	shift	1	Rm			
Data processing immediate	cond	0 0 1	opcode	S	Rn	Rd	rotate	immediate						
Load/store immediate offset	cond	0 1 0	P	U	B	W	L	Rn	Rd	immediate				
Load/store register offset	cond	0 1 1	P	U	B	W	L	Rn	Rd	shift amount	shift	0	Rm	
Load/store multiple	cond	1 0 0	P	U	S	W	L	Rn	register list					
Branch/branch with link	cond	1 0 1	L	24-bit offset										

S = For data processing instructions, signifies that the instruction updates the condition codes

S = For load/store multiple instructions, signifies whether instruction execution is restricted to supervisor mode

P, U, W = bits that distinguish among different types of addressing mode

B = Distinguishes between an unsigned byte (B==1) and a word (B==0) access

L = For load/store instructions, distinguishes between a Load (L==1) and a Store (L==0)

L = For branch instructions, determines whether a return address is stored in the link register

Figure 14.10 ARM Instruction Formats

IMMEDIATE CONSTANTS

To achieve a greater range of immediate values, the data processing immediate format specifies both an immediate value and a rotate value. The 8-bit immediate value is expanded to 32 bits and then rotated right by a number of bits equal to twice the 4-bit rotate value. Several examples are shown in [Figure 14.11](#).

Figure 14.11 Examples of Use of ARM Immediate Constants

THUMB INSTRUCTION SET

The Thumb instruction set is a re-encoded subset of the ARM instruction set. Thumb is designed to increase the performance of ARM implementations that use a 16-bit or narrower memory data bus and to allow better code density than provided by the ARM instruction for both 16-bit and 32-bit processors. The Thumb instruction set was created by analyzing the 32-bit ARM instruction set and deriving the best fit 16-bit instruction set, thus reducing code size. The savings is achieved in the following way:

1. Thumb instructions are unconditional, so the condition code field is not used. Also, all Thumb arithmetic and logic instructions update the condition flags, so that the update-flag bit is not needed. Savings: 5 bits.
2. Thumb has only a subset of the operations in the full instruction set and uses only a 2-bit opcode field, plus a 3-bit type field. Savings: 2 bits.
3. The remaining savings of 9 bits comes from reductions in the operand specifications. For example, Thumb instructions reference only registers r0 through r7, so only 3 bits are required for register references, rather than 4 bits. Immediate values do not include a 4-bit rotate field.

The ARM processor can execute a program consisting of a mixture of Thumb instructions and 32-bit ARM instructions. A bit in the processor control register determines which type of instruction is currently being executed. [Figure 14.12](#) shows an example. The figure shows both the general format and a specific instance of an instruction in both 16-bit and 32-bit formats.

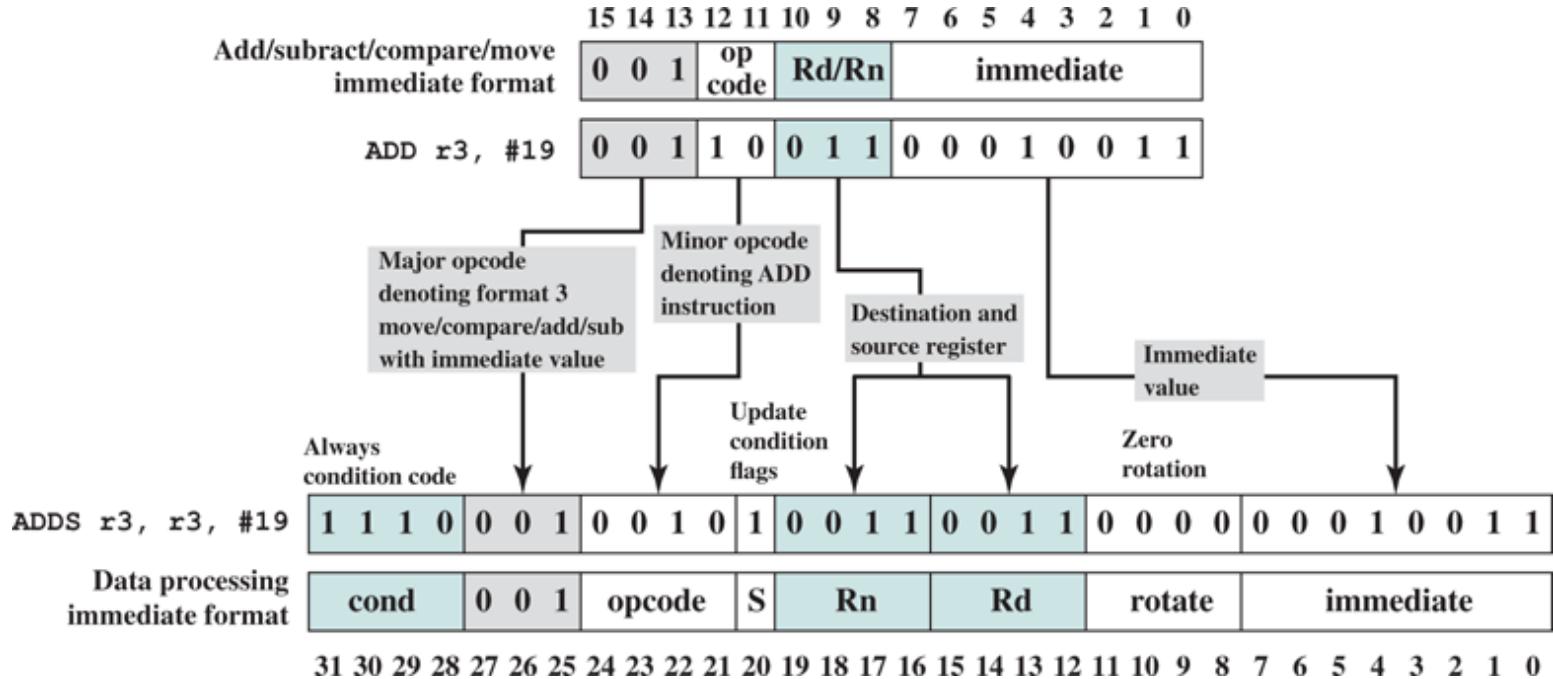

Figure 14.12 Expanding a Thumb ADD Instruction into its ARM Equivalent

THUMB-2 INSTRUCTION SET

With the introduction of the Thumb instruction set, the user was required to blend instruction sets by compiling performance critical code to ARM and the rest to Thumb. This manual code blending requires additional effort and it is difficult to achieve optimal results. To overcome these problems, ARM developed the Thumb-2 instruction set, which is the only instruction set available on the Cortex-M microcontroller products.

Thumb-2 is a major enhancement to the Thumb instruction set architecture (ISA). It introduces 32-bit instructions that can be intermixed freely with the older 16-bit Thumb instructions. These new 32-bit instructions cover almost all the functionality of the ARM instruction set. The most important difference between the Thumb ISA and the ARM ISA is that most 32-bit Thumb instructions are unconditional, whereas almost all ARM instructions can be conditional. However, Thumb-2 introduces a new If-Then (IT) instruction that delivers much of the functionality of the condition field in ARM instructions. Thumb-2 delivers overall code density comparable with Thumb, together with the performance levels associated with the ARM ISA. Before Thumb-2, developers had to choose between Thumb for size and ARM for performance.

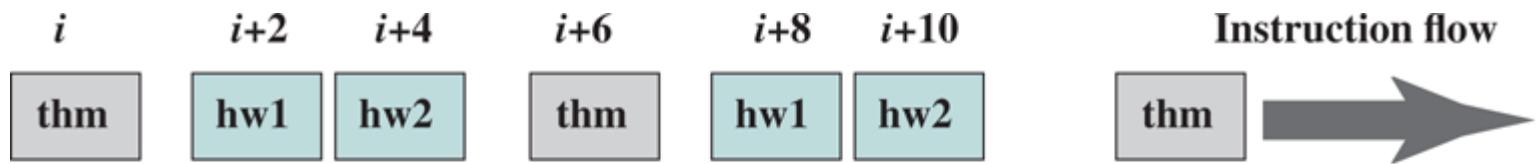

[ROBI07] reports on an analysis of the Thumb-2 instruction set compared with the ARM and original Thumb instruction sets. The analysis involved compiling and executing the Embedded Microprocessor Benchmark Consortium (EEMBC) benchmark suite using the three instruction sets, with the following results:

- With compilers optimized for performance, Thumb-2 size was 26% smaller than ARM, and slightly larger than original Thumb.
- With compilers optimized for space, Thumb-2 size was 32% smaller than ARM, and slightly smaller than original Thumb.
- With compilers optimized for performance, Thumb-2 performance on the benchmark suite was 98% of ARM performance and 125% of original Thumb performance.

These results confirm that Thumb-2 meets its design objectives.

Figure 14.13 shows how the new 32-bit Thumb instructions are encoded. The encoding is compatible with the existing Thumb unconditional branch instructions, which has the bit pattern 11100 in the five

leftmost bits of the instruction. No other 16-bit instruction begins with the pattern 111 in the three leftmost bits, so the bit patterns 11101, 11110, and 11111 indicate that this is a 32-bit Thumb instruction.

Halfword1 [15:13]	Halfword1 [12:11]	Length	Functionality
Not 111	xx	16 bits (1 halfword)	16-bit Thumb instruction
111	00	16 bits (1 halfword)	16-bit Thumb unconditional branch instruction
111	Not 00	32 bits (2 halfwords)	32-bit Thumb-2 instruction

Review Questions

14.1 Briefly define immediate addressing.

14.2 Briefly define **direct addressing**.

14.3 Briefly define indirect addressing.

14.4 Briefly define register addressing.

14.5 Briefly define register indirect addressing.

14.6 Briefly define displacement addressing.

14.7 Briefly define relative addressing.

14.8 What is the advantage of autoindexing?

14.9 What is the difference between postindexing and preindexing?

14.10 What facts go into determining the use of the addressing bits of an instruction?

14.11 What are the advantages and disadvantages of using a variable-length instruction format?

Problems

14.1 Given the following memory values and a one-address machine with an accumulator, what values do the following instructions load into the accumulator?

- Word 20 contains 40.
- Word 30 contains 50.

- Word 40 contains 60.
- Word 50 contains 70.
 - a. LOAD IMMEDIATE 20
 - b. LOAD DIRECT 20
 - c. LOAD INDIRECT 20
 - d. LOAD IMMEDIATE 30
 - e. LOAD DIRECT 30
 - f. LOAD INDIRECT 30

14.2 Let the address stored in the program counter be designated by the symbol X1. The instruction stored in X1 has an address part (operand reference) X2. The operand needed to execute the instruction is stored in the memory word with address X3. An index register contains the value X4. What is the relationship between these various quantities if the addressing mode of the instruction is (a) direct; (b) indirect; (c) PC relative; (d) indexed?

14.3 An address field in an instruction contains decimal value 14. Where is the corresponding operand located for

- a. immediate addressing?
- b. direct addressing?
- c. indirect addressing?
- d. register addressing?
- e. register indirect addressing?

14.4 Consider a 16-bit processor in which the following appears in main memory, starting at location 200:

	Load to AC	Mode
200		
201		500
202		Next instruction

The first part of the first word indicates that this instruction loads a value into an accumulator. The Mode field specifies an addressing mode and, if appropriate, indicates a source register; assume that when used, the source register is R1, which has a value of 400. There is also a base register that contains the value 100. The value of 500 in location 201 may be part of the address calculation. Assume that location 399 contains the value 999, location 400 contains the value 1000, and so on. Determine the effective address and the operand to be loaded for the following address modes:

- a. Direct
- b. Immediate
- c. Indirect
- d. PC relative
- e. Displacement
- f. Register
- g. Register indirect
- h. Autoindexing with increment, using R1

14.5 A PC-relative mode branch instruction is 3 bytes long. The address of the instruction, in decimal, is 256028. Determine the branch target address if the signed displacement in the instruction is -31.

14.6 A PC-relative mode branch instruction is stored in memory at address 620_{10} . The branch is made to location 530_{10} . The address field in the instruction is 10 bits long. What is the binary value in the instruction?

14.7 How many times does the processor need to refer to memory when it fetches and executes an indirect-address-mode instruction if the instruction is (a) a computation requiring a single operand; (b) a branch?

14.8 The IBM 370 does not provide indirect addressing. Assume that the address of an operand is in main memory. How would you access the operand?

14.9 In [COOK82], the author proposes that the PC-relative addressing modes be eliminated in favor of other modes, such as the use of a stack. What is the disadvantage of this proposal?

14.10 The x86 includes the following instruction:

IMUL op1, op2, immediate

This instruction multiplies op2, which may be either register or memory, by the immediate operand value, and places the result in op1, which must be a register. There is no other three-operand instruction of this sort in the instruction set. What is the possible use of such an instruction? (*Hint: Consider indexing.*)

14.11 Consider a processor that includes a base with indexing addressing mode. Suppose an instruction is encountered that employs this addressing mode and specifies a displacement of 1970, in decimal. Currently the base and index register contain the decimal numbers 48,022 and 8, respectively. What is the address of the operand?

14.12 Define: $EA = (X) +$ is the effective address equal to the contents of location X, with X incremented by one word length after the effective address is calculated; $EA = -(X)$ is the effective address equal to the contents of location X, with X decremented by one word length before the effective address is calculated; $EA = (X) -$ is the effective address equal to the contents of location X, with X decremented by one word length after the effective address is calculated. Consider the following instructions, each in the format (Operation Source Operand, Destination Operand), with the result of the operation placed in the destination operand.

- a. OP X, (X)
- b. OP(X) , (X) +
- c. OP(X) + , (X)
- d. OP -(X) , (X)
- e. OP -(X) , (X) +
- f. OP(X) + , (X) +
- g. OP(X) - , (X)

Using X as the stack pointer, which of these instructions can pop the top two elements from the stack, perform the designated operation (e.g., ADD source to destination and store in destination), and push the result back on the stack? For each such instruction, does the stack grow toward memory location 0 or in the opposite direction?

14.13 Assume a stack-oriented processor that includes the stack operations PUSH and POP. Arithmetic operations automatically involve the top one or two stack elements. Begin with an empty stack. What stack elements remain after the following instructions are executed?

PUSH	4
PUSH	7
PUSH	8

ADD	
PUSH	10
SUB	
MUL	

14.14 Justify the assertion that a 32-bit instruction is probably much less than twice as useful as a 16-bit instruction.

14.15 Why was IBM's decision to move from 36 bits to 32 bits per word wrenching, and to whom?

14.16 Assume an instruction set that uses a fixed 16-bit instruction length. Operand specifiers are 6 bits in length. There are K two-operand instructions and L zero-operand instructions. What is the maximum number of one-operand instructions that can be supported?

14.17 Design a variable-length opcode to allow all of the following to be encoded in a 36-bit instruction:

- instructions with two 15-bit addresses and one 3-bit register number;
- instructions with one 15-bit address and one 3-bit register number;
- instructions with no addresses or registers.

14.18 Consider the results of Problem 10.6. Assume that M is a 16-bit memory address and that X, Y, and Z are either 16-bit addresses or 4-bit register numbers. The one-address machine uses an accumulator, and the two- and three-address machines have 16 registers and instructions operating on all combinations of memory locations and registers. Assuming 8-bit opcodes and instruction lengths that are multiples of 4 bits, how many bits does each machine need to compute X?

14.19 Is there any possible justification for an instruction with two opcodes?

14.20 The 16-bit Zilog Z8001 has the following general instruction format:

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Mode		Opcode				w/b		Operand 2			Operand 1				

The *mode* field specifies how to locate the operands from the *operand* fields. The *w/b* field is used in certain instructions to specify whether the operands are bytes or 16-bit words. The *operand 1* field may (depending on the *mode field* contents) specify one of 16 general-purpose registers. The *operand 2* field may specify any general-purpose registers except register 0. When the *operand 2* field is all zeros, each of the original opcodes takes on a new meaning.

- a. How many opcodes are provided on the Z8001?
- b. Suggest an efficient way to provide more opcodes and indicate the trade-off involved.

Learning Objectives

After studying this chapter, you should be able to:

- Understand the distinction between machine language and assembly language.
- Discuss the advantages and disadvantages of using assembly language.
- Describe the key elements in assembly language.
- Be able to read and understand programs written in NASM.
- Summarize the steps of the assembly process.
- Present an overview of the loading and linking process.

This chapter is devoted to a discussion of assembly language and related topics. There are a number of reasons why it is worthwhile to study assembly language

programming (as compared with programming in a higher-level language), including the following:

1. *It clarifies the execution of instructions.*
2. *It shows how data are represented in memory.*
3. *It shows how a program interacts with the operating system, processor, and the I/O system.*
4. *It clarifies how a program accesses external devices.*
5. *Understanding assembly language programmers makes students better high-level language (HLL) programmers, by giving them a better idea of the target language that the HLL must be translated into.*

The chapter begins with an overview of assembly language concepts. This is followed by a study of the basic elements of an assembly language, using the x86 architecture for our examples. Next, we look at the operation of the assembler. This is followed by a discussion of linkers and loaders.

The examples in this chapter use the x86 architecture and machine instruction set, and the Netwide Assembler (NASM), designed for use on x86 machines. NASM has the advantage of being free and open source, and is popular for use on Linux and UNIX operating systems.

Table 15.1 defines some of the key terms used in this chapter.

Table 15.1 Key Terms for this Chapter

Assembler
A program that translates assembly language into machine code.
Assembly Language
A symbolic representation of the machine language of a specific processor, augmented by additional types of statements that facilitate program writing and that provide instructions to the assembler.
Compiler
A program that converts another program from some source language (or programming language) to machine language (object code). Some compilers output assembly language which is then converted to machine language by a separate assembler. A compiler is distinguished from an assembler by the fact that each input statement does not, in general, correspond to a single machine

instruction or fixed sequence of instructions. A compiler may support such features as automatic allocation of variables, arbitrary arithmetic expressions, control structures such as FOR and WHILE loops, variable scope, input/output operations, higher-order functions and portability of source code.

Executable Code

The machine code generated by a source code language processor such as an assembler or compiler. This is software in a form that can be run in the computer.

Instruction Set

The collection of all possible instructions for a particular computer; that is, the collection of machine language instructions that a particular processor understands.

Linker

A utility program that combines one or more files containing object code from separately compiled program modules into a single file containing loadable or executable code.

Loader

A program routine that copies an executable program into memory for execution.

Machine Language, or Machine Code

The binary representation of a computer program which is actually read and interpreted by the computer. A program in machine code consists of a sequence of machine instructions (possibly interspersed with data). Instructions are binary strings which may be either all the same size (e.g., one 32-bit word for many modern RISC microprocessors) or of different sizes.

Object Code

The machine language representation of programming source code. Object code is created by a compiler or assembler and is then turned into executable code by the linker.

15.1 Assembly Language Concepts

A processor can understand and execute machine instructions. Such instructions are simply binary numbers stored in the computer. If a programmer wished to program directly in machine language, then it would be necessary to enter the program as binary data.

Consider the simple statement in the C programming language.

$$n = i + j + k;$$

Suppose that we wished to program this statement in machine language and that the contents of i , j , and k have been initialized to 2, 3, and 4, respectively. Assume a simple machine with a 16-bit word length consisting of an 8-bit opcode and an 8-bit address, and the only available register is an accumulator (AC). The binary program is shown in [Figure 15.1a](#). The program starts in location 101 (decimal). Memory is reserved for the four variables starting at location 201. The program consists of four instructions:

1. Load the contents of location 201 into the AC.
2. Add the contents of location 202 to the AC.
3. Add the contents of location 203 to the AC.
4. Store the contents of the AC in location 204.

This is clearly a tedious and very error-prone process.

A slight improvement is to write the program in hexadecimal rather than binary notation ([Figure 15.1b](#)). We could write the program as a series of lines. Each line contains the address of a memory location and the hexadecimal code of the binary value to be stored in that location. Then we need a program that will accept this input, translate each line into a binary number, and store it in the specified location.

Address	Contents			
	Opcode	Operand		
101	0010	0010	1100	1001
102	0001	0010	1100	10 10
103	0001	0010	1100	10 11
104	0011	0010	1100	1100
201	0000	0000	0000	0010
202	0000	0000	00 00	0011
203	0000	0000	0000	01 00
204	0000	0000	0000	0000

(a) Binary program

Address	Contents
101	22 C9
102	12 CA
103	12 CB

	ADD	J
	ADD	K
	STA	N
I	DATA	2
J	DATA	3
K	DATA	4
N	DATA	0

(d) Assembly program

Figure 15.1 Programming the Statement $n = i + j + k$

For more improvement, we can make use of the symbolic name or mnemonic of each instruction; the documentation for any machine includes such names (e.g., [Table 13.9](#) for the x86 architecture). This results in the *symbolic program* shown in [Figure 15.1c](#). Each line of input still represents one memory location. Each line consists of three fields, separated by spaces. The first field contains the address of a location. For an instruction, the second field contains the three-letter symbol for the opcode. If it is a memory-referencing instruction, then a third field contains the address. To store arbitrary data in a location, we invent a *pseudoinstruction* with the symbol DAT. This is merely an indication that the third field on the line contains a hexadecimal number to be stored in the location specified in the first field.

For this type of input, we need a slightly more complex program. The program accepts each line of input, generates a binary number based on the second and third (if present) fields, and stores it in the location specified by the first field.

The use of a symbolic program makes life much easier, but it is still awkward. In particular, we must give an absolute address for each word. This means that the program and data can be loaded into only one place in memory, and we must know that place ahead of time. Worse, suppose that we wish to change the program some day by adding or deleting a line. This will change the addresses of all subsequent words.

A much better system, and one commonly used, is to use symbolic addresses. This is illustrated in [Figure 15.1d](#). Each line still consists of three fields. The first field is still for the address, but a symbol is used instead of an absolute numerical address. Some lines have no address, implying that the address of that line is one more than the address of the previous line. For memory-reference instructions, the third field also contains a symbolic address.

With this last refinement, we have an *assembly language*. Programs written in assembly language (assembly programs) are translated into machine language by an *assembler*. This program must not only do the symbolic translation discussed earlier, but also assign some form of memory addresses to symbolic addresses.

The development of assembly language was a major milestone in the evolution of computer technology. It was the first step to the high-level languages in use today. Although few programmers use assembly language, virtually all machines provide one. They are used, if at all, for systems programs such as compilers and I/O routines.

15.2 Motivation For Assembly Language Programming

Assembly language is a programming language that is one step away from machine language. Typically, each assembly language instruction is translated into one machine instruction by the assembler. Assembly language is hardware dependent, with a different assembly language for each type of processor. In particular, assembly language instructions can make reference to specific registers in the processor, include all of the opcodes of the processor, and reflect the bit length of the various registers of the processor and operands of the machine language. An assembly language programmer must therefore understand the computer's architecture.

Programmers rarely use assembly language for applications, or even systems programs. HLLs provide an expressive power and conciseness that greatly eases the programmer's tasks. The disadvantages of using an assembly language rather than an HLL include the following [FOG17]:

1. **Development time.** Writing code in assembly language takes much longer than writing in a high-level language.
2. **Reliability and security.** It is easy to make errors in assembly code. The assembler is not checking if the calling conventions and register save conventions are obeyed. Nobody is checking for you if the number of PUSH and POP instructions is the same in all possible branches and paths. There are so many possibilities for hidden errors in assembly code that it affects the reliability and security of the project unless you have a very systematic approach to testing and verifying.
3. **Debugging and verifying.** Assembly code is more difficult to debug and verify because there are more possibilities for errors than in high-level code.
4. **Maintainability.** Assembly code is more difficult to modify and maintain because the language allows unstructured spaghetti code and all kinds of tricks that are difficult for others to understand. Thorough documentation and a consistent programming style are needed.
5. **Portability.** Assembly code is platform-specific. Porting to a different platform is difficult.
6. **System code can use intrinsic functions instead of assembly.** The best modern C++ compilers have intrinsic functions for accessing system control registers and other system instructions. Assembly code is no longer needed for device drivers and other system code when intrinsic functions are available.
7. **Application code can use intrinsic functions or vector classes instead of assembly.** The best modern C++ compilers have intrinsic functions for vector operations and other special instructions that previously required assembly programming.
8. **Compilers have been improved a lot in recent years.** The best compilers are now quite good. It takes a lot of expertise and experience to optimize better than the best C++ compiler.

Yet there are still some advantages to the occasional use of assembly language, including the following [FOG17]:

1. **Debugging and verifying.** Looking at compiler-generated assembly code or the disassembly window in a debugger is useful for finding errors and for checking how well a compiler optimizes a particular piece of code.
2. **Making compilers.** Understanding assembly coding techniques is necessary for making compilers, debuggers, and other development tools.
3. **Embedded systems.** Small embedded systems have fewer resources than PCs and mainframes. Assembly programming can be necessary for optimizing code for speed or size in small embedded systems.
4. **Hardware drivers and system code.** Accessing hardware, system control registers, and so on may sometimes be difficult or impossible with high level code.

5. **Accessing instructions that are not accessible from high-level language.** Certain assembly instructions have no high-level language equivalent.
6. **Self-modifying code.** Self-modifying code is generally not profitable because it interferes with efficient code caching. It may, however, be advantageous, for example, to include a small compiler in math programs where a user-defined function has to be calculated many times.
7. **Optimizing code for size.** Storage space and memory is so cheap nowadays that it is not worth the effort to use assembly language for reducing code size. However, cache size is still such a critical resource that it may be useful in some cases to optimize a critical piece of code for size in order to make it fit into the code cache.
8. **Optimizing code for speed.** Modern C++ compilers generally optimize code quite well in most cases. But there are still cases where compilers perform poorly and where dramatic increases in speed can be achieved by careful assembly programming.
9. **Function libraries.** The total benefit of optimizing code is higher in function libraries that are used by many programmers.
10. **Making function libraries compatible with multiple compilers and operating systems.** It is possible to make library functions with multiple entries that are compatible with different compilers and different operating systems. This requires assembly programming.

The terms **assembly language** and **machine language** are sometimes, erroneously, used synonymously. Machine language consists of instructions directly executable by the processor. Each machine language instruction is a binary string containing an opcode, operand references, and perhaps other bits related to execution, such as flags. For convenience, instead of writing an instruction as a bit string, it can be written symbolically, with names for opcodes and registers. An assembly language makes much greater use of symbolic names, including assigning names to specific main memory locations and specific instruction locations. Assembly language also includes statements that are not directly executable but serve as instructions to the assembler that produces machine code from an assembly language program.

15.3 Assembly Language Elements

Statements

The heart of any assembly language program are statements. A statement in a typical assembly language has the form shown in **Figure 15.2**. It consists of four elements: label, mnemonic, operand, and comment.

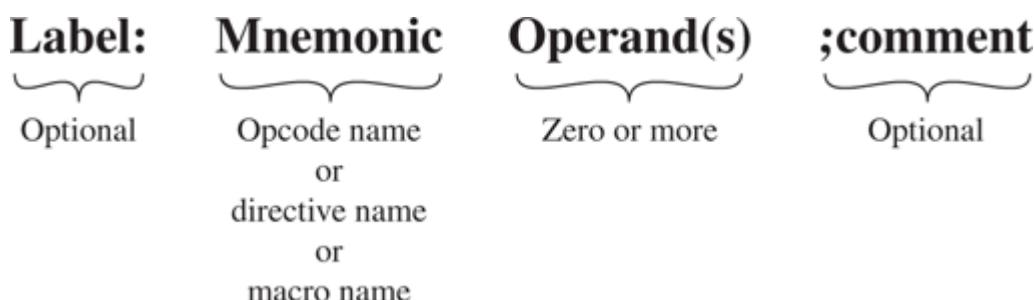

Figure 15.2 Assembly-Language Statement Structure

LABEL

If a label is present, the assembler defines the label as equivalent to the address into which the first byte of the object code generated for that instruction will be loaded. The programmer may subsequently use the label as an address or as data in another instruction's address field. The assembler replaces the label with the assigned value when creating an object program. Labels are most frequently used in branch instructions.

As an example, here is a program fragment:

```
L2:    SUB     EAX, EDX      ; subtract contents of register EDX
       from
                  ; contents of EAX and store result in
EAX
       JG     L2      ; jump to L2 if result of subtraction is
                      ; positive
```

The program will continue to loop back to location L2 until the result is zero or negative. Thus, when the `jg` instruction is executed, if the result is positive, the processor places the address equivalent to the label L2 in the program counter.

Reasons for using a label include the following:

1. A label makes a program location easier to find and remember.
2. The label can easily be moved to correct a program. The assembler will automatically change the address in all instructions that use the label when the program is reassembled.
3. The programmer does not have to calculate relative or absolute memory addresses, but just uses labels as needed.

MNEMONIC

The mnemonic is the name of the operation or function of the assembly language statement. As discussed subsequently, a statement can correspond to a machine instruction, an assembler directive, or a macro. In the case of a machine instruction, a mnemonic is the symbolic name associated with a particular opcode.

Table 13.3 lists the mnemonic, or instruction name, of many of the x86 instructions. **Appendix A** of [CART06] lists the x86 instructions, together with the operands for each and the effect of the instruction on the condition codes. **Appendix B** of the NASM manual provides a more detailed description of each x86 instruction. Both documents are available at box.com/COA11e.

OPERAND(S)

An assembly language statement includes zero or more operands. Each operand identifies an immediate value, a register value, or a memory location. Typically, the assembly language provides conventions for distinguishing among the three types of operand references, as well as conventions for indicating addressing mode.

For the x86 architecture, an assembly language statement may refer to a register operand by name. **Figure 15.3** illustrates the general-purpose x86 registers, with their symbolic name and their bit encoding. The assembler will translate the symbolic name into the binary identifier for the register.

General-purpose registers		0	16-bit	32-bit
	AH		AX	EAX (000)
	BH		BX	EBX (011)
	CH		CX	ECX (001)
	DH		DX	EDX (010)
				ESI (110)
				EDI (111)
				EBP (101)
				ESP (100)

15	Segment registers	0
	CS	
	DS	
	SS	
	ES	
	FS	
	GS	

Figure 15.3 Intel x86 Program Execution Registers

As discussed in [Section 14.2](#), the x86 architecture has a rich set of addressing modes, each of which must be expressed symbolically in the assembly language. Here we cite a few of the common examples. For **register addressing**, the name of the register is used in the instruction. For example, `MOV ECX, EBX` copies the contents of register EBX into register ECX. **Immediate addressing** indicates that the value is encoded in the instruction. For example, `MOV EAX, 100H` copies the hexadecimal value 100 into register EAX. The immediate value can also be expressed as a binary number with the suffix B or a decimal number with no suffix. Thus, equivalent statements to the preceding one are `MOV EAX, 10000000B` and `MOV EAX, 256`. **Direct addressing** refers to a memory location and is expressed as a displacement from the DS segment register. This is best explained by example. Assume that the 16-bit data segment register DS contains the value 1000H. Then the following sequence occurs:

```
MOV AX, 1234H  
MOV [3518H], AX
```

First the 16-bit register AX is initialized to 1234H. Then, in line two, the contents of AX are moved to the logical address DS:3518. This address formed by shifting the contents of DS left 4 bits and adding 3518H to form the 32-bit logical address 13518H.

COMMENT

All assembly languages allow the placement of comments in the program. A comment can either occur at the right-hand end of an assembly statement or can occupy an entire text line. In either case, the comment begins with a special character that signals to the assembler that the rest of the line is a comment and is to be ignored by the assembler. Typically, assembly languages for the x86 architecture use a semicolon (;) for the special character.

Pseudo-instructions

Pseudo-instructions are statements which, though not real x86 machine instructions, are used in the instruction field anyway because that's the most convenient place to put them. The NASM pseudo-instructions are DB, DW, DD, DQ, DT, DO, DY, and DZ; their uninitialized counterparts RESB, RESW, RESD, RESQ, REST, RESO, RESY, and RESZ; the INCBIN command, the EQU command, and the TIMES prefix.

Pseudo-instructions are not directly translated into machine language instructions. Instead, directives are instructions to the assembler to perform specified actions during the assembly process. Examples include the following:

- Define constants
- Designate areas of memory for data storage
- Initialize areas of memory
- Place tables or other fixed data in memory
- Allow references to other programs

Table 15.2 lists the NASM directives. As an example, consider the following sequence of statements:

```
L2      DB      "A"      ; byte initialized to ASCII code for A (65)  
        MOV     AL, [L1]    ; copy byte at L1 into AL
```

```

MOV     EAX, L1 ; store address of byte at L1 in EAX
MOV     [L1], AH   ; copy contents of AH into byte at L1

```

Table 15.2 Some NASM Assembly-Language Directives

(a) Letters for RES x and Dx Directives	
Unit	Letter
byte	B
word (2 bytes)	W
double word (4 bytes)	D
quad word (8 bytes)	Q
ten bytes	T

(b) Directives		
Name	Description	Example
DB, DW, DD, DQ, DT	Initialize locations	<pre> L6 DD 1A92H ;doubleword at L6 initialized to 1A92H </pre>
RESB, RESW, RESD, RESQ, REST	Reserve uninitialized locations	<pre> BUFFER RESB 64 ;reserve 64 bytes starting at BUFFER </pre>
INCBIN	Include binary file in output	<pre> INCBIN "file.dat" ; include this file </pre>
EQU	Define a symbol to a given constant value	<pre> MSGLEN EQU 25 ;the constant MSGLEN equals decimal 25 </pre>

TIMES	Repeat instruction multiple times	<pre>ZEROBUF TIMES 64 DB 0 ;initialize 64-byte buffer to all zeros</pre>
-------	-----------------------------------	--

If a plain label is used, it is interpreted as the address (or offset) of the data. If the label is placed inside square brackets, it is interpreted as the data at the address.

Macro Definitions

A macro definition is similar to a subroutine in several ways. A subroutine is a section of a program that is written once, and can be used multiple times by calling the subroutine from any point in the program. When a program is compiled or assembled, the subroutine is loaded only once. A call to the subroutine transfers control to the subroutine and a return instruction in the subroutine returns control to the point of the call. Similarly, a macro definition is a section of code that the programmer writes once, and then can use many times. The main difference is that when the assembler encounters a macro call, it replaces the macro call with the macro itself. This process is called **macro expansion**. So, if a macro is defined in an assembly language program and invoked 10 times in the source program, then 10 instances of the macro will appear in the assembled code. In essence, subroutines are handled by the hardware at run time, whereas macros are handled by the assembler at assembly time. Macros provide the same advantage as subroutines in terms of modular programming, but without the runtime overhead of a subroutine call and return. The tradeoff is that the macro approach uses more space in the object code.

In NASM and many other assemblers, a distinction is made between a single-line macro and a multi-line macro. In NASM, single-line macros are defined using the %DEFINE directive. Here is an example in which multiple single-line macros are expanded. First, we define two macros:

```
%DEFINE B (X) = 2*X
%DEFINE A (X) = 1 + B (X)
```

At some point in the assembly language program, the following statement appears:

```
MOV AX, A(8)
```

The assembler expands this statement to:

```
MOV AX, 1+2*8
```

which assembles to a machine instruction to move the immediate value 17 to register AX.

Multiline macros are defined using the mnemonic %MACRO. Here is an example of a multiline macro definition:

```
%MACRO PROLOGUE 1
    PUSH EBP      ; push contents of EBP onto stack
    ; pointed to by ESP and
    ; decrement contents of ESP by 4
    MOV EBP, ESP   ; copy contents of ESP to EBP
    SUB ESP, %1     ; subtract first parameter value from ESP
```

The number `1` after the macro name in the `%MACRO` line defines the number of parameters the macro expects to receive. The use of `%1` inside the macro definition refers to the first parameter to the macro call.

The macro call expands to the following lines of code:

<code>MYFUNC:</code>	<code>PROLOGUE 12</code>
<code>MYFUNC:</code>	<code>PUSH EBP</code>
	<code>MOV EBP, ESP</code>
	<code>SUB ESP, 12</code>

Directives

A directive is a command embedded in the assembly source code that is recognized and acted upon by the assembler. NASM includes the following directives.

- **BITS:** Specifies whether NASM should generate code designed to run on a processor operating in 16-bit mode, 32-bit mode, or 64-bit mode. The syntax is BITS XX, where XX is 16, 32, or 64. Normally, this is set by default by the operating system.
- **DEFAULT:** Can change some assembler defaults, such as whether to use relative or absolute addressing.
- **SECTION or SEGMENT:** Changes that section of the output file the source code will be assembled into. This is discussed subsequently.
- **EXTERN:** used to declare a symbol which is not defined anywhere in the module being assembled, but is assumed to be defined in some other module and needs to be referred to by this one.
- **GLOBAL:** GLOBAL is the other end of EXTERN: if one module declares a symbol as EXTERN and refers to it, then in order to prevent linker errors, some other module must actually define the symbol and declare it as GLOBAL.
- **COMMON:** Used to declare common variables. A common variable is much like a global variable declared in the uninitialized data section. The difference is that if more than one module defines the same common variable, then at link time those variables will be merged and will point at the same piece of memory.
- **CPU:** Restricts assembly to those instructions that are available on the specified CPU. For example, this directive can specify 8086, 186, and so on.
- **FLOAT:** Allows the programmer to change some of the default settings to options other than those used in IEEE 754.
- **[WARNING]:** Used to enable or disable classes of warnings.

Three sections can be defined by NASM. The data section is used for declaring initialized data or constants. This data does not change at runtime. The programmer can declare various constant values, file names, buffer size, and so on in this section. The bss section is used for declaring variables. The text section is used for keeping the actual code. This section must begin with the declaration global main, which tells the kernel where the program execution begins. The formats for

the three sections are as follows:

section.data

section.bss

section.text

System Calls

The assembler makes use of the x86 INT instruction to make system calls. For example, for Linux and UNIX systems, the programmer uses the following steps for a system call:

- Put the system call number in the EAX register.
- Store the arguments to the system call in the registers EBX, ECX, and so on.
- Call the relevant interrupt (80h).
- The result is usually returned in the EAX register.

There are six registers that store the arguments of the system call used. These are the EBX, ECX, EDX, ESI, EDI, and EBP. These registers take the consecutive arguments, starting with the EBX register. If there are more than six arguments, then the memory location of the first argument is stored in the EBX register.

15.4 EXAMPLES

In this section, we look at three examples of use of the NASM language. We compare these with corresponding C programs and, in two cases, show the difference between compiled code and assembly language code.

Greatest Common Divisor

We define the greatest common divisor of the integers a and b as follows:

$$gcd(a, b) = \max[k, \text{such that } k \text{ divides } a \text{ and } k \text{ divides } b]$$

where we say that k divides a if there is no remainder. Euclid's algorithm for the greatest common divisor is based on the following theorem. For any nonnegative integers a and b ,

$$gcd(a, b) = gcd(b, a \bmod b)$$

Here is a C language program that implements Euclid's algorithm:

```
unsigned int gcd (unsigned int a, unsigned int b)
{
    if (a == 0 && b == 0)
        b = 1;
    else if (b == 0)
        b = a;
    else if (a != 0)
        while (a != b)
            if (a < b)
                b -= a;
            else
                a -= b;
    return b;
}
```

Figure 15.4 shows two x86 assembly language versions of the preceding program. The program on the left was done by a C compiler. The program starts with the value of variable a in register ebx, the value of b in register edx, and returns the result in eax. At the beginning, there is some unnecessary movement of values among registers. The x86 TEST instruction is used to test for zero ([Table 13.3](#)). The JAE instruction tests for greater than or equal to ([Table 13.9](#)).

Figure 15.4 Assembly Programs for Greatest Common Divisor

(a) Compiled program

gcd:	mov	ebx, eax
	mov	eax, edx
	test	ebx, ebx
	jne	L1
	test	edx, edx
	jne	L1
	mov	eax, 1

```

    ret
L1:   test    eax,eax
        jne     L2
        mov     eax,ebx
        ret
L2:   test    ebx,ebx
        je      L5
L3:   cmp     ebx,eax
        je      L5
        jae     L4
        sub     eax,ebx
        jmp     L3
L4:   sub     ebx,eax
        jmp     L3
L5:   ret

```

(b) Written directly in assembly language

```

gcd:    neg    eax
        je     L3
L1:    neg    eax
        xchg  eax,edx
L2:    sub    eax,edx
        jg     L2
        jne   L1
L3:    add    eax,edx
        jne   L4
        inc    eax
L4:    ret

```

Figure 15.4b was programmed by hand. The program uses a number of programmer's tricks to produce a tighter, more efficient implementation. The programmer has the advantage of understanding the mathematical relationships involved. Although xchg is not a particularly fast x86 instruction, it does help make the program very compact, and probably not more than a cycle off for optimal performance. The main loop of the routine exists entirely within an instruction pre-fetch buffer.

Prime Number Program

We now look at an example that includes directives. This example looks at a program that finds prime numbers. Recall that prime numbers are evenly divisible by only 1 and themselves. There is no simple and efficient method for determining if a number is prime. The basic method this program uses is to find the factors of all odd numbers below a given limit. If no factor can be found for an odd number, it is prime. **Figure 15.5** shows the simple algorithm written in C that prints all the prime numbers less than or equal to an input variable limit. The program checks all odd numbers up to the limit. The current number being checked is assigned to the variable guess. Then, the program begins at 3 and keeps incrementing until it finds an odd number that divides guess or until it reaches an odd number whose square exceeds guess. If no factor is found, guess is printed out and then incremented by 2.

Figure 15.5 C Program for Generating Prime Numbers

```
unsigned guess;                                /* current guess for prime */
unsigned factor;                               /* possible factor of guess */
*/
unsigned limit;                                /* find primes up to this
value */
printf ("Find primes up to : ");
scanf("%u", &limit);
printf ("2\n");                                /* treat first two primes as
*/
guess = 5;                                    /* special case */
/* initial guess */
/* look for a factor of guess */
while (guess <= limit) {
/*
    factor = 3;
    while (factor * factor < guess && guess% factor != 0)
        factor += 2;
    if (guess % factor != 0)
        printf ("%d\n", guess);
    guess += 2;                                /* only look at odd numbers
*/
}
}
```

Figure 15.6 shows the same algorithm written in NASM. This program uses the segment and global NASM directives and the db pseudo-instruction.

Figure 15.6 Assembly Program for Generating Prime Numbers

```
%include "asm_io.inc"
segment .data
Message db "Find primes up to: ", 0
segment .bss
Limit resd 1                                ; find primes up to this limit
Guess resd 1                                 ; the current guess for prime
segment .text
    global _asm_main
_asm_main:
    enter 0,0                                ; setup routine
    pusha
    mov eax, Message
    call print_string
    call read_int                             ; scanf("%u", & limit);
    mov [Limit], eax
    mov eax, 2                                ; printf("2\n");
    call print_int
    call print_nl
    mov eax, 3                                ; printf("3\n");
    call print_int
    call print_nl
    mov dword [Guess], 5                      ; Guess = 5;
```

```

while_limit:                                ; while (Guess <= Limit)
    mov eax, [Guess]
    cmp eax, [Limit]
    jnbe end_while_limit
    mov ebx, 3
while_factor:
    mov eax, ebx
    mul eax
    jo end_while_factor
    cmp eax, [Guess]
    jnb end_while_factor
    mov eax, [Guess]
    mov edx, 0
    div ebx
    cmp edx, 0
    je end_while_factor
    add ebx, 2; factor += 2;
    jmp while_factor
end_while_factor:
    je end_if
    mov eax, [Guess]
    call print_int
    call print_nl
end_if:
    add dword [Guess], 2
    jmp while_limit
end_while_limit:
    popa
    mov eax, 0
    leave
    ret

```

; use jnbe since numbers are unsigned
; ebx is factor = 3;
;
; edx:eax = eax*eax
; if answer won't fit in eax alone
;
; if !(factor*factor < guess)
;
; edx = edx:eax% ebx
;
; if !(guess% factor != 0)
;
; if !(guess% factor != 0)
; printf("%u\n")
;
; guess += 2
;
; return back to C

String Manipulation

Before looking at this example, we first look at string data types and operations in x86.

STRING CONSTANTS AND OPERATIONS

Strings are continuous sequences of bits, bytes, words, or doublewords. A bit string can begin at any bit position of any byte and can contain up to $2^{32} - 1$ bits. A byte string can contain bytes, words, or doublewords and can range from zero to $2^{32} - 1$ bytes (4 GB).

Table 15.3 shows the x86 instructions for byte strings. Similar instructions are available for word, and doubleword strings. The MOVS, CMPS, SCAS, LODS, and STOS instructions permit large data structures, such as alphanumeric character strings, to be moved and examined in memory. These instructions operate on individual elements in a string, which can be a byte, word, or doubleword. The string elements to be operated on are identified with the ESI (source string element) and EDI (destination string element) registers. Both of these registers contain absolute addresses (offsets into a segment) that point to a string element.

Table 15.3 x86 String Instructions

Operation Name	Description
MOVSB	Moves the string byte addressed by the ESI register to the location addressed by the EDI register.
CMPSB	Subtracts the destination string byte from the source string element and updates the status flags in the EFLAGS register according to the results.
SCASB	Subtracts the destination string byte from the contents of the AL register and updates the status flags according to the results.
LODSB	Loads the source string byte identified by the ESI register into the EAX register.
STOSSB	Stores the source string byte from the AL register into the memory location identified with the EDI register.
REP	Repeat while the ECX register is not zero.
REPE/REPZ	Repeat while the ECX register is not zero and the ZF flag is set.
REPNE/REPNZ	Repeat while the ECX register is not zero and the ZF flag is clear.

The string instructions just described perform one iteration of a string operation. To operate strings longer than a doubleword, the string instructions can be combined with a repeat prefix (REP) to create a repeating instruction or be placed in a loop. The number of iterations, corresponding to the number of string elements to be operated on, is in the ECX register. When used in string instructions, the ESI and EDI registers are automatically incremented or decremented after each iteration of an instruction point to the next element (byte, word, or doubleword) in the string. String operations can thus begin at higher addresses and work toward lower ones, or they can begin at lower addresses and work toward higher ones. The DF flag in the EFLAGS register controls whether the registers are incremented ($DF=0$) or decremented ($DF=1$). The STD and CLD instructions set and clear this flag, respectively. When a string instruction has a repeat prefix, the operation executes until one of the termination conditions specified by the prefix is satisfied. The REPE/REPZ and REPNE/REPNZ prefixes are used only with the CMPS and SCAS instructions. Also, note that an REP STOS instruction is the fastest way to initialize a large block of memory.

MOVING A STRING

Figure 15.7 shows a program using the MOVSB instruction to move a character string from a source to a destination. The example shows the use of the .bss, .data, and .text sections and system calls. The CLD x86 instruction clears the DF flag.

Figure 15.7 Assembly Program for Moving a String

```
section .text
    global main           ;must be declared for using
gcc

s2      resb     20                ;destination
```

15.5 Types of assemblers

An assembler is a software that translates assembly language into machine language. Although all assemblers perform the same tasks, their implementations vary. The following define some of the common terms that describe types of assemblers:

- **Cross-assembler:** Runs on a computer other than the one for which it assembles object programs. Typically, the host machine for the assembler is a larger system, while the target machine may be a small embedded system or other type of system with limited resources and programming support software.
- **Resident assembler:** Runs on the computer for which it assembles programs.
- **Macroassembler:** Allows the user to define sequences of instructions as macros.
- **Microassembler:** Used to write the microprograms that define the instruction set of a microprogrammed computer.
- **Meta-assembler:** Can handle multiple instruction sets.
- **One-pass assembler:** Makes a single pass through the assembly code to produce the machine code.
- **Two-pass assembler:** Makes two passes through the assembly code to produce the machine code. Most assemblers require two passes.

15.6 Assemblers

The assembler is a software utility that takes an assembly program as input and produces object code as output. The object code is a binary file. The assembler views this file as a block of memory starting at relative location 0.

There are two general approaches to assemblers: the two-pass assembler and the one-pass assembler.

Two-Pass Assembler

We look first at the two-pass assembler, which is more common and somewhat easier to understand. The assembler makes two passes through the source code ([Figure 15.8](#)):

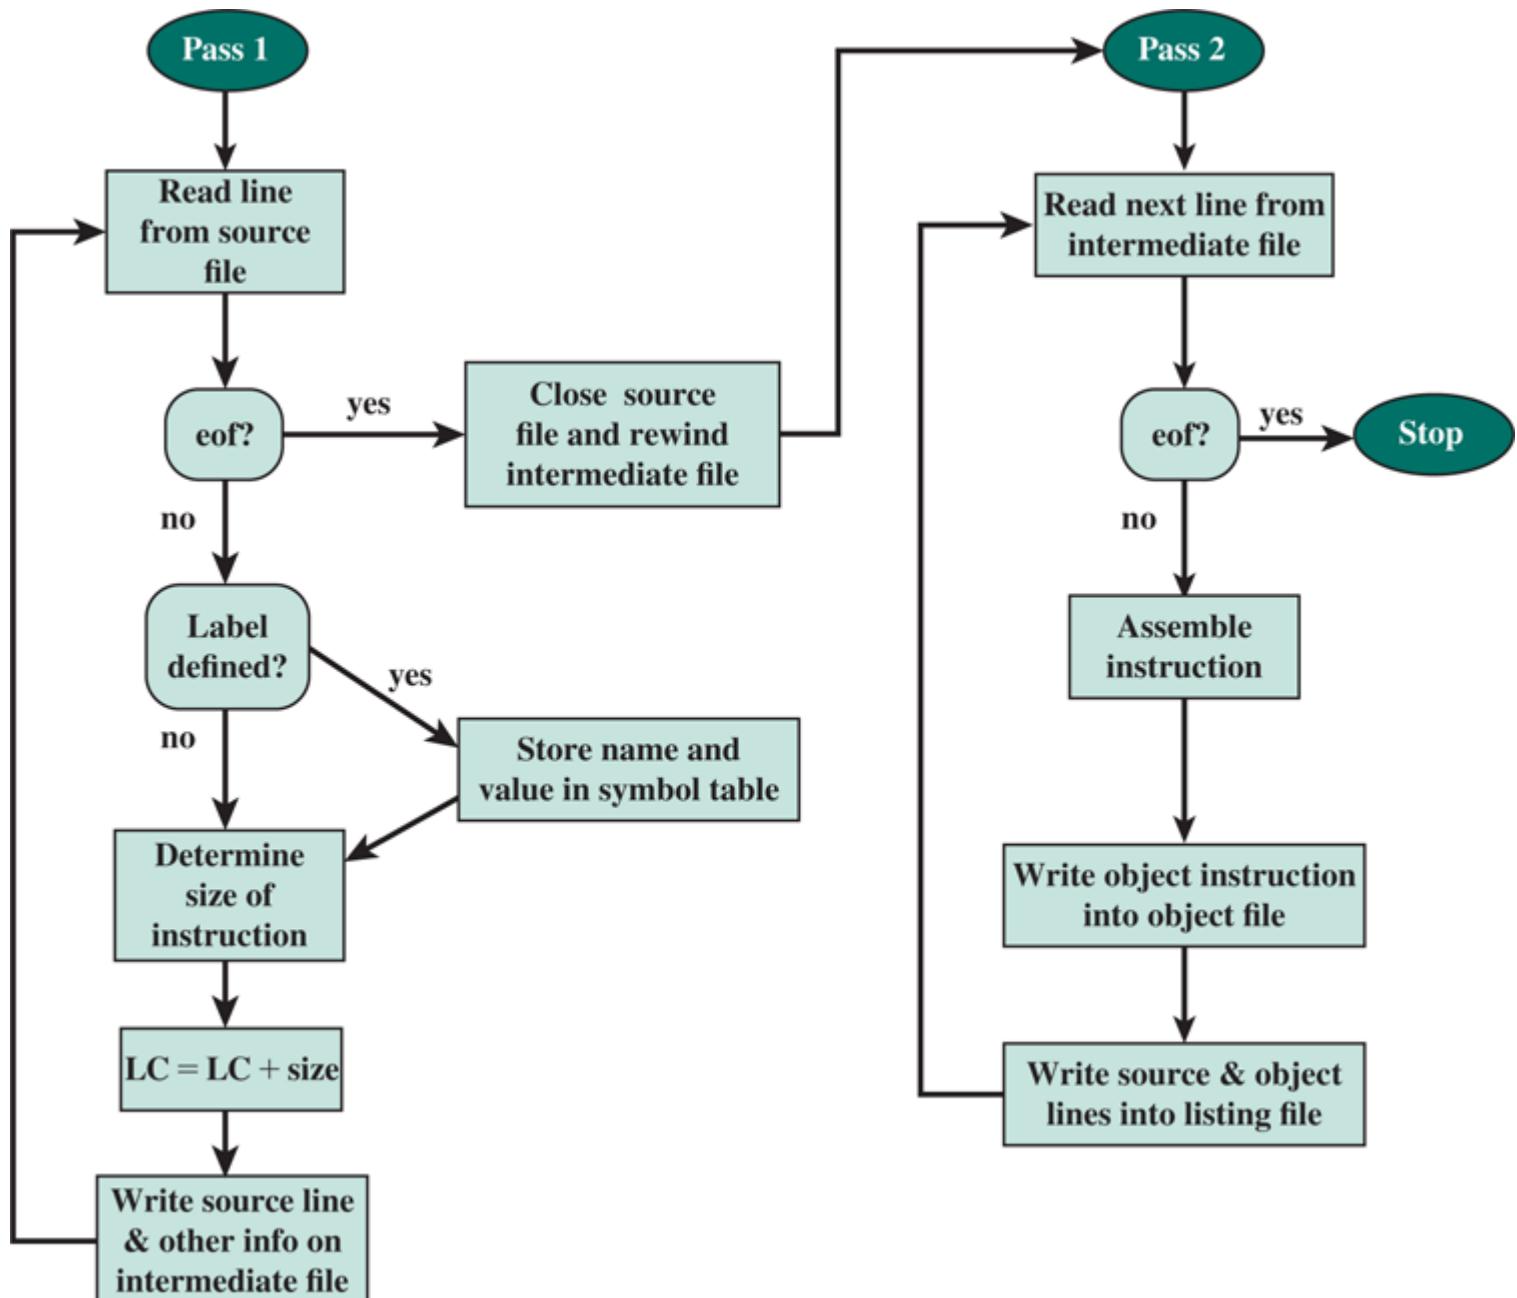

Figure 15.8 Flowchart of Two-Pass Assembler

In the first pass, the assembler is only concerned with label definitions. The first pass is used to construct a **symbol table** that contains a list of all labels and their associated **location counter** (LC) values. The first byte of the object code will have the LC value of 0. The first pass examines each assembly statement. Although the assembler is not yet ready to translate instructions, it must examine each instruction sufficiently to determine the length of the corresponding machine instruction and therefore how much to increment the LC. This may require not only examining the opcode but also looking at the operands and the addressing modes.

Directives such as DQ and REST (see [Table 15.2](#)) cause the location counter to be adjusted according to how much storage is specified.

When the assembler encounters a statement with a label, it places the label into the symbol table along with the current LC value. The assembler continues until it has read all of the assembly language statements.

SECOND PASS

The second pass reads the program again from the beginning. Each instruction is translated into the appropriate binary machine code. Translation includes the following operations:

1. Translate the mnemonic into a binary opcode.
2. Use the opcode to determine the format of the instruction and the location and length of the various fields in the instruction.
3. Translate each operand name into the appropriate register or memory code.
4. Translate each immediate value into a binary string.
5. Translate any references to labels into the appropriate LC value using the symbol table.
6. Set any other bits in the instruction that are needed, including addressing mode indicators, condition code bits, and so on.

A simple example, using the ARM assembly language, is shown in [Figure 15.9](#). The ARM assembly language instruction ADDS r3, r3, #19 is translated into the binary machine instruction 1110 0010 0101 0011 0011 0000 0001 0011.

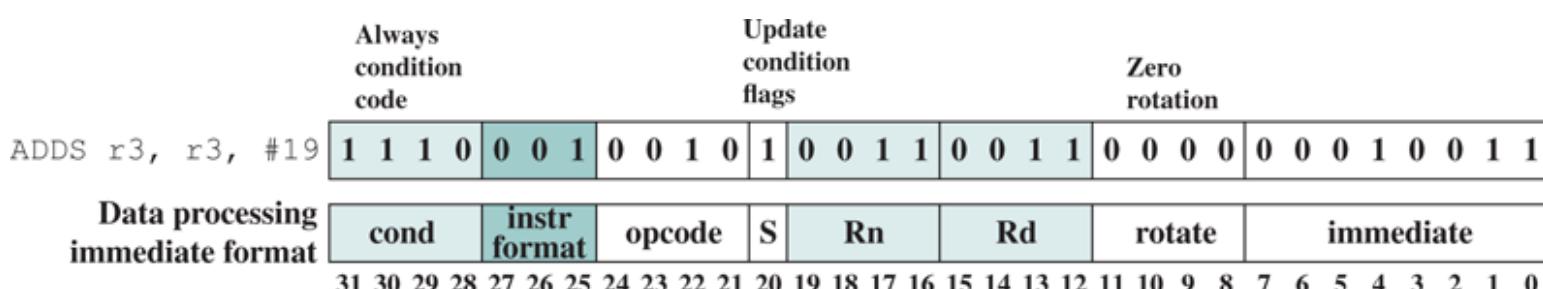

Figure 15.9 Translating an ARM Assembly Instruction into a Binary Machine Instruction

ZEROTH PASS

Most assembly language includes the ability to define macros. When macros are present there is an additional pass that the assembler must make before the first pass. Typically, the assembly language requires that all macro definitions must appear at the beginning of the program.

The assembler begins this “zeroth pass” by reading all macro definitions. Once all the macros are recognized, the assembler goes through the source code and expands the macros with their associated parameters whenever a macro call is encountered. The macro processing pass generates

a new version of the source code with all of the macro expansions in place and all of the macro definitions removed.

One-Pass Assembler

It is possible to implement an assembler that makes only a single pass through the source code (not counting the macro processing pass). The main difficulty in trying to assemble a program in one pass involves forward references to labels. Instruction operands may be symbols that have not yet been defined in the source program. Therefore, the assembler does not know what relative address to insert in the translated instruction.

In essence, the process of resolving forward references works as follows. When the assembler encounters an instruction operand that is a symbol that is not yet defined, the assembler does the following:

1. It leaves the instruction operand field empty (all zeros) in the assembled binary instruction.
2. The symbol used as an operand is entered in the symbol table. The table entry is flagged to indicate that the symbol is undefined.
3. The address of the operand field in the instruction that refers to the undefined symbol is added to a list of forward references associated with the symbol table entry.

When the symbol definition is encountered so that an LC value can be associated with it, the assembler inserts the LC value in the appropriate entry in the symbol table. If there is a forward reference list associated with the symbol, then the assembler inserts the proper address into any instruction previously generated that is on the forward reference list.

Example: Prime Number Program

We now look at an example that includes directives. This example looks at a program that finds prime numbers. Recall that prime numbers are evenly divisible by only 1 and themselves. There is no formula for doing this. The basic method this program uses is to find the factors of all odd numbers below a given limit. If no factor can be found for an odd number, it is prime. [Figure 15.6](#) shows the basic algorithm written in C. [Figure 15.7](#) shows the same algorithm written in NASM assembly language.

15.7 Loading and Linking

The first step in the creation of an active process is to load a program into main memory and create a process image ([Figure 15.10](#)). [Figure 15.11](#) depicts a scenario typical for most systems. The application consists of a number of compiled or assembled modules in object-code form. These are linked to resolve any references between modules. At the same time, references to library routines are resolved. The library routines themselves may be incorporated into the program or referenced as shared code that must be supplied by the operating system at run time. In this section, we summarize the key features of linkers and loaders. First, we discuss the concept of relocation. Then, for clarity in the presentation, we describe the loading task when a single program module is involved; no linking is required. We can then look at the linking and loading functions as a whole.

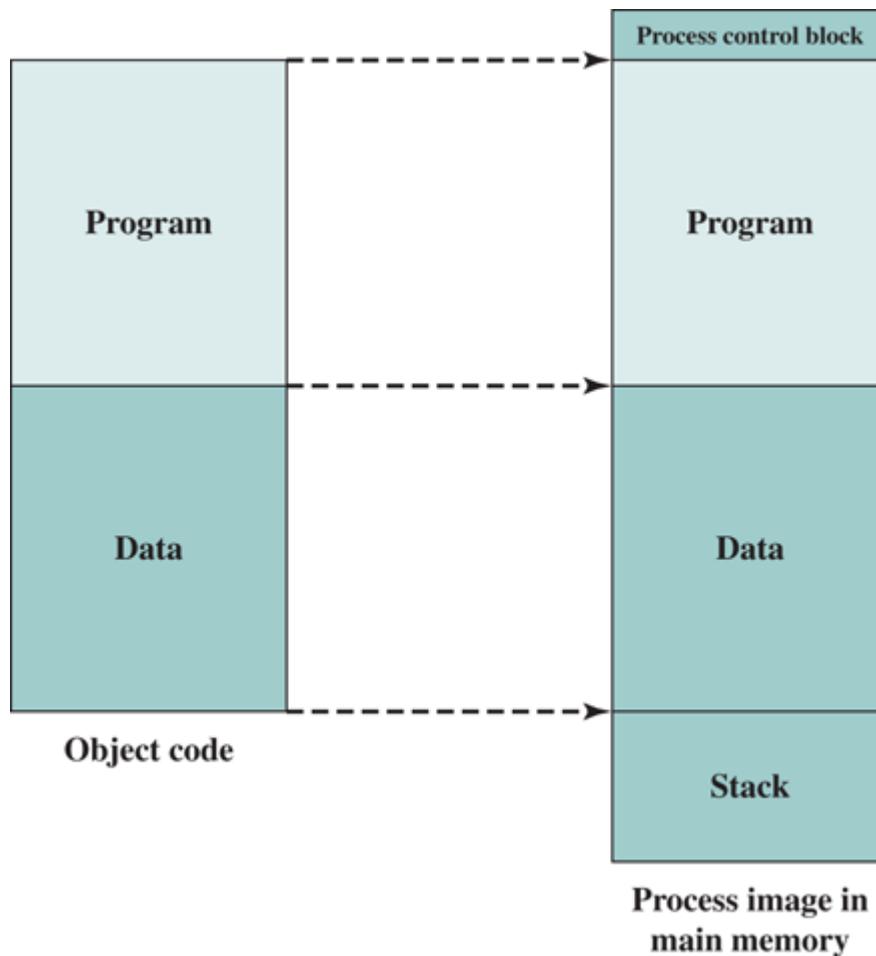

Figure 15.10 The Loading Function

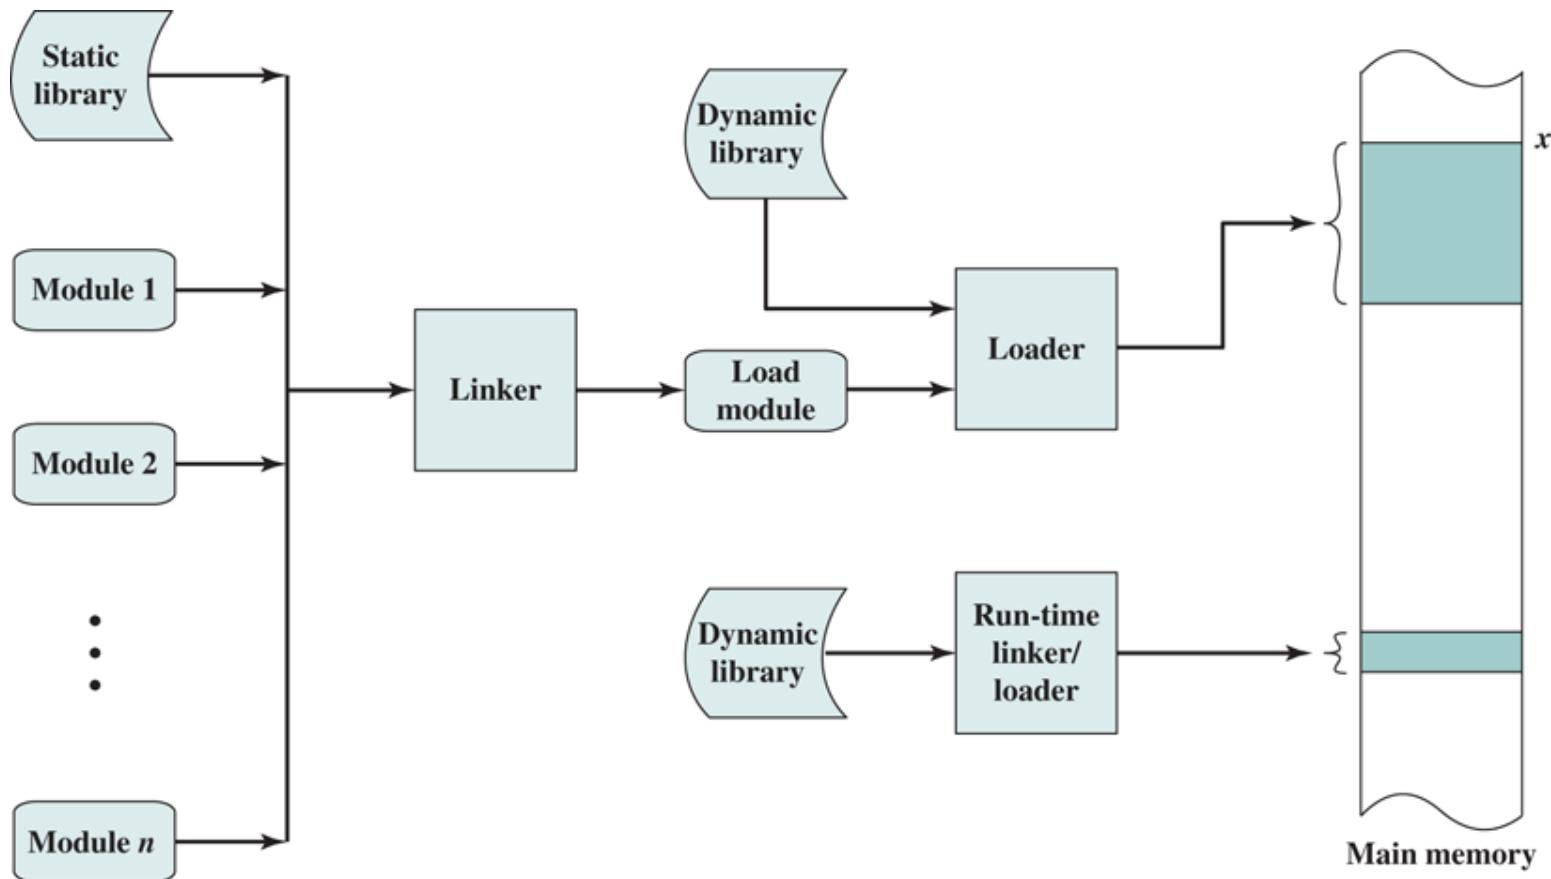

Figure 15.11 A Linking and Loading Scenario

Relocation

In a multiprogramming system, the available main memory is generally shared among a number of processes. Typically, it is not possible for the programmer to know in advance which other programs will be resident in main memory at the time of execution of his or her program. In addition, we would like to be able to swap active processes in and out of main memory to maximize processor utilization by providing a large pool of ready processes to execute. Once a program has been swapped out to disk, it would be quite limiting to declare that when it is next swapped back in, it must be placed in the same main memory region as before. Instead, we may need to **relocate** the process to a different area of memory.

Thus, we cannot know ahead of time where a program will be placed, and we must allow that the program may be moved about in main memory due to swapping. These facts raise some technical concerns related to addressing, as illustrated in [Figure 15.12](#). The figure depicts a process image. For simplicity, let us assume that the process image occupies a contiguous region of main memory. Clearly, the operating system will need to know the location of process control information and of the execution stack, as well as the entry point, to begin execution of the program for this process. Because the operating system is managing memory and is responsible for bringing this process into main memory, these addresses are easy to come by. In addition, however, the processor must deal with memory references within the program. Branch instructions contain an address to reference the instruction to be executed next. Data reference instructions contain the address of the byte or word of data referenced. Somehow, the processor hardware and operating system software must be able to translate the memory references found in the code of the program into actual physical memory addresses, reflecting the current location of the program in main memory.

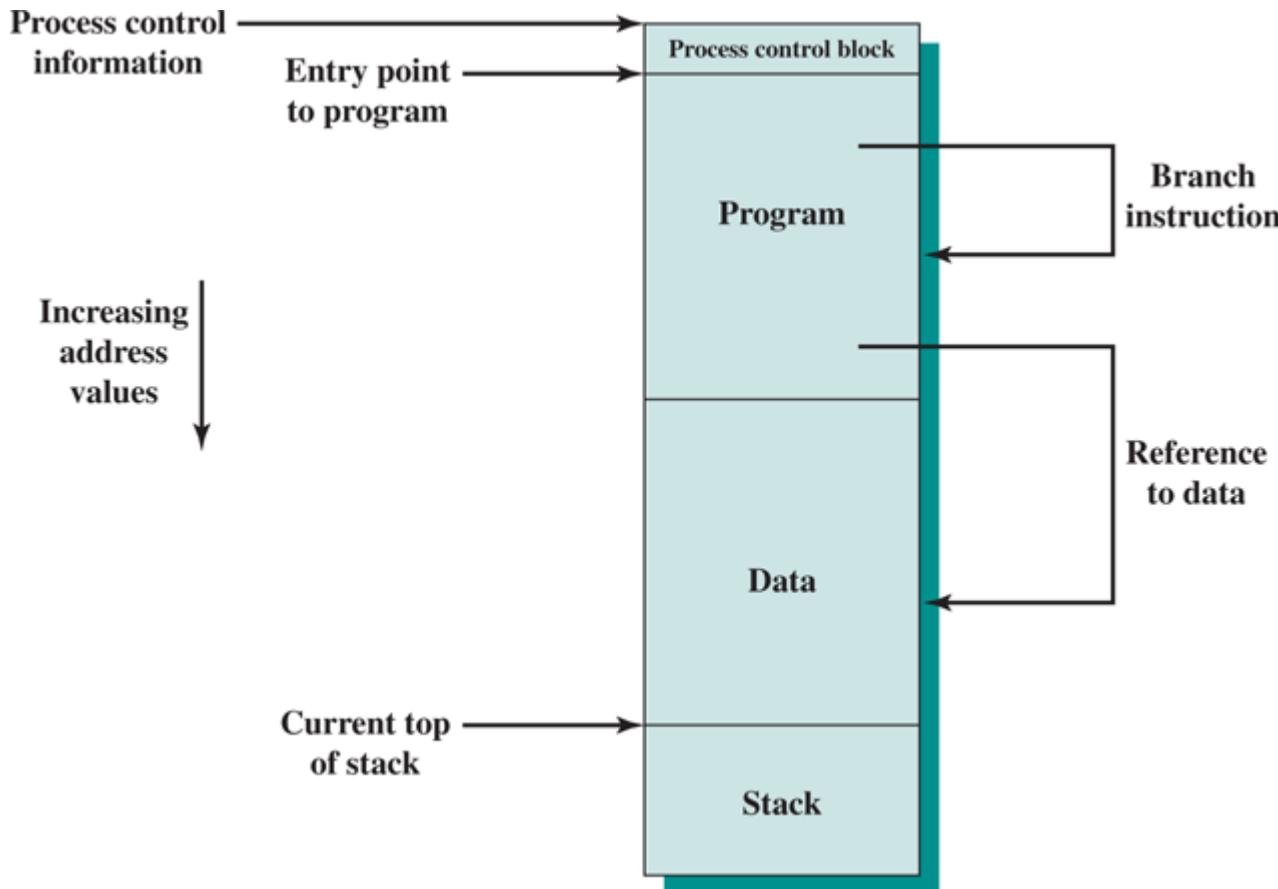

Figure 15.12 Addressing Requirements for a Process

Loading

In [Figure 15.11](#), the loader places the load module in main memory starting at location x . In loading the program, the addressing requirement illustrated in [Figure 15.12](#) must be satisfied. In general, three approaches can be taken:

- Absolute loading
- Relocatable loading
- Dynamic run-time loading

ABSOLUTE LOADING

An absolute loader requires that a given load module always be loaded into the same location in main memory. Thus, in the load module presented to the loader, all address references must be to specific, or absolute, main memory addresses. For example, if x in [Figure 15.11](#) is location 1024, then the first word in a load module destined for that region of memory has address 1024.

The assignment of specific address values to memory references within a program can be done either by the programmer or at compile or assembly time ([Table 15.4a](#)). There are several disadvantages to the former approach. First, every programmer would have to know the intended assignment strategy for placing modules into main memory. Second, if any modifications are made to the program that involve insertions or deletions in the body of the module, then all of the addresses will have to be altered. Accordingly, it is preferable to allow memory references within programs to be expressed symbolically and then resolve those symbolic references at the time of compilation or assembly. This is illustrated in [Figure 15.13](#). Every reference to an instruction or item of data is initially represented by a symbol. In preparing the module for input to an absolute loader, the assembler or compiler will

convert all of these references to specific addresses (in this example, for a module to be loaded starting at location 1024), as shown in [Figure 15.13b](#).

Table 15.4 Address Binding

(a) Loader	
Binding Time	Function
Programming time	All actual physical addresses are directly specified by the programmer in the program itself.
Compile or assembly time	The program contains symbolic address references, and these are converted to actual physical addresses by the compiler or assembler.
Load time	The compiler or assembler produces relative addresses. The loader translates these to absolute addresses at the time of program loading.
Run time	The loaded program retains relative addresses. These are converted dynamically to absolute addresses by processor hardware.
(b) Linker	
Linkage Time	Function
Programming time	No external program or data references are allowed. The programmer must place into the program the source code for all subprograms that are referenced.
Compile or assembly time	The assembler must fetch the source code of every subroutine that is referenced and assemble them as a unit.
Load module creation	All object modules have been assembled using relative addresses. These modules are linked together, and all references are restated relative to the origin of the final load module.
Load time	External references are not resolved until the load module is to be loaded into main memory. At that time, referenced dynamic link modules are appended to the load module, and the entire package is loaded into main or virtual memory.
Run time	External references are not resolved until the external call is executed by the processor. At that time, the process is interrupted and the desired module is linked to the calling program.

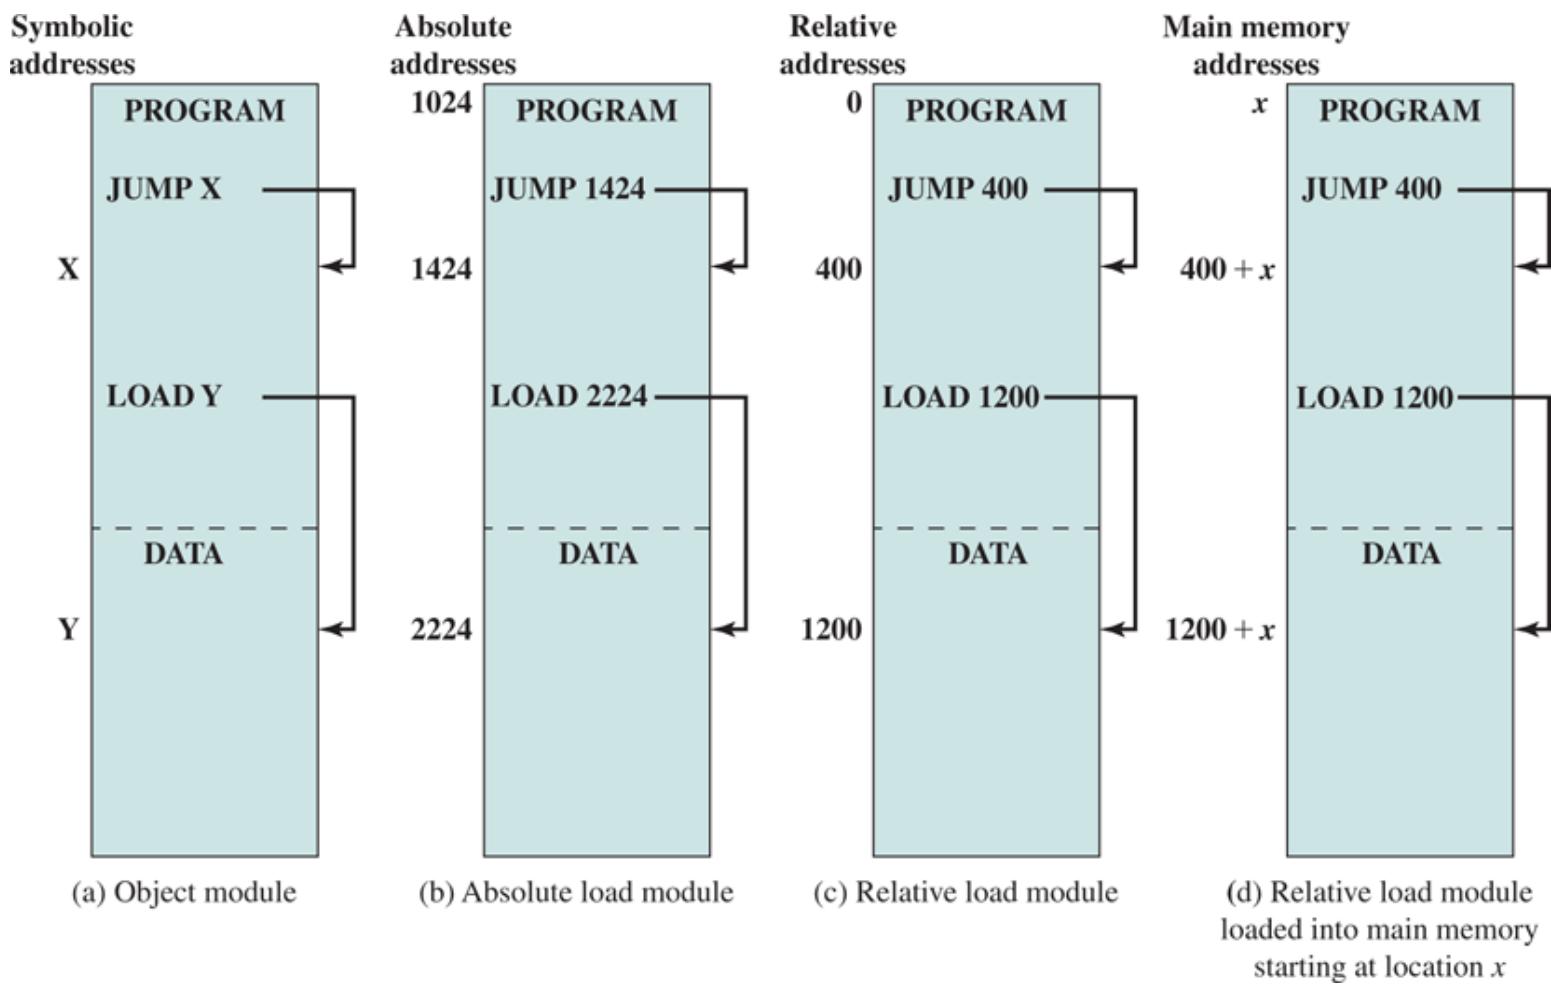

Figure 15.13 Absolute and Relocatable Load Modules

RELOCATABLE LOADING

The disadvantage of binding memory references to specific addresses prior to loading is that the resulting load module can only be placed in one region of main memory. However, when many programs share main memory, it may not be desirable to decide ahead of time into which region of memory a particular module should be loaded. It is better to make that decision at load time. Thus we need a load module that can be located anywhere in main memory.

To satisfy this new requirement, the assembler or compiler produces not actual main memory addresses (absolute addresses) but addresses that are relative to some known point, such as the start of the program. This technique is illustrated in [Figure 15.13c](#). The start of the load module is assigned the relative address 0, and all other memory references within the module are expressed relative to the beginning of the module.

With all memory references expressed in relative format, it becomes a simple task for the loader to place the module in the desired location. If the module is to be loaded beginning at location x , then the loader must simply add x to each memory reference as it loads the module into memory. To assist in this task, the load module must include information that tells the loader where the address references are and how they are to be interpreted (usually relative to the program origin, but also possibly relative to some other point in the program, such as the current location). This set of information is prepared by the compiler or assembler, and is usually referred to as the relocation dictionary.

DYNAMIC RUN-TIME LOADING

Relocatable loaders are common and provide obvious benefits relative to absolute loaders. However, in a multiprogramming environment, even one that does not depend on virtual memory, the relocatable loading scheme is inadequate. We have referred to the need to swap process images in and out of main memory to maximize the utilization of the processor. To maximize main memory utilization, we would like to be able to swap the process image back into different locations at different times. Thus, a program, once loaded, may be swapped out to disk and then swapped back in at a different location. This would be impossible if memory references had been bound to absolute addresses at the initial load time.

The alternative is to defer the calculation of an absolute address until it is actually needed at run time. For this purpose, the load module is loaded into main memory with all memory references in relative form ([Figure 15.13c](#)). It is not until an instruction is actually executed that the absolute address is calculated. To assure that this function does not degrade performance, it must be done by special processor hardware rather than software. This hardware is described in [Chapter 9](#).

Dynamic address calculation provides complete flexibility. A program can be loaded into any region of main memory. Subsequently, the execution of the program can be interrupted and the program can be swapped out of main memory, to be later swapped back in at a different location.

Linking

The function of a linker is to take as input a collection of object modules and produce a load module, consisting of an integrated set of program and data modules, to be passed to the loader. In each object module, there may be address references to locations in other modules. Each such reference can only be expressed symbolically in an unlinked object module. The linker creates a single load module that is the contiguous joining of all of the object modules. Each intramodule reference must be changed from a symbolic address, to a reference to a location within the overall load module. For example, module A in [Figure 15.14a](#) contains a procedure invocation of module 15. When these modules are combined in the load module, this symbolic reference to module B is changed to a specific reference to the location of the entry point of B within the load module.

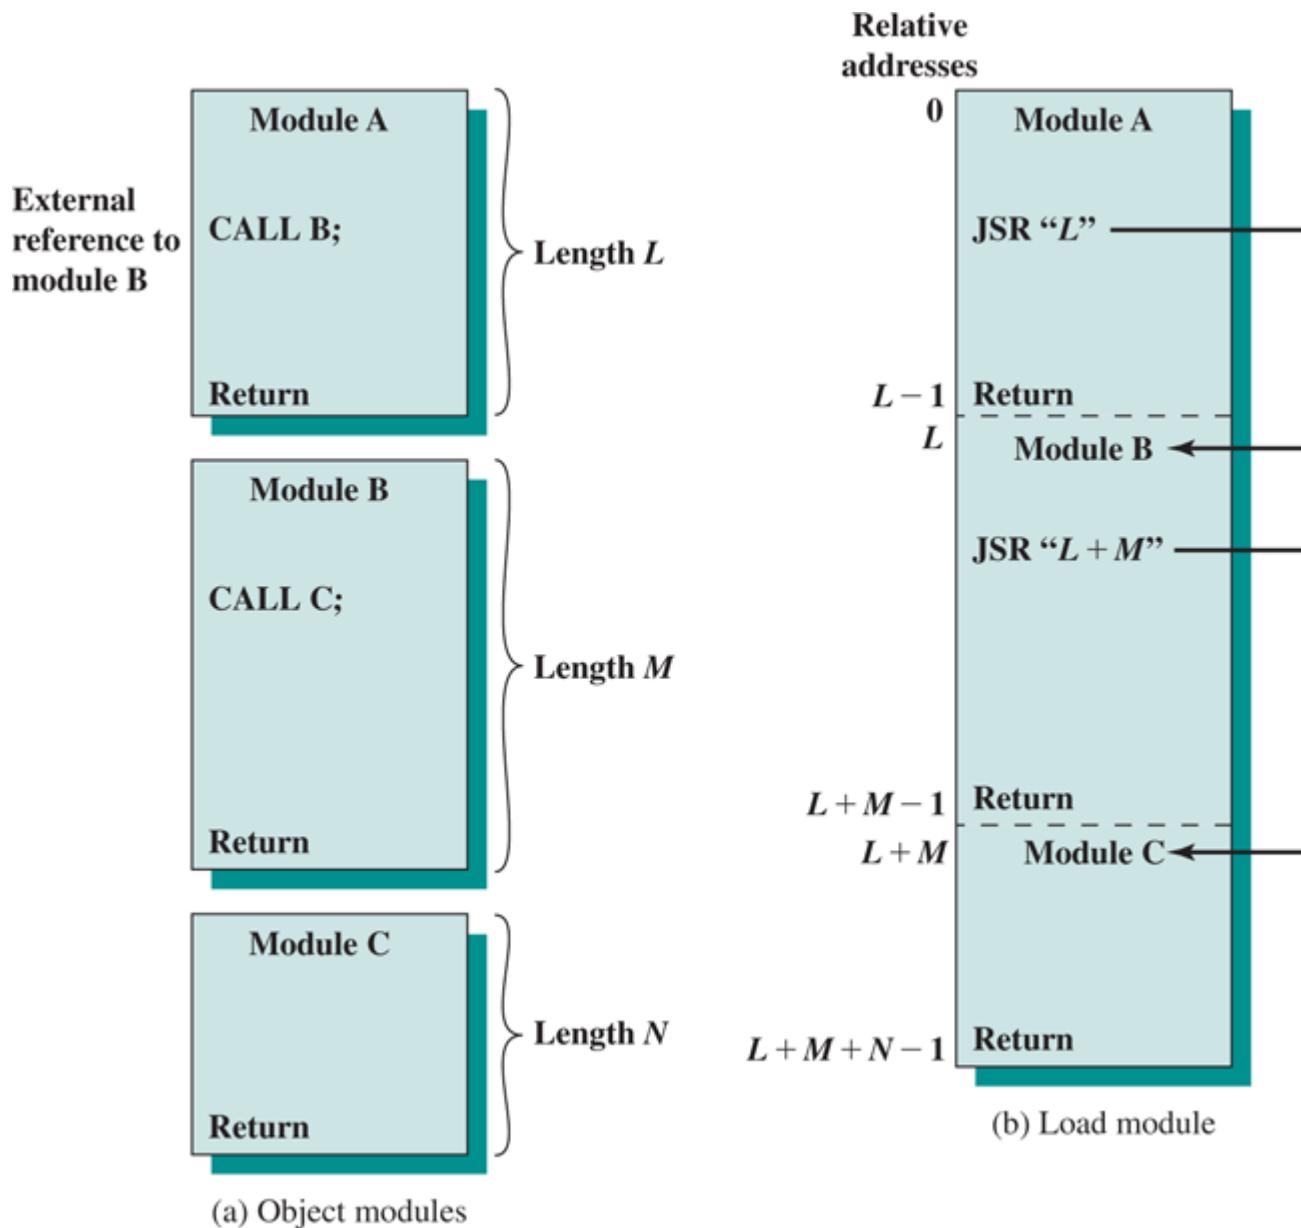

Figure 15.14 The Linking Function

LINKAGE EDITOR

The nature of this address linkage will depend on the type of load module to be created and when the linkage occurs ([Table 15.4b](#)). If, as is usually the case, a relocatable load module is desired, then linkage is usually done in the following fashion. Each compiled or assembled object module is created with references relative to the beginning of the object module. All of these modules are put together into a single relocatable load module with all references relative to the origin of the load module. This module can be used as input for relocatable loading or dynamic run-time loading.

A linker that produces a relocatable load module is often referred to as a linkage editor. [Figure 15.14](#) illustrates the linkage editor function.

DYNAMIC LINKER

As with loading, it is possible to defer some linkage functions. The term *dynamic linking* is used to refer to the practice of deferring the linkage of some external modules until after the load module has been created. Thus, the load module contains unresolved references to other programs. These references can be resolved either at load time or run time.

For **load-time dynamic linking** (involving the upper dynamic library in **Figure 15.11**), the following steps occur. The load module (application module) to be loaded is read into memory. Any reference to an external module (target module) causes the loader to find the target module, load it, and alter the reference to a relative address in memory from the beginning of the application module. There are several advantages to this approach over what might be called static linking:

- It becomes easier to incorporate changed or upgraded versions of the target module, which may be an operating system utility or some other general-purpose routine. With static linking, a change to such a supporting module would require the relinking of the entire application module. Not only is this inefficient, but it may be impossible in some circumstances. For example, in the personal computer field, most commercial software is released in load module form; source and object versions are not released.
- Having target code in a dynamic link file paves the way for automatic code sharing. The operating system can recognize that more than one application is using the same target code because it loaded and linked that code. It can use that information to load a single copy of the target code and link it to both applications, rather than having to load one copy for each application.
- It becomes easier for independent software developers to extend the functionality of a widely-used operating system such as Linux. A developer can come up with a new function that may be useful to a variety of applications and package it as a dynamic link module.

With **run-time dynamic linking** (involving the lower dynamic library in **Figure 15.11**), some of the linking is postponed until execution time. External references to target modules remain in the loaded program. When a call is made to the absent module, the operating system locates the module, loads it, and links it to the calling module. Such modules are typically shareable. In the Windows environment, these are called dynamic-link libraries (DLLs). Thus, if one process is already making use of a dynamically linked shared module, then that module is in main memory and a new process can simply link to the already-loaded module.

The use of DLLs can lead to a problem commonly referred to as **DLL hell**. DLL hell occurs if two or more processes are sharing a DLL module, but expect different versions of the module. For example, an application or system function might be re-installed and bring in with it an older version of a DLL file.

We have seen that dynamic loading allows an entire load module to be moved around; however, the structure of the module is static, being unchanged throughout the execution of the process and from one execution to the next. However, in some cases, it is not possible to determine prior to execution which object modules will be required. This situation is typified by transaction-processing applications, such as an airline reservation system or a banking application. The nature of the transaction dictates which program modules are required, and they are loaded as appropriate and linked with the main program. The advantage of the use of such a dynamic linker is that it is not necessary to allocate memory for program units unless those units are referenced. This capability is used in support of segmentation systems.

One additional refinement is possible: An application need not know the names of all the modules or entry points that may be called. For example, a charting program may be written to work with a variety of plotters, each of which is driven by a different driver package. The application can learn the name of the plotter that is currently installed on the system from another process or by looking it up in a configuration file. This allows the user of the application to install a new plotter that did not exist at the time the application was written.

Review Questions

15.1 List some reasons why it is worthwhile to study assembly language programming.

15.2 What is an assembly language?

15.3 List some disadvantages of assembly language compared to high-level languages.

15.4 List some advantages of assembly language compared to high-level languages.

15.5 What are the typical elements of an assembly language statement?

15.6 List and briefly define four different kinds of assembly language statements.

15.7 What is the difference between a one-pass assembler and a two-pass assembler?

Problems

15.1 Core War is a programming game introduced to the public in the early 1980s [DEWD84], which was popular for a period of 15 years or so. Core War has four main components: a memory array of 8000 addresses; a simplified assembly language Redcode; an executive program called MARS (an acronym for Memory Array Redcode Simulator); and the set of

contending battle programs. Two battle programs are entered into the memory array at randomly chosen positions; neither program knows where the other one is. MARS executes the programs in a simple version of time-sharing. The two programs take turns; a single instruction of the first program is executed, then a single instruction of the second, and so on. What a battle program does during the execution cycles allotted to it is entirely up to the programmer. The aim is to destroy the other program by ruining its instructions. In this problem and the next several, we use an even simpler language, called CodeBlue, to explore some Core War concepts. CodeBlue contains only five assembly language statements and uses three addressing modes (**Table 15.5**). Addresses wrap around, so that for the last location in memory, the relative address of +1 refers to the first location in memory. For example, `ADD #4, 6` adds 4 to the contents of relative location 6 and stores the results in location 6; `JUMP @5` transfers execution to the memory address contained in the location five slots past the location of the current `JUMP` instruction.

Table 15.5 CodeBlue Assembly Language

(a) Instruction Set	
Format	Meaning
DATA <value>	<value> set at current location
COPY A, B	copies source A to destination B
ADD A, B	adds A to B, putting result in B
JUMP A	transfer execution to A
JUMPZ A, B	if B = 0, transfer to A

(b) Addressing Modes		
Mode	Format	Meaning
Literal	# followed by value	This is an immediate mode, the operand value is in the instruction.
Relative	Value	The value represents an offset from the current location, which contains the operand.
Indirect	@ followed by value	The value represents an offset from the current location; the offset location contains the relative address of the location that contains the operand.

Loop COPY #0, -1

```
JUMP -1
```

Hint: Remember that instruction execution alternates between the two opposing programs.

- a. The program Imp is the single instruction `COPY 0, 1`. What does it do?
- b. The program Dwarf is the following sequence of instructions:

```
ADD #4, 3
COPY 2, @2
JUMP -2
DATA 0
```

What does it do?

- c. Rewrite Dwarf using symbols, so that it looks more like a typical assembly language program.

15.2 What happens if we pit Imp against Dwarf?

15.3 Write a “carpet bombing” program in CodeBlue that zeros out all of memory (with the possible exception of the program locations).

15.4 How would the previous program fare against Imp?

15.5

- a. What is the value of the C status flag after the following sequence:

```
mov al, 3
add al, 4
```

- b. What is the value of the C status flag after the following sequence:

```
mov al, 3
sub al, 4
```

15.6 Consider the following NAMS instruction:

```
cmp vleft, vright
```

For signed integers, there are three status flags that are relevant. If $vleft = vright$, then ZF is set.

If $vleft > vright$, ZF is unset (set to 0) and SF=OF. If $vleft < vright$, ZF is unset and SF \neq OF.

Why does SF=OF if $vleft > vright$?

15.7 Consider the following NASM code fragment:

```
mov al, 0
cmp al, al
je next
```

Write an equivalent program consisting of a single instruction.

15.8 Consider the following C program:

```
/* a simple C program to average 3 integers */
main ()
{ int avg;
  int i1 = 20;
  int i2 = 13;
  int i3 = 82;
  avg = (i1 + i2 + i3)/3;
}
```

Write an NASM version of this program.

15.9 Consider the following C code fragment:

```
if (EAX == 0) EBX = 1;
else EBX = 2;
```

Write an equivalent NASM code fragment.

15.10 The initialize data directives can be used to initialize multiple locations. For example,

```
db 0x55,0x56,0x57
```

reserves three bytes and initializes their values.

NASM supports the special token \$ to allow calculations to involve the current assembly position. That is, \$ evaluates to the assembly position at the beginning of the line containing the expression. With the preceding two facts in mind, consider the following sequence of directives:

```
message db 'hello, world'
msglen equ $-message
```

What value is assigned to the symbol msglen?

15.11 Assume the three symbolic variables V1, V2, V3 contain integer values. Write an NASM code fragment that moves the smallest value into integer ax. Use only the instructions `mov`, `cmp`, and `jbe`.

15.12 Describe the effect of this instruction: `cmp eax, 1` Assume that the immediately preceding instruction updated the contents of eax.

15.13 The `xchg` instruction can be used to exchange the contents of two registers. Suppose that the x86 instruction set did not support this instruction.

- Implement `xchg ax, bx` using only push and pop instructions.
- Implement `xchg ax, bx` using only the `xor` instruction (do not involve other registers).

15.14 In the following program, assume that a, b, x, y are symbols for main memory locations. What does the program do? You can answer the question by writing the equivalent logic in C.

```
mov    eax,a
mov    ebx,b
xor    eax,x
xor    ebx,y
```

```

        or      eax,ebx
        jnz     L2
L1:          ;sequence of instructions...
        jmp     L3
L2:          ;another sequence of instructions...
L3:

```

15.15 [Section 15.4](#) includes a C program that calculates the greatest common divisor of two integers.

- Describe the algorithm in words and show how the program does implement the Euclid algorithm approach to calculating the greatest common divisor.
- Add comments to the assembly program of [Figure 15.4a](#) to clarify that it implements the same logic as the C program.
- Repeat part (b) for the program of [Figure 15.4b](#).

15.16

- A 2-pass assembler can handle future symbols and an instruction can therefore use a future symbol as an operand. This is not always true for directives. The EQU directive, for example, cannot use a future symbol. The directive “A EQU B + 1” is easy to execute if B is previously defined, but impossible if B is a future symbol. What’s the reason for this?
- Suggest a way for the assembler to eliminate this limitation such that any source line could use future symbols.

15.17 Consider a symbol directive MAX of the following form: symbol MAX list of expressions
The label is mandatory and is assigned the value of the largest expression in the operand field.
Example:

```
MSGLEN MAX A, B, C ;where A, B, C are defined symbols
```

How is MAX executed by the Assembler and in what pass?

Learning Objectives

After studying this chapter, you should be able to:

- Distinguish between **user-visible** and **control/status registers**, and discuss the purposes of registers in each category.
- Summarize the **instruction cycle**.
- Discuss the principle behind **instruction pipelining** and how it works in practice.

- Compare and contrast the various forms of pipeline hazards.
- Present an overview of the x86 processor structure.
- Present an overview of the ARM processor structure.

This chapter discusses aspects of the processor not covered in Part Four and sets the stage for the discussion of RISC and superscalar architecture in Chapters 17 and 18.

We begin with a summary of processor organization. Registers, which form the internal memory of the processor, are then analyzed. We are then in a position to return to the discussion (begun in Section 3.2) of the instruction cycle. A description of the instruction cycle and a common technique known as instruction pipelining complete our description. The chapter concludes with an examination of some aspects of the x86 and ARM organizations.

16.1 Processor Organization

To understand the organization of the processor, let us consider the requirements placed on the processor, the things that it must do:

- **Fetch instruction:** The processor reads an instruction from memory (register, cache, main memory).
- **Interpret instruction:** The instruction is decoded to determine what action is required.
- **Fetch data:** The execution of an instruction may require reading data from memory or an I/O module.
- **Process data:** The execution of an instruction may require performing some arithmetic or logical operation on data.
- **Write data:** The results of an execution may require writing data to memory or an I/O module.

To do these things, it should be clear that the processor needs to store some data temporarily. It must remember the location of the last instruction so that it can know where to get the next instruction. It needs to store instructions and data temporarily while an instruction is being executed. In other words, the processor needs a small internal memory.

Figure 16.1 is a simplified view of the internal structure of a processor. The reader will recall that the major components of the processor are an *arithmetic and logic unit* (ALU) and a *control unit* (CU). The ALU does the actual computation or processing of data. The control unit controls the movement of data and instructions into and out of the processor, and controls the operation of the ALU. In addition, the figure shows a minimal internal memory, consisting of a set of storage locations, called *registers*. The data transfer and logic control paths are indicated, including an element labeled *internal processor bus*. This element is needed to transfer data between the various registers and the ALU, because the ALU in fact operates only on data in the internal processor memory. The figure also shows typical basic elements of the ALU. Note the similarity between the internal structure of the computer as a whole, and the internal structure of the processor. In both cases, there is a small collection of major elements (computer: processor, I/O, memory; processor: control unit, ALU, registers) connected by data paths.

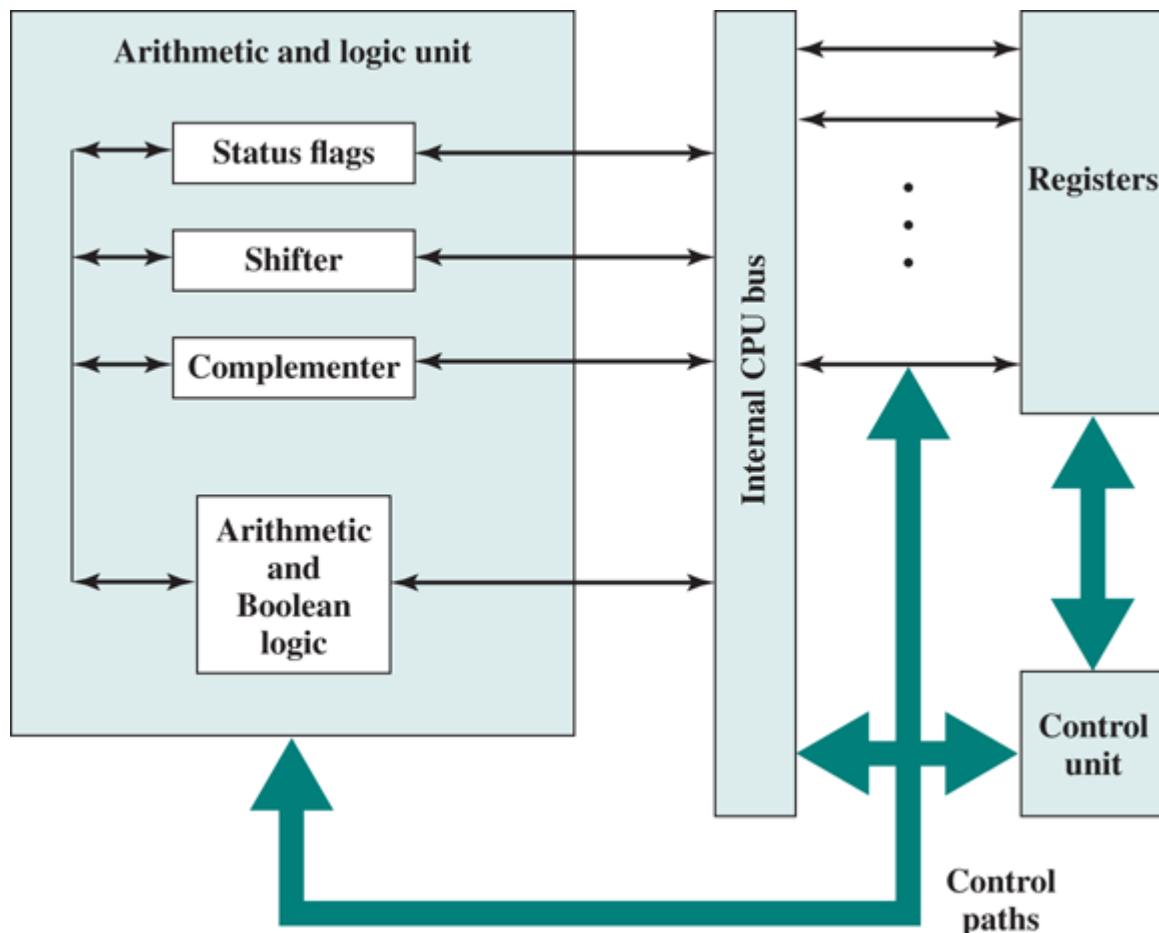

Figure 16.1 Internal Structure of the CPU

16.2 Register Organization

As we discussed in [Chapter 4](#), a computer system employs a memory hierarchy. At higher levels of the hierarchy, memory is faster, smaller, and more expensive (per bit). Within the processor, there is a set of registers that function as a level of memory above main memory and cache in the hierarchy. The registers in the processor perform two roles:

- **User-visible registers:** Enable the machine- or assembly language programmer to minimize main memory references by optimizing use of registers.
- **Control and status registers:** Used by the control unit to control the operation of the processor and by privileged, operating system programs to control the execution of programs.

There is not a clean separation of registers into these two categories. For example, on some machines the program counter is user visible (e.g., x86), but on many it is not. For purposes of the following discussion, however, we will use these categories.

User-Visible Registers

A user-visible register is one that may be referenced by means of the machine language that the processor executes. We can characterize these in the following categories:

- General purpose
- Data
- Address
- Condition codes

General-purpose registers can be assigned to a variety of functions by the programmer.

Sometimes their use within the instruction set is orthogonal to the operation. That is, any general-purpose register can contain the operand for any opcode. This provides true general-purpose register use. Often, however, there are restrictions. For example, there may be dedicated registers for floating-point and stack operations.

In some cases, general-purpose registers can be used for addressing functions (e.g., register indirect, displacement). In other cases, there is a partial or clean separation between data registers and address registers. **Data registers** may be used only to hold data and cannot be employed in the calculation of an operand address. **Address registers** may themselves be somewhat general purpose, or they may be devoted to a particular addressing mode. Examples include the following:

- **Segment pointers:** In a machine with segmented addressing (see [Section 9.3](#)), a segment register holds the address of the base of the segment. There may be multiple registers: for example, one for the operating system and one for the current process.
- **Index registers:** These are used for indexed addressing and may be autoindexed.
- **Stack pointer:** If there is user-visible stack addressing, then typically there is a dedicated register that points to the top of the stack. This allows implicit addressing; that is, push, pop, and other stack instructions need not contain an explicit stack operand.

There are several design issues to be addressed here. An important issue is whether to use completely general-purpose registers or to specialize their use. We have already touched on this issue in the preceding chapter because it affects instruction set design. With the use of specialized registers, it can generally be implicit in the opcode which type of register a certain operand specifier refers to. The operand specifier must only identify one of a set of specialized registers rather than one out of all the registers, thus saving bits. On the other hand, this specialization limits the programmer's flexibility.

Another design issue is the number of registers, either general purpose or data plus address, to be provided. Again, this affects instruction set design because more registers require more operand specifier bits. As we previously discussed, somewhere between 8 and 32 registers appears optimum [LUND77]. Fewer registers result in more memory references; more registers do not noticeably reduce memory references (e.g., see [WILL90]). However, a new approach, which finds advantage in the use of hundreds of registers, is exhibited in some RISC systems and is discussed in [Chapter 17](#).

Finally, there is the issue of register length. Registers that must hold addresses obviously must be at least long enough to hold the largest address. Data registers should be able to hold values of most data types. Some machines allow two contiguous registers to be used as one for holding double-length values.

A final category of registers, which is at least partially visible to the user, holds **condition codes** (also referred to as *flags*). Condition codes are bits set by the processor hardware as the result of operations. For example, an arithmetic operation may produce a positive, negative, zero, or overflow result. In addition to the result itself being stored in a register or memory, a condition code is also set. The code may subsequently be tested as part of a conditional branch operation.

Condition code bits are collected into one or more registers. Usually, they form part of a control register. Generally, machine instructions allow these bits to be read by implicit reference, but the programmer cannot alter them.

Many processors, including those based on the IA-64 architecture and the MIPS processors, do not use condition codes at all. Rather, conditional branch instructions specify a comparison to be made and act on the result of the comparison, without storing a condition code. [Table 16.1](#), based on [DERO87], lists key advantages and disadvantages of condition codes.

Table 16.1 Condition Codes

Advantages	Disadvantages
<ol style="list-style-type: none">Because condition codes are set by normal arithmetic and data movement instructions, they should reduce the number of COMPARE and TEST instructions needed.Conditional instructions such as BRANCH are simplified relative to composite instructions, such as TEST and BRANCH.Condition codes facilitate multiway branches. For example, a TEST instruction can be followed by two branches, one on less than or equal to zero and one on greater than zero.Condition codes can be saved on the stack during subroutine calls	<ol style="list-style-type: none">Condition codes add complexity, both to the hardware and software. Condition code bits are often modified in different ways by different instructions, making life more difficult for both the microprogrammer and compiler writer.Condition codes are irregular; they are typically not part of the main data path, so they require extra hardware connections.Often condition code machines must add special non-condition-code instructions for special situations anyway, such as bit checking, loop control, and atomic semaphore operations.In a pipelined implementation, condition codes require special synchronization to avoid conflicts.

along with other register information.

In some machines, a subroutine call will result in the automatic saving of all user-visible registers, to be restored on return. The processor performs the saving and restoring as part of the execution of call and return instructions. This allows each subroutine to use the user-visible registers independently. On other machines, it is the responsibility of the programmer to save the contents of the relevant user-visible registers prior to a subroutine call, by including instructions for this purpose in the program.

Control and Status Registers

There are a variety of processor registers that are employed to control the operation of the processor. Most of these, on most machines, are not visible to the user. Some of them may be visible to machine instructions executed in a control or operating system mode.

Of course, different machines will have different register organizations and use different terminology. We list here a reasonably complete list of register types, with a brief description.

Four registers are essential to instruction execution:

- **Program counter (PC):** Contains the address of an instruction to be fetched.
- **Instruction register (IR):** Contains the instruction most recently fetched.
- **Memory address register (MAR):** Contains the address of a location in memory.
- **Memory buffer register (MBR):** Contains a word of data to be written to memory or the word most recently read.

Not all processors have internal registers designated as MAR and MBR, but some equivalent buffering mechanism is needed whereby the bits to be transferred to the system bus are staged, and the bits to be read from the data bus are temporarily stored.

Typically, the processor updates the PC after each instruction fetch so that the PC always points to the next instruction to be executed. A branch or skip instruction will also modify the contents of the PC. The fetched instruction is loaded into an IR, where the opcode and operand specifiers are analyzed. Data are exchanged with memory using the MAR and MBR. In a bus-organized system, the MAR connects directly to the address bus, and the MBR connects directly to the data bus. User-visible registers, in turn, exchange data with the MBR.

The four registers just mentioned are used for the movement of data between the processor and memory. Within the processor, data must be presented to the ALU for processing. The ALU may have direct access to the MBR and user-visible registers. Alternatively, there may be additional buffering registers at the boundary to the ALU; these registers serve as input and output registers for the ALU and exchange data with the MBR and user-visible registers.

Many processor designs include a register or set of registers, often known as the *program status word* (PSW), that contain status information. The PSW typically contains condition codes plus other status information. Common fields or flags include the following:

- **Sign:** Contains the sign bit of the result of the last arithmetic operation.
- **Zero:** Set when the result is 0.
- **Carry:** Set if an operation resulted in a carry (addition) into or borrow (subtraction) out of a high-order bit. Used for multiword arithmetic operations.
- **Equal:** Set if a logical compare result is equality.

- **Overflow:** Used to indicate arithmetic overflow.
- **Interrupt Enable/Disable:** Used to enable or disable interrupts.
- **Supervisor:** Indicates whether the processor is executing in supervisor or user mode. Certain privileged instructions can be executed only in supervisor mode, and certain areas of memory can be accessed only in supervisor mode.

A number of other registers related to status and control might be found in a particular processor design. There may be a pointer to a block of memory containing additional status information (e.g., process control blocks). In machines using vectored interrupts, an interrupt vector register may be provided. If a stack is used to implement certain functions (e.g., subroutine call), then a system stack pointer is needed. A page table pointer is used with a virtual memory system. Finally, registers may be used in the control of I/O operations.

A number of factors go into the design of the control and status register organization. One key issue is operating system support. Certain types of control information are of specific utility to the operating system. If the processor designer has a functional understanding of the operating system to be used, then the register organization can to some extent be tailored to the operating system.

Another key design decision is the allocation of control information between registers and memory. It is common to dedicate the first (lowest) few hundred or thousand words of memory for control purposes. The designer must decide how much control information should be in registers and how much in memory. The usual trade-off of cost versus speed arises.

Example Microprocessor Register Organizations

It is instructive to examine and compare the register organization of comparable systems. In this section, we look at two 16-bit microprocessors that were designed at about the same time: the Motorola MC68000 [STR179] and the Intel 8086 [MORS78]. **Figures 16.2a** and **b** depict the register organization of each; purely internal registers, such as a memory address register, are not shown.

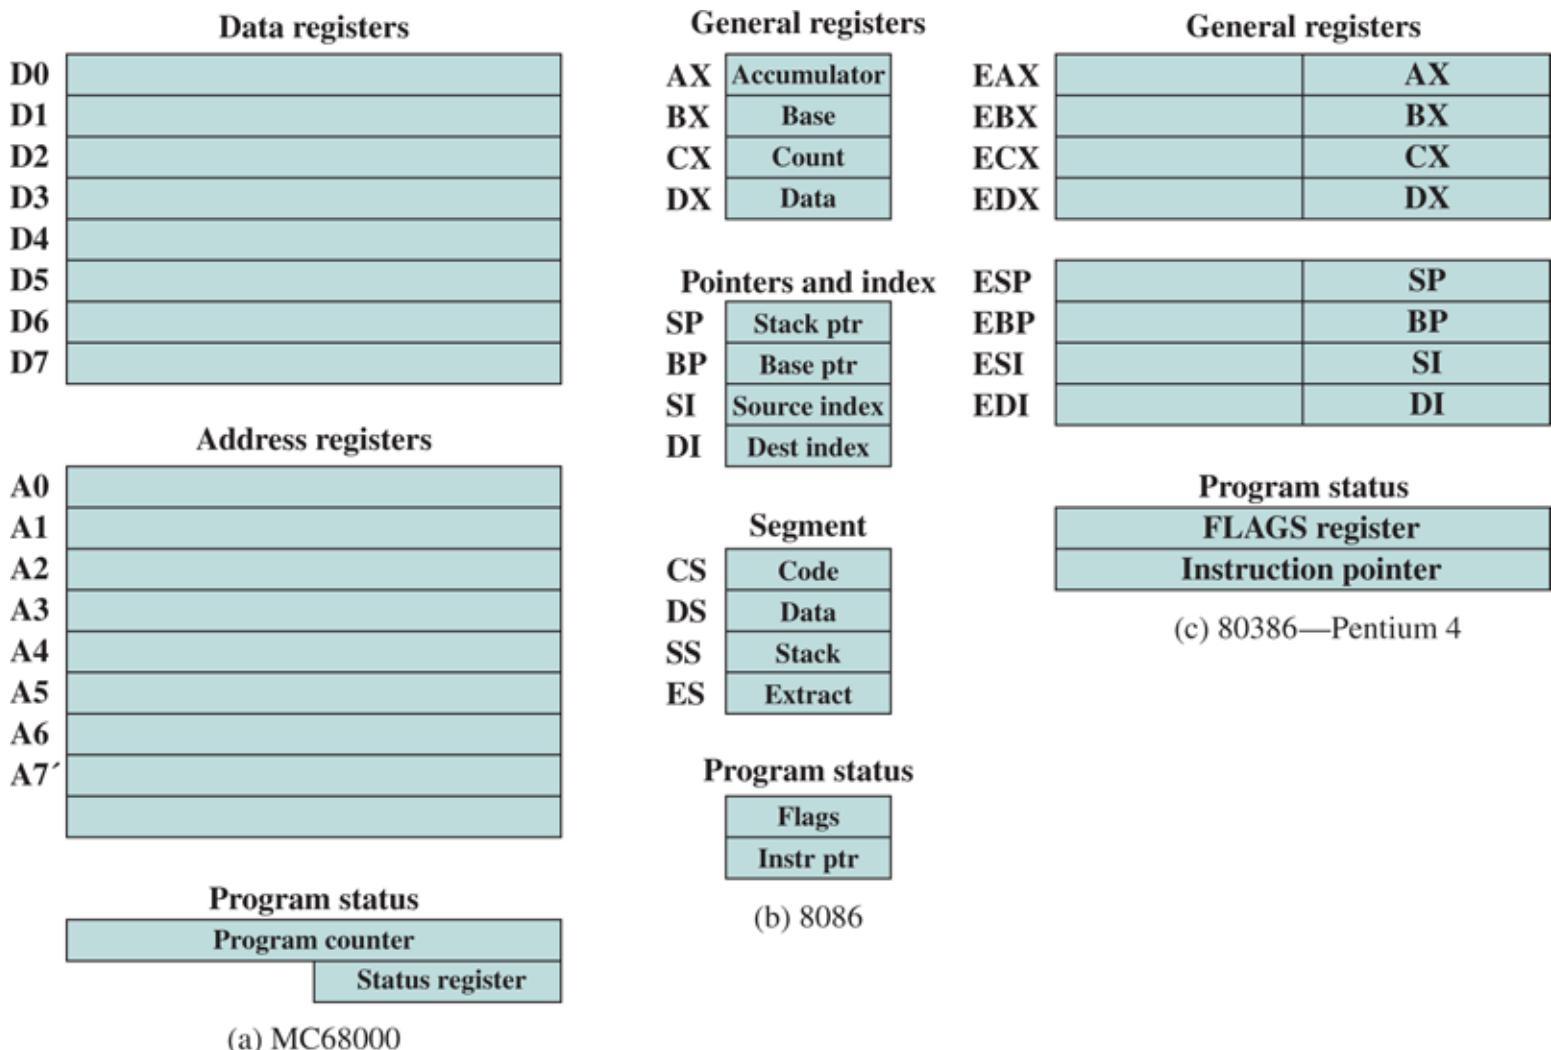

Figure 16.2 Example Microprocessor Register Organizations

The MC68000 partitions its 32-bit registers into eight data registers and nine address registers. The eight data registers are used primarily for data manipulation and are also used in addressing as index registers. The width of the registers allows 8-, 16-, and 32-bit data operations, determined by opcode. The address registers contain 32-bit (no segmentation) addresses; two of these registers are also used as stack pointers, one for users and one for the operating system, depending on the current execution mode. Both registers are numbered 7, because only one can be used at a time. The MC68000 also includes a 32-bit program counter and a 16-bit status register.

The Motorola team wanted a very regular instruction set, with no special-purpose registers. A concern for code efficiency led them to divide the registers into two functional components, saving one bit on each register specifier. This seems a reasonable compromise between complete generality and code compaction.

The Intel 8086 takes a different approach to register organization. Every register is special purpose, although some registers are also usable as general purpose. The 8086 contains four 16-bit data registers that are addressable on a byte or 16-bit basis, and four 16-bit pointer and index registers. The data registers can be used as general purpose in some instructions. In others, the registers are used implicitly. For example, a multiply instruction always uses the accumulator. The four pointer registers are also used implicitly in a number of operations; each contains a segment offset. There are also four 16-bit segment registers. Three of the four segment registers are used in a dedicated, implicit fashion, to point to the segment of the current instruction (useful for branch instructions), a segment containing data, and a segment containing a stack, respectively. These dedicated and implicit uses provide for compact encoding at the cost of reduced flexibility. The 8086 also includes an

instruction pointer and a set of 1-bit status and control flags.

The point of this comparison should be clear. There is no universally accepted philosophy concerning the best way to organize processor registers [TOON81]. As with overall instruction set design and so many other processor design issues, it is still a matter of judgment and taste.

A second instructive point concerning register organization design is illustrated in [Figure 16.2c](#). This figure shows the user-visible register organization for the Intel 80386 [ELAY85], which is a 32-bit microprocessor designed as an extension of the 8086.¹ The 80386 uses 32-bit registers. However, to provide upward compatibility for programs written on the earlier machine, the 80386 retains the original register organization embedded in the new organization. Given this design constraint, the architects of the 32-bit processors had limited flexibility in designing the register organization.

¹ Because the MC68000 already uses 32-bit registers, the MC68020 [MACD84], which is a full 32-bit architecture, uses the same register organization.

16.3 Instruction Cycle

In [Section 3.2](#), we described the processor's instruction cycle ([Figure 3.9](#)). To recall, an instruction cycle includes the following stages:

- **Fetch:** Read the next instruction from memory into the processor.
- **Execute:** Interpret the opcode and perform the indicated operation.
- **Interrupt:** If interrupts are enabled and an interrupt has occurred, save the current process state and service the interrupt.

We are now in a position to elaborate somewhat on the instruction cycle. First, we must introduce one additional stage, known as the indirect cycle.

The Indirect Cycle

We have seen in [Chapter 14](#) that the execution of an instruction may involve one or more operands in memory, each of which requires a memory access. Further, if indirect addressing is used, then additional memory accesses are required.

We can think of the fetching of indirect addresses as one or more instruction stages. The result is shown in [Figure 16.3](#). The main line of activity consists of alternating instruction fetch and instruction execution activities. After an instruction is fetched, it is examined to determine if any indirect addressing is involved. If so, the required operands are fetched using indirect addressing. Following execution, an interrupt may be processed before the next instruction fetch.

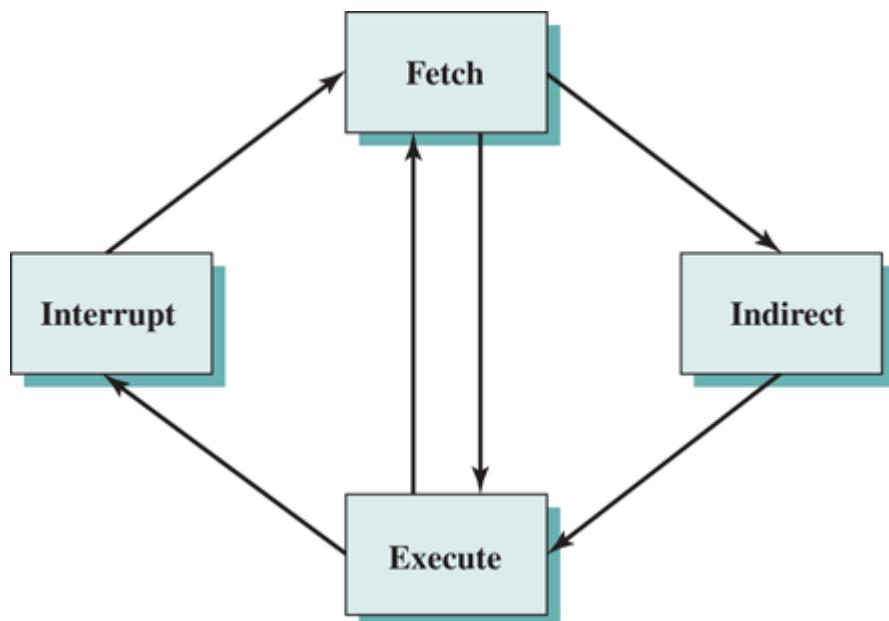

Figure 16.3 The Instruction Cycle

Another way to view this process is shown in [Figure 16.4](#), which is a revised version of [Figure 3.12](#). This illustrates more correctly the nature of the instruction cycle. Once an instruction is fetched, its operand specifiers must be identified. Each input operand in memory is then fetched, and this process may require indirect addressing. Register-based operands need not be fetched. Once the opcode is executed, a similar process may be needed to store the result in main memory.

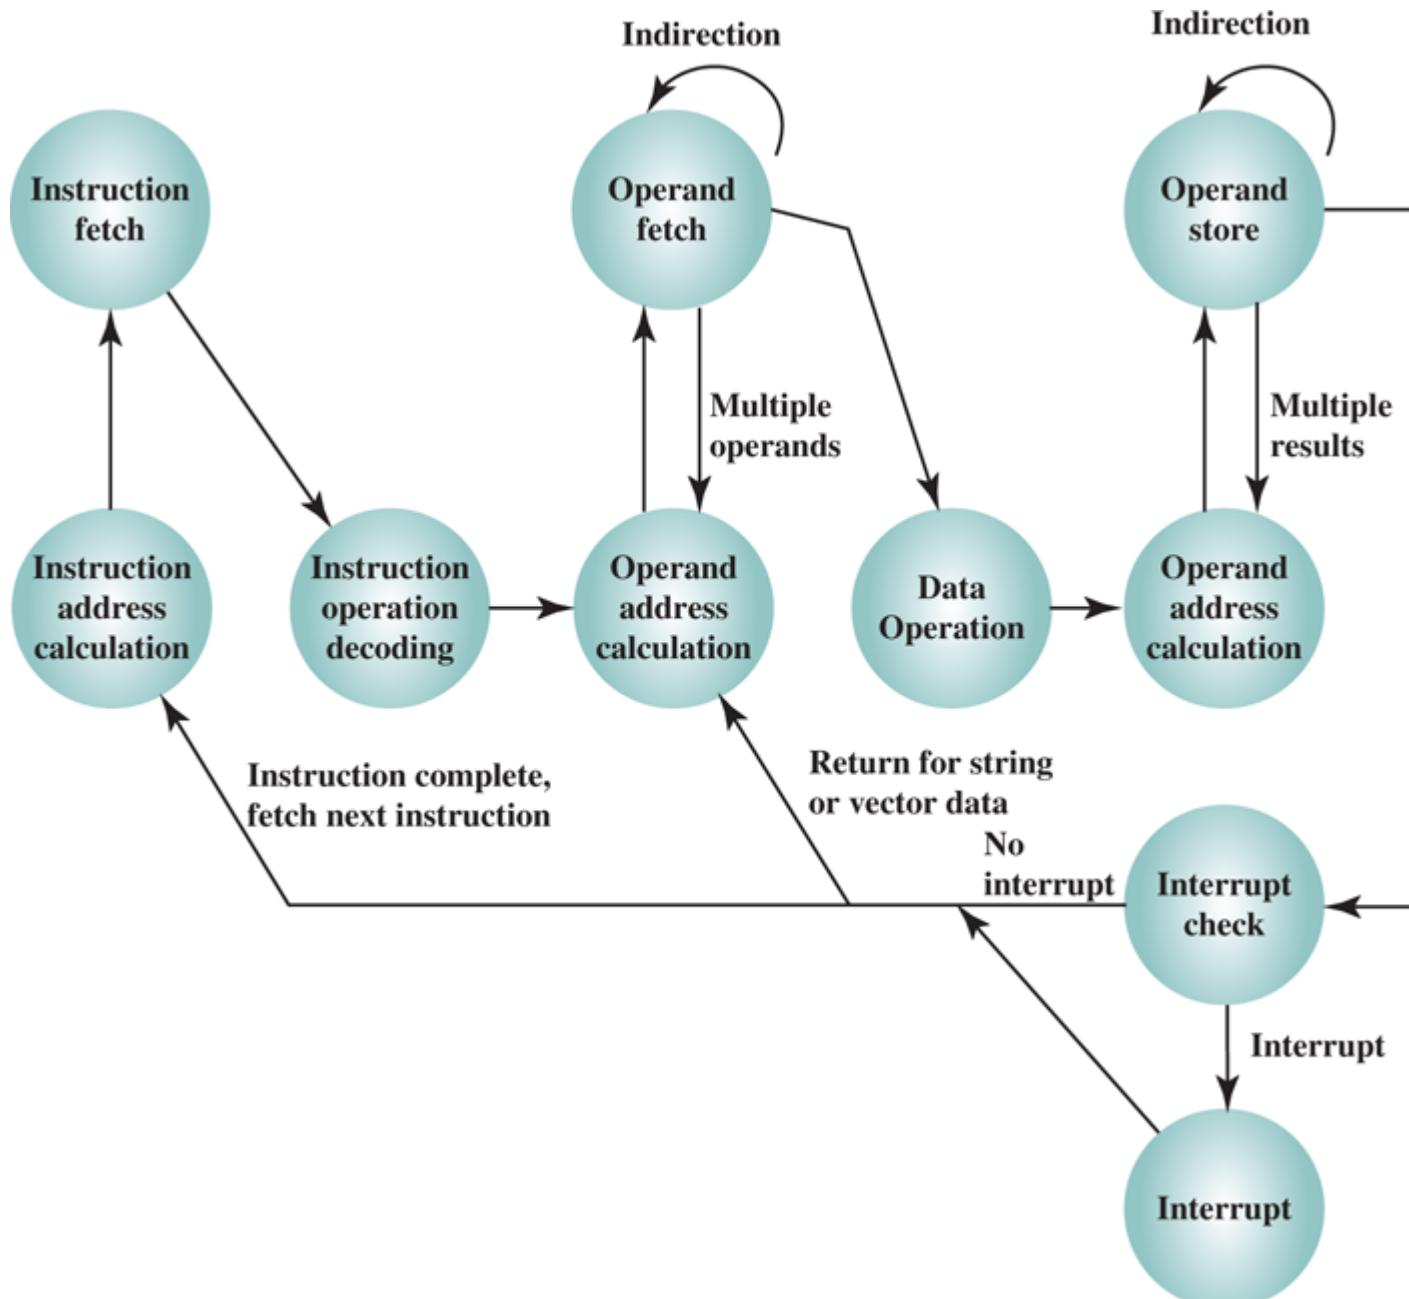

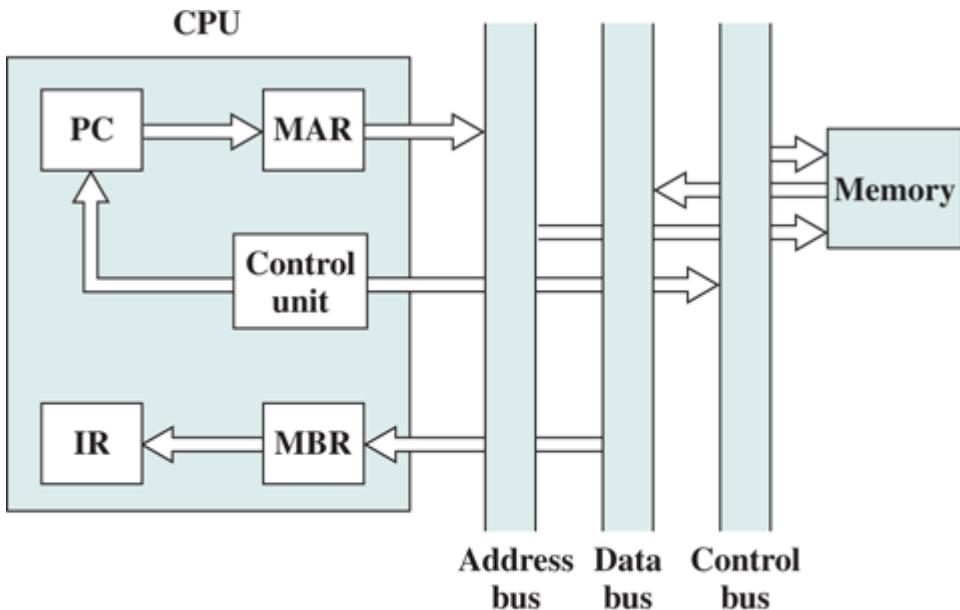

Figure 16.4 Instruction Cycle State Diagram

Data Flow

The exact sequence of events during an instruction cycle depends on the design of the processor. We can, however, indicate in general terms what must happen. Let us assume a processor that employs a memory address register (MAR), a memory buffer register (MBR), a program counter (PC), and an instruction register (IR).

During the *fetch cycle*, an instruction is read from memory. **Figure 16.5** shows the flow of data during this cycle. The PC contains the address of the next instruction to be fetched. This address is moved to the MAR and placed on the address bus. The control unit requests a memory read, and the result is placed on the data bus and copied into the MBR and then moved to the IR. Meanwhile, the PC is incremented by 1, preparatory for the next fetch.

MBR = Memory buffer register

MAR = Memory address register

IR = Instruction register

PC = Program counter

Figure 16.5 Data Flow, Fetch Cycle

Once the fetch cycle is over, the control unit examines the contents of the IR to determine if it contains an operand specifier using indirect addressing. If so, an *indirect cycle* is performed. As shown in Figure 16.6, this is a simple cycle. The right-most N bits of the MBR, which contain the address reference, are transferred to the MAR. Then the control unit requests a memory read, to get the desired address of the operand into the MBR.

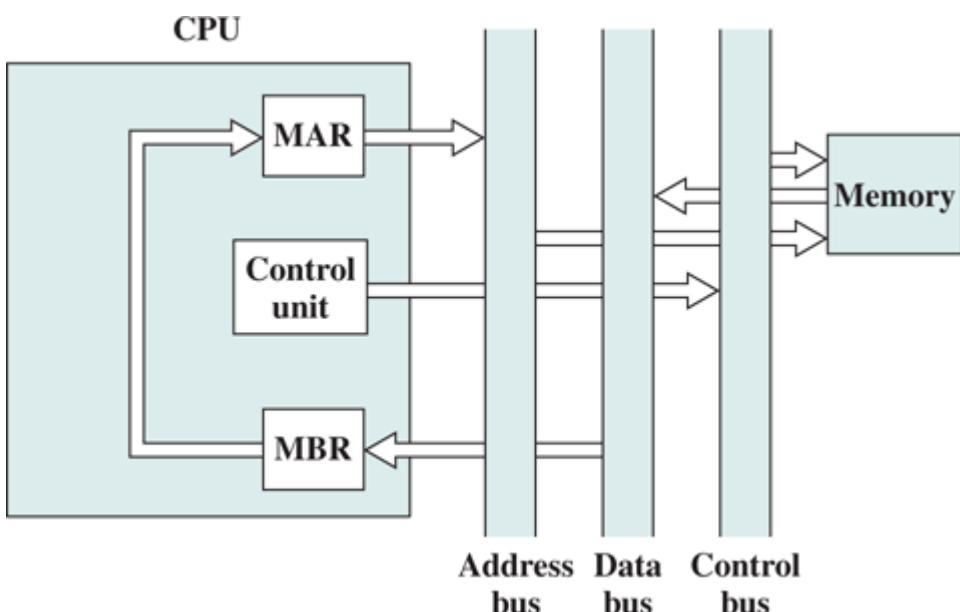

Figure 16.6 Data Flow, Indirect Cycle

The fetch and indirect cycles are simple and predictable. The *execute cycle* takes many forms, depending on which of the various machine instructions is in the IR. This cycle may involve transferring data among registers, read or write from memory or I/O, and/or the invocation of the ALU.

Like the fetch and indirect cycles, the *interrupt cycle* is simple and predictable (Figure 16.7). The

current contents of the PC must be saved so that the processor can resume normal activity after the interrupt. Thus, the contents of the PC are transferred to the MBR to be written into memory. The special memory location reserved for this purpose is loaded into the MAR from the control unit. It might, for example, be a stack pointer. The PC is loaded with the address of the interrupt routine. As a result, the next instruction cycle will begin by fetching the appropriate instruction.

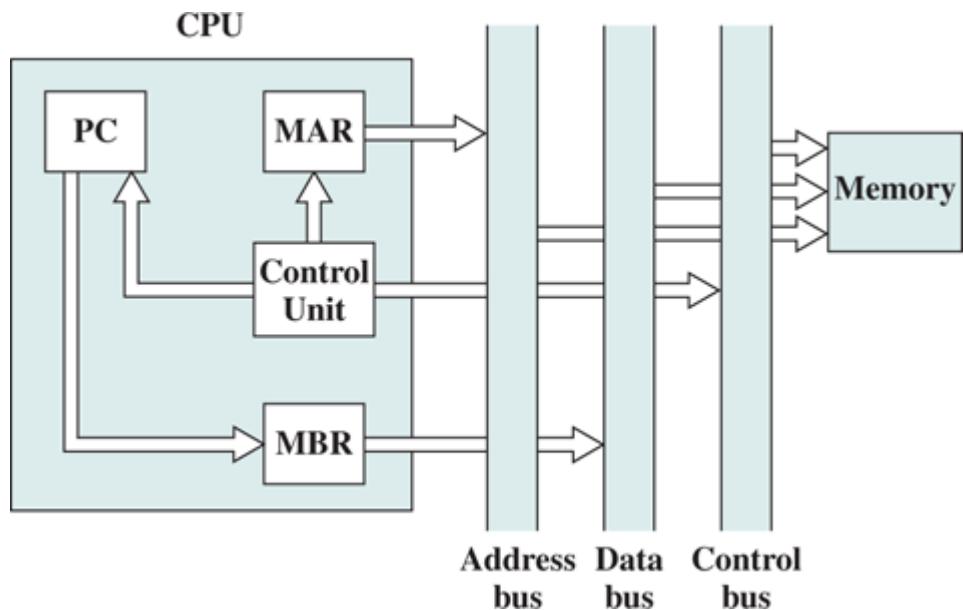

Figure 16.7 Data Flow, Interrupt Cycle

16.4 Instruction Pipelining

As computer systems evolve, greater performance can be achieved by taking advantage of improvements in technology, such as faster circuitry. In addition, organizational enhancements to the processor can improve performance. We have already seen some examples of this, such as the use of multiple registers rather than a single accumulator, and the use of a cache memory. Another organizational approach, which is quite common, is instruction pipelining.

Pipelining Strategy

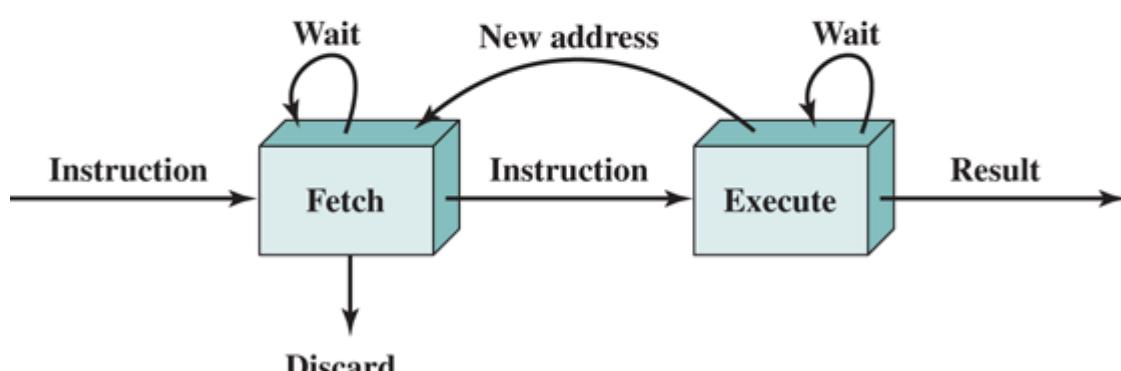

Instruction pipelining is similar to the use of an assembly line in a manufacturing plant. An assembly line takes advantage of the fact that a product goes through various stages of production. By laying the production process out in an assembly line, products at various stages can be worked on simultaneously. This process is also referred to as **pipelining** because, as in a pipeline, new inputs are accepted at one end before previously accepted inputs appear as outputs at the other end.

To apply this concept to instruction execution, we must recognize that, in fact, an instruction has a number of stages. **Figure 16.4** for example breaks the instruction cycle up into 10 tasks, which occur in sequence. Clearly, there should be some opportunity for pipelining.

As a simple approach, consider subdividing instruction processing into two stages: **fetch instruction** and **execute instruction**. There are times during the **execution of an instruction** when main memory is not being accessed. This time could be used to fetch the next instruction in parallel with the execution of the current one. **Figure 16.8a** depicts this approach. The pipeline has two independent stages. The first stage fetches an instruction and buffers it. When the second stage is free, the first stage passes it to the second stage. While the second stage is executing the instruction, the first stage takes advantage of any unused memory cycles to fetch and buffer the next instruction. This is called **instruction prefetch** or **fetch overlap**. Note that this approach, which involves instruction buffering, requires more registers.

(a) Simplified view

(b) Expanded view

Figure 16.8 Two-Stage Instruction Pipeline

In general, pipelining requires fast registers, called **latches**, that store intermediate values between stages. [Figure 16.9](#) illustrates this in simplified form for a three-stage pipeline. The latches serve to decouple the stages from each other. Information flows between adjacent stages under the control of a common clock applied to all the latches simultaneously. As each clock cycle ends, the latches gate in their inputs and forward them into the next stage, where the required operation is performed. This simplified picture omits several details. Each stage may consist of multiple execution units that cooperate in performing the required operations. In addition, the latches may be extended with multiplexers that allow the input to a latch to come from a subsequent stage (feed back) or from a stage prior to the just preceding stage (feed forward).

It should be clear that this process will speed up instruction execution. If the fetch and execute stages were of equal duration, the instruction cycle time would be halved. However, if we look more closely at this pipeline ([Figure 16.8b](#)), we will see that this doubling of execution rate is unlikely for two reasons:

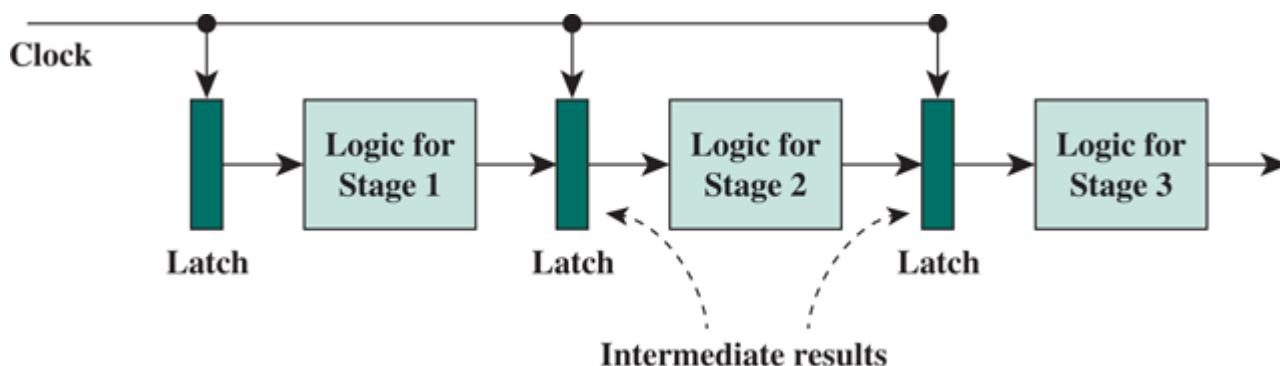

Figure 16.9 Simplified Pipeline Architecture

1. The execution time will generally be longer than the fetch time. Execution will involve reading and storing operands and the performance of some operation. Thus, the fetch stage may have to wait for some time before it can empty its buffer.
2. A conditional branch instruction makes the address of the next instruction to be fetched unknown. Thus, the fetch stage must wait until it receives the next instruction address from the execute stage. The execute stage may then have to wait while the next instruction is fetched.

Guessing can reduce the time loss from the second reason. A simple rule is the following: When a conditional branch instruction is passed on from the fetch to the execute stage, the fetch stage fetches the next instruction in memory after the branch instruction. Then, if the branch is not taken, no time is lost. If the branch is taken, the fetched instruction must be discarded and a new instruction fetched.

While these factors reduce the potential effectiveness of the two-stage pipeline, some speedup occurs. To gain further speedup, the pipeline must have more stages. Let us consider the following decomposition of the instruction processing.

- **Fetch instruction (FI):** Read the next expected instruction into a buffer.
- **Decode instruction (DI):** Determine the opcode and the operand specifiers.
- **Calculate operands (CO):** Calculate the effective address of each source operand. This may involve displacement, register indirect, indirect, or other forms of address calculation.
- **Fetch operands (FO):** Fetch each operand from memory. Operands in registers need not be fetched.
- **Execute instruction (EI):** Perform the indicated operation and store the result, if any, in the specified destination operand location.
- **Write operand (WO):** Store the result in memory.

With this decomposition, the various stages will be of more nearly equal duration. For the sake of

illustration, let us assume equal duration. Using this assumption, [Figure 16.10](#) shows that a six-stage pipeline can reduce the execution time for 9 instructions from 54 time units to 14 time units.

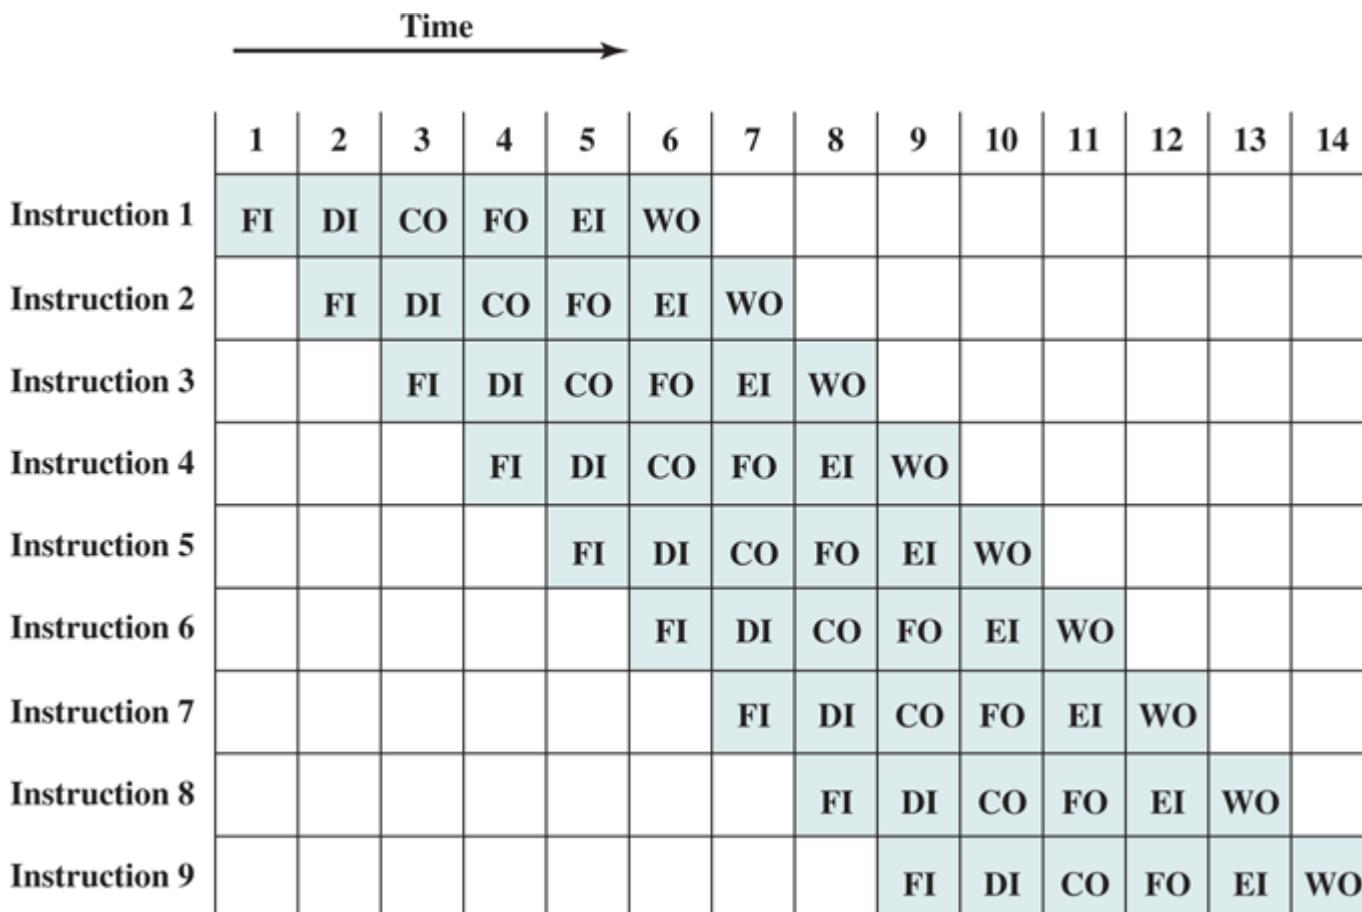

Figure 16.10 Timing Diagram for Instruction Pipeline Operation

Several comments are in order: The diagram assumes that each instruction goes through all six stages of the pipeline. This will not always be the case. For example, a load instruction does not need the WO stage. However, to simplify the pipeline hardware, the timing is set up assuming that each instruction requires all six stages. Also, the diagram assumes that all of the stages can be performed in parallel. In particular, it is assumed that there are no memory conflicts. For example, the FI, FO, and WO stages involve a memory access. The diagram implies that all these accesses can occur simultaneously. Most memory systems will not permit that. However, the desired value may be in cache, or the FO or WO stage may be null. Thus, much of the time, memory conflicts will not slow down the pipeline.

Several other factors serve to limit the performance enhancement. If the six stages are not of equal duration, there will be some waiting involved at various pipeline stages, as discussed before for the two-stage pipeline. Another difficulty is the conditional branch instruction, which can invalidate several instruction fetches. A similar unpredictable event is an interrupt. [Figure 16.11](#) illustrates the effects of the conditional branch, using the same program as [Figure 16.10](#). Assume that instruction 3 is a conditional branch to instruction 15. Until the instruction is executed, there is no way of knowing which instruction will come next. The pipeline, in this example, simply loads the next instruction in sequence (instruction 4) and proceeds. In [Figure 16.10](#), the branch is not taken, and we get the full performance benefit of the enhancement. In [Figure 16.11](#), the branch is taken. This is not determined until the end of time unit 7. At this point, the pipeline must be cleared of instructions that are not useful. During time unit 8, instruction 15 enters the pipeline. No instructions complete during time units 9 through 12; this is the performance penalty incurred because we could not anticipate the branch. [Figure 16.12](#) indicates the logic needed for pipelining to account for branches and interrupts.

	Time							Branch penalty						
	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Instruction 1	FI	DI	CO	FO	EI	WO								
Instruction 2		FI	DI	CO	FO	EI	WO							
Instruction 3			FI	DI	CO	FO	EI	WO						
Instruction 4				FI	DI	CO	FO							
Instruction 5					FI	DI	CO							
Instruction 6						FI	DI							
Instruction 7							FI							
Instruction 15								FI	DI	CO	FO	EI	WO	
Instruction 16									FI	DI	CO	FO	EI	WO

Figure 16.11 The Effect of a Conditional Branch on Instruction Pipeline Operation

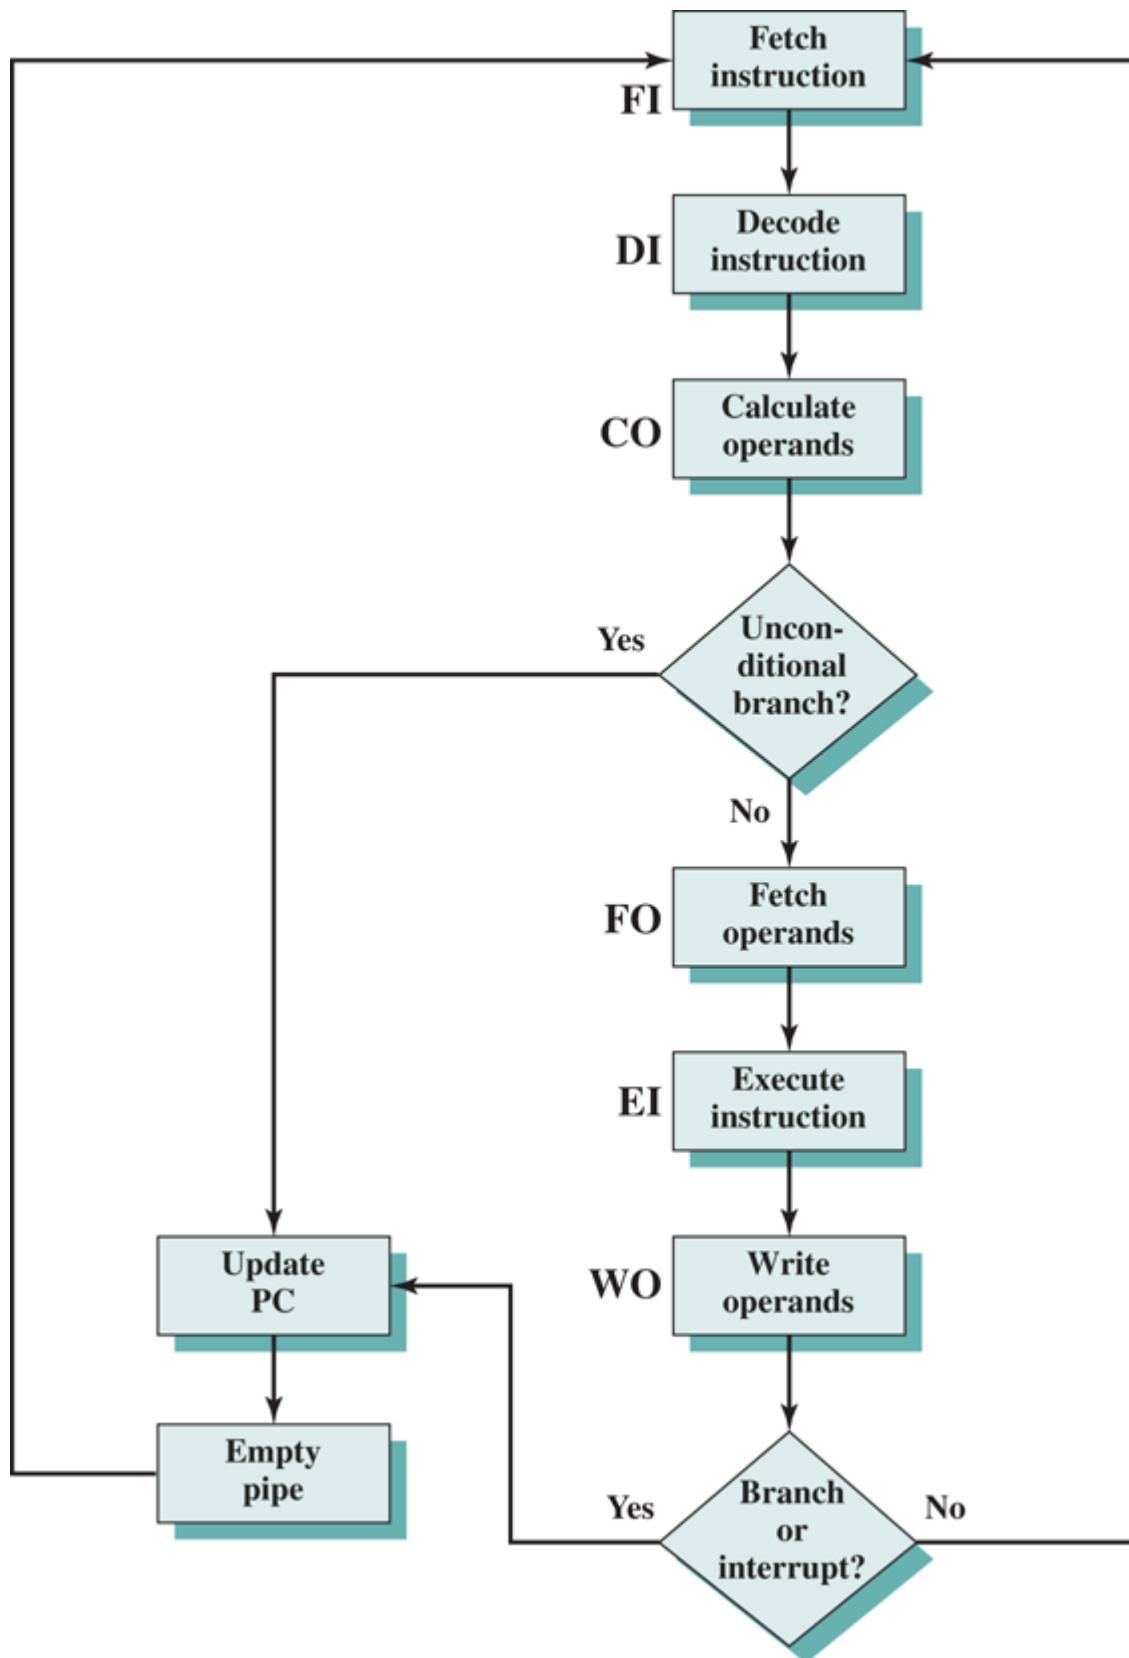

Figure 16.12 Six-Stage CPU Instruction Pipeline

Other problems arise that did not appear in our simple two-stage organization. The CO stage may depend on the contents of a register that could be altered by a previous instruction that is still in the pipeline. Other such register and memory conflicts could occur. The system must contain logic to account for this type of conflict.

To clarify pipeline operation, it might be useful to look at an alternative depiction. **Figures 16.10** and **16.11** show the progression of time horizontally across the figures, with each row showing the

progress of an individual instruction. **Figure 16.13** shows the same sequence of events with time progressing vertically down the figure, and each row showing the state of the pipeline at a given point in time. In **Figure 16.13a** (which corresponds to **Figure 16.10**), the pipeline is full at time 6, with 6 different instructions in various stages of execution, and remains full through time 9; we assume that instruction I9 is the last instruction to be executed. In **Figure 16.13b**, (which corresponds to **Figure 16.11**), the pipeline is full at times 6 and 7. At time 7, instruction 3 is in the execute stage and executes a branch to instruction 15. At this point, **instructions I4 through I7 are flushed from the pipeline, so that at time 8, only two instructions are in the pipeline, I3 and I15.**

Figure 16.13 An Alternative Pipeline Depiction

From the preceding discussion, it might appear that the greater the number of stages in the pipeline, the faster the execution rate. Some of the IBM S/360 designers pointed out two factors that frustrate this seemingly simple pattern for high-performance design [ANDE67a], and they remain elements that designer must still consider:

1. At each stage of the pipeline, there is some overhead involved in moving data from buffer to buffer and in performing various preparation and delivery functions. This overhead can appreciably lengthen the total execution time of a single instruction. This is significant when sequential instructions are logically dependent, either through heavy use of branching or through memory access dependencies.
2. The amount of control logic required to handle memory and register dependencies and to optimize the use of the pipeline increases enormously with the number of stages. This can lead to a situation where the logic controlling the gating between stages is more complex than the

stages being controlled.

Another consideration is latching delay: It takes time for pipeline buffers to operate, and this adds to instruction cycle time.

Instruction pipelining is a powerful technique for enhancing performance, but requires careful design to achieve optimum results with reasonable complexity.

Pipeline Performance

In this subsection, we develop some simple measures of pipeline performance and relative speedup (based on a discussion in [HWAN93]). The cycle time τ of an **instruction pipeline** is the time needed to advance a set of instructions one stage through the pipeline; each column in **Figures 16.10** and **16.11** represents one cycle time. The cycle time can be determined as

$$\tau = \max_i [\tau_i] + d = \tau_m + d \quad 1 \leq i \leq k$$

where

- τ_i = time delay of the circuitry in the i th stage of the pipeline
- τ_m = maximum stage delay (delay through stage which experiences the largest delay)
- k = number of stages in the instruction pipeline
- d = time delay of a latch, needed to advance signals and data from one stage to the next

In general, the time delay d is equivalent to a clock pulse and $\tau_m \gg d$. Now suppose that n instructions are processed, with no branches. Let $T_{k,n}$ be the total time required for a pipeline with k stages to execute n instructions. Then

$$T_{k,n} = [k + (n - 1)]\tau \quad (16.1)$$

A total of k cycles are required to complete the execution of the first instruction, and the remaining $n - 1$ instructions require $n - 1$ cycles.² This equation is easily verified from **Figure 16.10**. The ninth instruction completes at time cycle 14:

² We are being a bit sloppy here. The cycle time will only equal the maximum value of τ when all the stages are full. At the beginning, the cycle time may be less for the first one or few cycles.

$$14 = [6 + (9 - 1)]$$

Now consider a processor with equivalent functions but no pipeline, and assume that the instruction cycle time is $k\tau$. The **speedup factor** for the instruction pipeline compared to execution without the pipeline is defined as

$$S_k = \frac{T_{1,n}}{T_{k,n}} = \frac{n k \tau}{[k + (n - 1)]\tau} = k + \frac{n k}{(n - 1)} \quad (16.2)$$

Figure 16.14a plots the speedup factor as a function of the number of instructions that are executed without a branch. As might be expected, at the limit ($n \rightarrow \infty$), we have a k -fold speedup. **Figure**

16.14b shows the speedup factor as a function of the number of stages in the instruction pipeline.³ In this case, the speedup factor approaches the number of instructions that can be fed into the pipeline without branches. Thus, the larger the number of pipeline stages, the greater the potential for speedup. However, as a practical matter, the potential gains of additional pipeline stages are countered by increases in cost, delays between stages, and the fact that branches will be encountered requiring the flushing of the pipeline.

³ Note that the x-axis is logarithmic in **Figure 16.14a** and linear in **Figure 16.14b**.

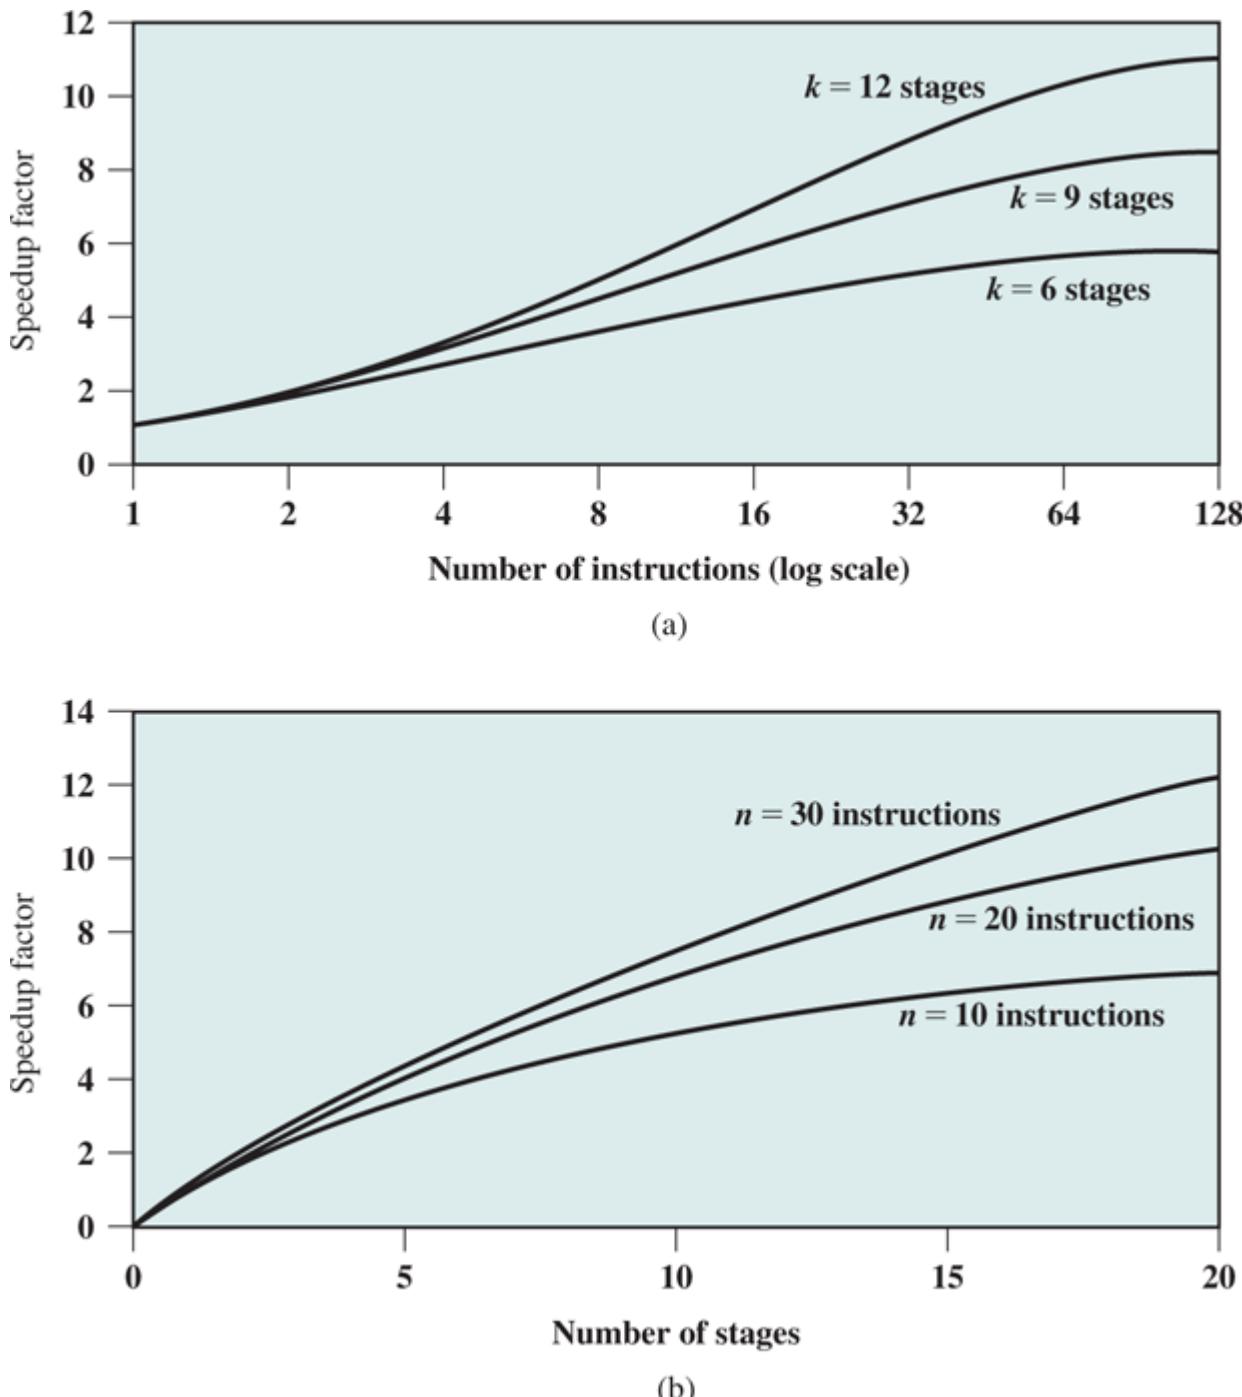

Figure 16.14 Speedup Factors with Instruction Pipelining

Pipeline Hazards

In the previous subsection, we mentioned some of the situations that can result in less than optimal

pipeline performance. In this subsection, we examine this issue in a more systematic way. [Chapter 18](#) revisits this issue in more detail, after we have introduced the complexities found in superscalar pipeline organizations.

A **pipeline hazard** occurs when the pipeline, or some portion of the pipeline, must stall because conditions do not permit continued execution. Such a pipeline stall is also referred to as a **pipeline bubble**. There are three types of hazards: resource, data, and control.

RESOURCE HAZARDS

A resource hazard occurs when two (or more) instructions that are already in the pipeline need the same resource. The result is that the instructions must be executed in serial rather than parallel for a portion of the pipeline. A resource hazard is sometimes referred to as a *structural hazard*.

Let us consider a simple example of a resource hazard. Assume a simplified five-stage pipeline, in which each stage takes one clock cycle. [Figure 16.15a](#) shows the ideal case, in which a new instruction enters the pipeline each clock cycle. Now assume that main memory has a single port and that all instruction fetches and data reads and writes must be performed one at a time. Further, ignore the cache. In this case, an operand read to or write from memory cannot be performed in parallel with an instruction fetch. This is illustrated in [Figure 16.15b](#), which assumes that the source operand for instruction I1 is in memory, rather than a register. Therefore, the fetch instruction stage of the pipeline must idle for one cycle before beginning the instruction fetch for instruction I3. The figure assumes that all other operands are in registers.

	Clock cycle								
	1	2	3	4	5	6	7	8	9
I1	FI	DI	FO	EI	WO				
I2		FI	DI	FO	EI	WO			
I3			FI	DI	FO	EI	WO		
I4				FI	DI	FO	EI	WO	

(a) Five-stage pipeline, ideal case

	Clock cycle

I2		FI	DI	FO	EI	WO			
I3			Idle	FI	DI	FO	EI	WO	
I4					FI	DI	FO	EI	WO

(b) I1 source operand in memory

Figure 16.15 Example of Resource Hazard

Another example of a resource conflict is a situation in which multiple instructions are ready to enter the execute instruction phase and there is a single ALU. One solutions to such resource hazards is to increase available resources, such as having multiple ports into main memory and multiple ALU units.

Aleksandr Lukin/123RF

Reservation Table Analyzer

One approach to analyzing resource conflicts and aiding in the design of pipelines is the reservation table. We examine reservation tables in Appendix I.

DATA HAZARDS

A data hazard occurs when there is a conflict in the access of an operand location. In general terms, we can state the hazard in this form: Two instructions in a program are to be executed in sequence and both access a particular memory or register operand. If the two instructions are executed in strict sequence, no problem occurs. However, if the instructions are executed in a pipeline, then it is possible for the operand value to be updated in such a way as to produce a different result than would occur with strict sequential execution. In other words, the program produces an incorrect result because of the use of pipelining.

As an example, consider the following x86 machine instruction sequence:

```
ADD EAX, EBX /* EAX = EAX + EBX
SUB ECX, EAX /* ECX = ECX - EAX
```

The first instruction adds the contents of the 32-bit registers EAX and EBX, and stores the result in EAX. The second instruction subtracts the contents of EAX from ECX and stores the result in ECX.

Figure 16.16 shows the pipeline behavior. The ADD instruction does not update register EAX until the end of stage 5, which occurs at clock cycle 5. But the SUB instruction needs that value at the beginning of its stage 2, which occurs at clock cycle 4. To maintain correct operation, the pipeline must stall for two clocks cycles. Thus, in the absence of special hardware and specific avoidance algorithms, such a data hazard results in inefficient pipeline usage.

	Clock cycle									
	1	2	3	4	5	6	7	8	9	10
ADD EAX, EBX	FI	DI	FO	EI	WO					
SUB ECX, EAX		FI	DI	Idle		FO	EI	WO		
I3			FI			DI	FO	EI	WO	
I4						FI	DI	FO	EI	WO

Figure 16.16 Example of Data Hazard

There are three types of data hazards:

- **Read after write (RAW), or true dependency:** An instruction modifies a register or memory location, and a succeeding instruction reads the data in that memory or register location. A hazard occurs if the read takes place before the write operation is complete. This type of hazard is referred to as a true dependency because it is a real data dependency that is not just due to a shortage of registers. It can occur whether or not the first instruction stalls, and cannot be avoided by reassigning or renaming registers.
- **Write after read (WAR), or antidependency:** An instruction reads a register or memory location and a succeeding instruction writes to the location. A hazard occurs if the write operation completes before the read operation takes place.
- **Write after write (WAW), or output dependency:** Two instructions both write to the same location. A hazard occurs if the write operations take place in the reverse order of the intended sequence.

The example of [Figure 16.16](#) is a RAW hazard. The other two hazards are best discussed in the context of superscalar organization, discussed in [Chapter 18](#).

CONTROL HAZARDS

A control hazard, also known as a *branch hazard*, occurs when the pipeline makes the wrong decision on a branch prediction and therefore brings instructions into the pipeline that must subsequently be discarded. We discuss approaches to dealing with control hazards next.

Dealing with Branches

One of the major problems in designing an instruction pipeline is assuring a steady flow of instructions to the initial stages of the pipeline. The primary impediment, as we have seen, is the conditional branch instruction. Until the instruction is actually executed, it is impossible to determine whether the branch will be taken or not.

A variety of approaches have been taken for dealing with conditional branches:

- Multiple streams
- Prefetch branch target
- Loop buffer
- Branch prediction
- Delayed branch

MULTIPLE STREAMS

A simple pipeline suffers a penalty for a branch instruction because it must choose one of two instructions to fetch next and may make the wrong choice. A brute-force approach is to replicate the initial portions of the pipeline and allow the pipeline to fetch both instructions, making use of two streams. There are two problems with this approach:

- With multiple pipelines there are contention delays for access to the registers and to memory.
- Additional branch instructions may enter the pipeline (either stream) before the original branch decision is resolved. Each such instruction needs an additional stream.

Despite these drawbacks, this strategy can improve performance. Examples of machines with two or

more pipeline streams are the IBM 370/168 and the IBM 3033.

PREFETCH BRANCH TARGET

When a conditional branch is recognized, the target of the branch is prefetched, in addition to the instruction following the branch. This target is then saved until the branch instruction is executed. If the branch is taken, the target has already been prefetched.

The IBM 360/91 uses this approach.

LOOP BUFFER

A loop buffer is a small, very-high-speed memory maintained by the instruction fetch stage of the pipeline and containing the n most recently fetched instructions, in sequence. If a branch is to be taken, the hardware first checks whether the branch target is within the buffer. If so, the next instruction is fetched from the buffer. The loop buffer has three benefits:

1. With the use of prefetching, the loop buffer will contain some instruction sequentially ahead of the current instruction fetch address. Thus, instructions fetched in sequence will be available without the usual memory access time.
2. If a branch occurs to a target just a few locations ahead of the address of the branch instruction, the target will already be in the buffer. This is useful for the rather common occurrence of IF–THEN and IF–THEN–ELSE sequences.
3. This strategy is particularly well suited to dealing with loops, or iterations; hence the name *loop buffer*. If the loop buffer is large enough to contain all the instructions in a loop, then those instructions need to be fetched from memory only once, for the first iteration. For subsequent iterations, all the needed instructions are already in the buffer.

The loop buffer is similar in principle to a cache dedicated to instructions. The differences are that the loop buffer only retains instructions in sequence and is much smaller in size and hence lower in cost.

Figure 16.17 gives an example of a loop buffer. If the buffer contains 256 bytes, and byte addressing is used, then the least significant 8 bits are used to index the buffer. The remaining most significant bits are checked to determine if the branch target lies within the environment captured by the buffer.

Branch address

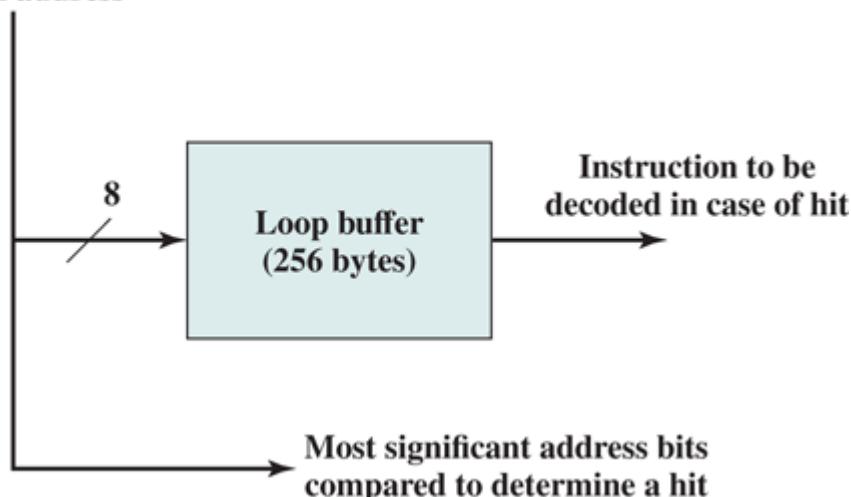

Figure 16.17 Loop Buffer

Among the machines using a loop buffer are some of the CDC machines (Star-100, 6600, 7600) and

the CRAY-1. A specialized form of loop buffer is available on the Motorola 68010, for executing a three-instruction loop involving the DBcc (decrement and branch on condition) instruction (see Problem 16.14). A three-word buffer is maintained, and the processor executes these instructions repeatedly until the loop condition is satisfied.

Aleksandr Lukin/123RF

Branch Prediction Simulator

Branch Target Buffer

BRANCH PREDICTION

Various techniques can be used to predict whether a branch will be taken. Among the more common are the following:

- Predict never taken
- Predict always taken
- Predict by opcode
- Taken/not taken switch
- Branch history table

The first three approaches are static: they do not depend on the execution history up to the time of the conditional branch instruction. The latter two approaches are dynamic: They depend on the execution history.

The first two approaches are the simplest. These either always assume that the branch will not be taken and continue to fetch instructions in sequence, or they always assume that the branch will be taken and always fetch from the branch target. The predict-never-taken approach is the most popular of all the branch prediction methods.

Studies analyzing program behavior have shown that conditional branches are taken more than 50% of the time [LILJ88], and so if the cost of prefetching from either path is the same, then always prefetching from the branch target address should give better performance than always prefetching from the sequential path. However, in a paged machine, prefetching the branch target is more likely to cause a page fault than prefetching the next instruction in sequence, and so this performance penalty should be taken into account. An avoidance mechanism may be employed to reduce this penalty.

The final static approach makes the decision based on the opcode of the branch instruction. The processor assumes that the branch will be taken for certain branch opcodes and not for others. [LILJ88] reports success rates of greater than 75% with this strategy.

Dynamic branch strategies attempt to improve the accuracy of prediction by recording the history of conditional branch instructions in a program. For example, one or more bits can be associated with each conditional branch instruction that reflect the recent history of the instruction. These bits are referred to as a taken/not taken switch that directs the processor to make a particular decision the next time the instruction is encountered. Typically, these history bits are not associated with the instruction in main memory. Rather, they are kept in temporary high-speed storage. One possibility is to associate these bits with any conditional branch instruction that is in a cache. When the instruction

is replaced in the cache, its history is lost. Another possibility is to maintain a small table for recently executed branch instructions with one or more history bits in each entry. The processor could access the table associatively, like a cache, or by using the low-order bits of the branch instruction's address.

With a single bit, all that can be recorded is whether the last execution of this instruction resulted in a branch or not. A shortcoming of using a single bit appears in the case of a conditional branch instruction that is almost always taken, such as a loop instruction. With only one bit of history, an error in prediction will occur twice for each use of the loop: once on entering the loop, and once on exiting.

If two bits are used, they can be used to record the result of the last two instances of the execution of the associated instruction, or to record a state in some other fashion. **Figure 16.18** shows a typical approach (see Problem 16.13 for other possibilities). Assume that the algorithm starts at the upper-left-hand corner of the flowchart. As long as each succeeding conditional branch instruction that is encountered is taken, the decision process predicts that the next branch will be taken. If a single prediction is wrong, the algorithm continues to predict that the next branch is taken. Only if two successive branches are not taken does the algorithm shift to the right-hand side of the flowchart. Subsequently, the algorithm will predict that branches are not taken until two branches in a row are taken. Thus, the algorithm requires two consecutive wrong predictions to change the prediction decision.

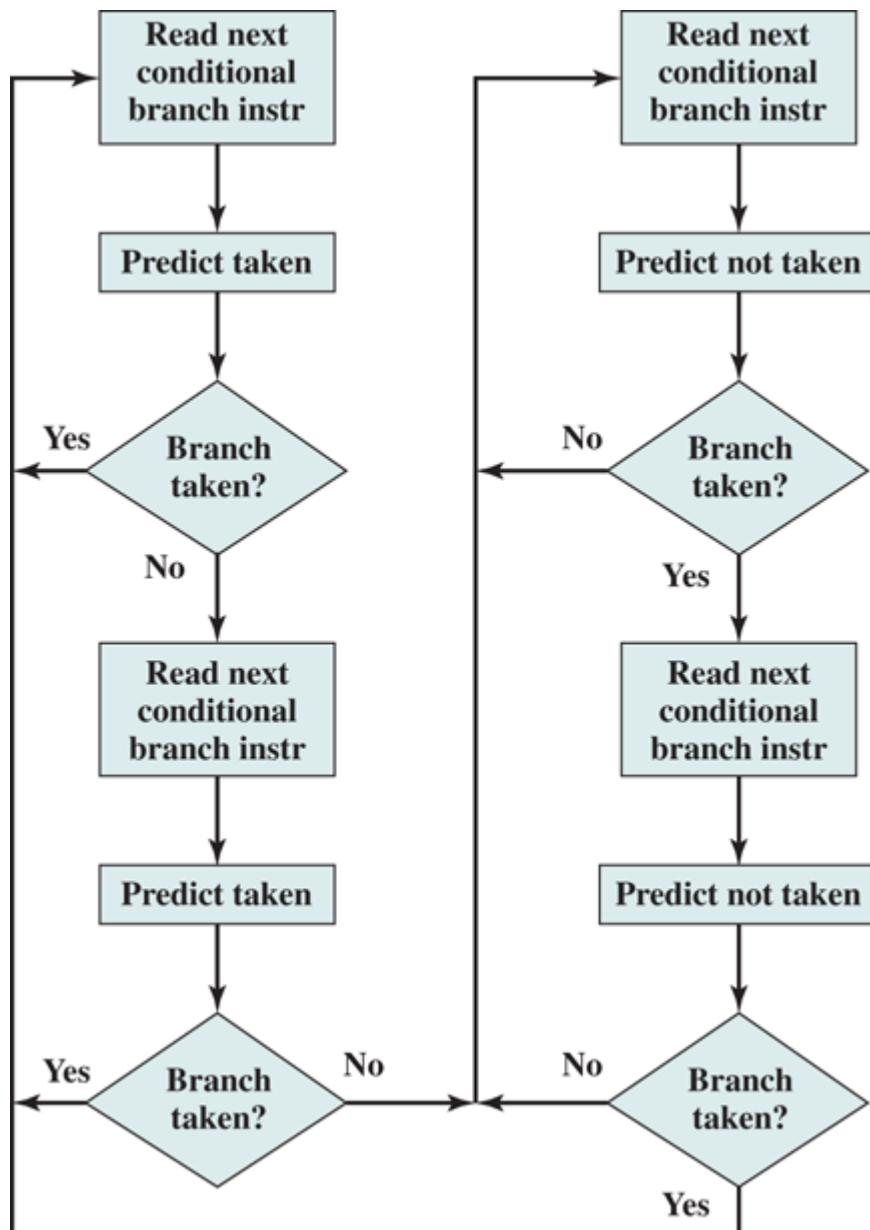

Figure 16.18 Branch Prediction Flowchart

The decision process can be represented more compactly by a finite-state machine, shown in [Figure 16.19](#). The finite-state machine representation is commonly used in the literature.

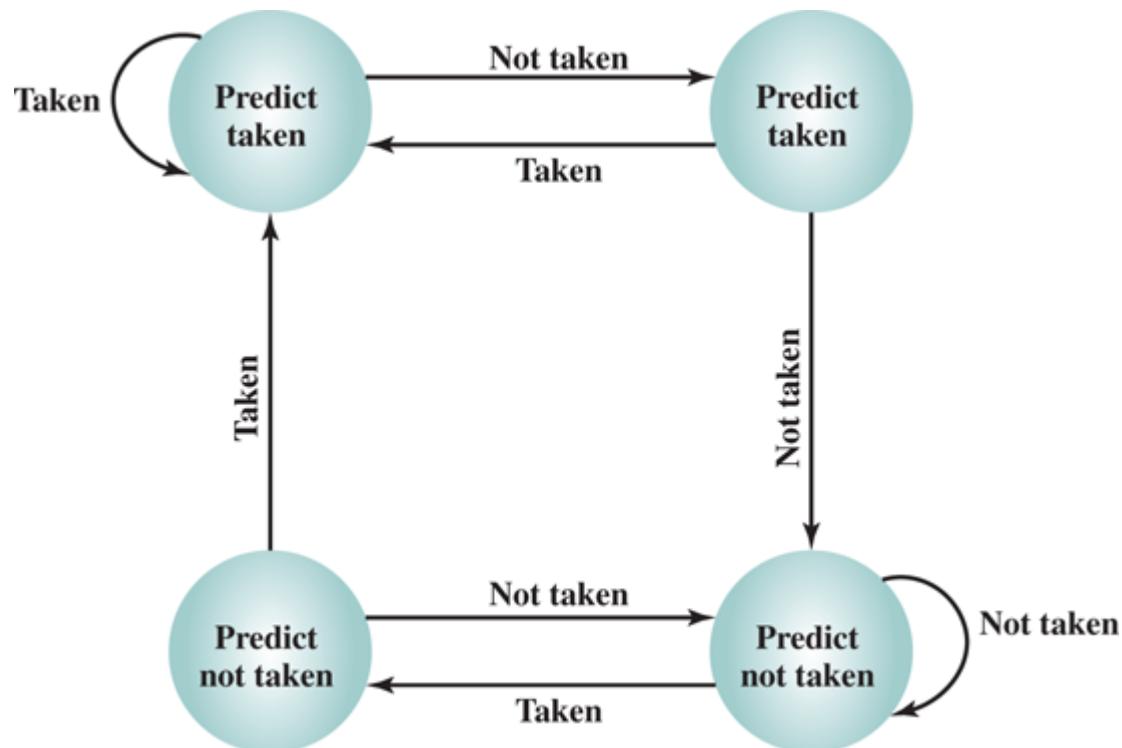

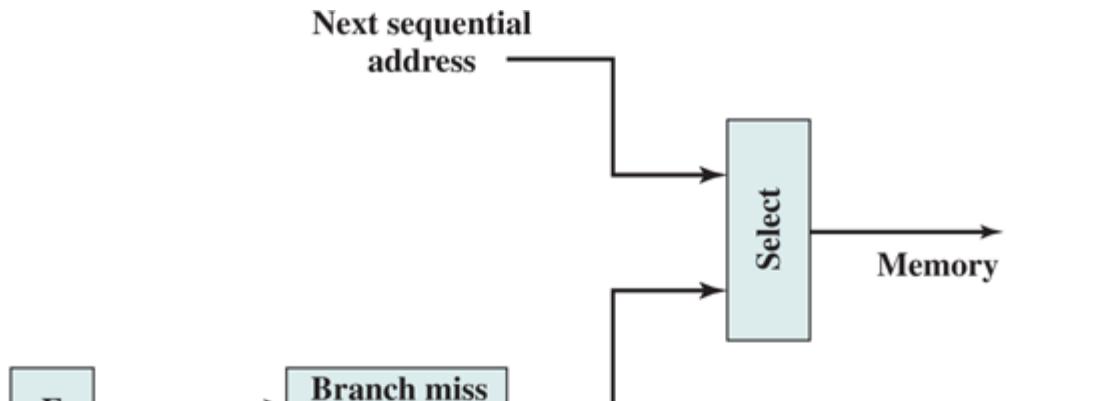

Figure 16.19 Branch Prediction State Diagram

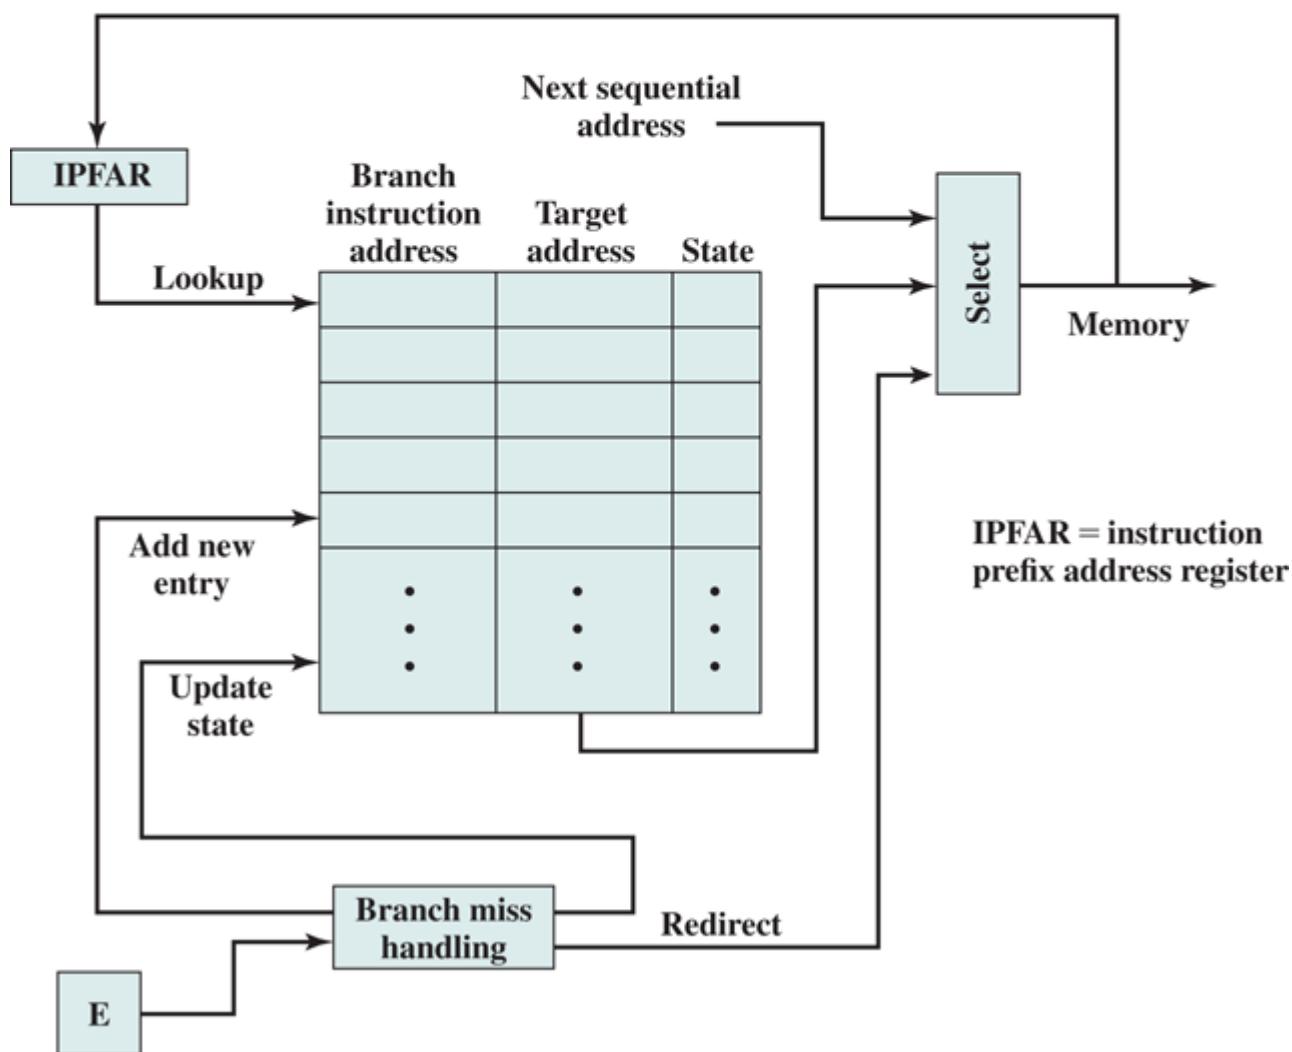

The use of history bits, as just described, has one drawback: If the decision is made to take the branch, the target instruction cannot be fetched until the target address, which is an operand in the conditional branch instruction, is decoded. Greater efficiency could be achieved if the instruction fetch could be initiated as soon as the branch decision is made. For this purpose, more information must be saved, in what is known as a branch target buffer, or a branch history table.

The branch history table is a small cache memory associated with the instruction fetch stage of the pipeline. Each entry in the table consists of three elements: the address of a branch instruction, some number of history bits that record the state of use of that instruction, and information about the target instruction. In most proposals and implementations, this third field contains the address of the target instruction. Another possibility is for the third field to actually contain the target instruction. The trade-off is clear: Storing the target address yields a smaller table but a greater instruction fetch time compared with storing the target instruction [RECH98].

[Figure 16.20](#) contrasts this scheme with a predict-never-taken strategy. With the former strategy, the instruction fetch stage always fetches the next sequential address. If a branch is taken, some logic in the processor detects this and instructs that the next instruction be fetched from the target address (in addition to flushing the pipeline). The branch history table is treated as a cache. Each prefetch triggers a lookup in the branch history table. If no match is found, the next sequential address is used for the fetch. If a match is found, a prediction is made based on the state of the instruction: Either the next sequential address or the branch target address is fed to the select logic.

(a) Predict never taken strategy

IPFAR = instruction prefix address register

(b) Branch history table strategy

Figure 16.20 Dealing with Branches

When the branch instruction is executed, the execute stage signals the branch history table logic with the result. The state of the instruction is updated to reflect a correct or incorrect prediction. If the prediction is incorrect, the select logic is redirected to the correct address for the next fetch. When a conditional branch instruction is encountered that is not in the table, it is added to the table and one of the existing entries is discarded, using one of the cache replacement algorithms discussed in [Chapter 5](#).

A refinement of the branch history approach is referred to as two-level or correlation-based branch history [YEH91]. This approach is based on the assumption that whereas in loop-closing branches, the past history of a particular branch instruction is a good predictor of future behavior, with more complex control-flow structures the direction of a branch is frequently correlated with the direction of related branches. An example is an if-then-else or case structure. There are a number of possible strategies. Typically, recent global branch history (i.e., the history of the most recent branches, not just of this branch instruction) is used in addition to the history of the current branch instruction. The general structure is defined as an (m, n) correlator, which uses the behavior of the last m branches to choose from 2^m n -bit branch predictors for the current branch instruction. In other words, an n -bit history is kept for a given branch for each possible combination of branches taken by the most recent m branches.

DELAYED BRANCH

It is possible to improve pipeline performance by automatically rearranging instructions within a program, so that branch instructions occur later than actually desired. This intriguing approach is examined in [Chapter 17](#).

Intel 80486 Pipelining

An instructive example of an instruction pipeline is that of the Intel 80486. The 80486 implements a five-stage pipeline:

- **Fetch:** Instructions are fetched from the cache or from external memory and placed into one of the two 16-byte prefetch buffers. The objective of the fetch stage is to fill the prefetch buffers with new data as soon as the old data have been consumed by the instruction decoder. Because instructions are of variable length (from 1 to 11 bytes not counting prefixes), the status of the prefetcher relative to the other pipeline stages varies from instruction to instruction. On average, about five instructions are fetched with each 16-byte load [CRAW90]. The fetch stage operates independently of the other stages to keep the prefetch buffers full.
- **Decode stage 1:** All opcode and addressing-mode information is decoded in the D1 stage. The required information, as well as instruction-length information, is included in at most the first 3 bytes of the instruction. Hence, 3 bytes are passed to the D1 stage from the prefetch buffers. The D1 decoder can then direct the D2 stage to capture the rest of the instruction (displacement and immediate data), which is not involved in the D1 decoding.
- **Decode stage 2:** The D2 stage expands each opcode into control signals for the ALU. It also controls the computation of the more complex addressing modes.
- **Execute:** This stage includes ALU operations, cache access, and register update.
- **Write back:** This stage, if needed, updates registers and status flags modified during the preceding execute stage. If the current instruction updates memory, the computed value is sent to the cache and to the bus-interface write buffers at the same time.

With the use of two decode stages, the pipeline can sustain a throughput of close to one instruction per clock cycle. Complex instructions and conditional branches can slow down this rate.

[Figure 16.21](#) shows examples of the operation of the pipeline. [Figure 16.21a](#) shows that there is no delay introduced into the pipeline when a memory access is required. However, as [Figure 16.21b](#) shows, there can be a delay for values used to compute memory addresses. That is, if a value is loaded from memory into a register and that register is then used as a base register in the next instruction, the processor will stall for one cycle. In this example, the processor accesses the cache in the EX stage of the first instruction and stores the value retrieved in the register during the WB stage. However, the next instruction needs this register in its D2 stage. When the D2 stage lines up with the WB stage of the previous instruction, bypass signal paths allow the D2 stage to have access to the

same data being used by the WB stage for writing, saving one pipeline stage.

Fetch	D1	D2	EX	WB		MOV Reg1, Mem1
Fetch	D1	D2	EX	WB		MOV Reg1, Reg2
Fetch	D1	D2	EX	WB		MOV Mem2, Reg1

(a) No data load delay in the pipeline

Fetch	D1	D2	EX	WB		MOV Reg1, Mem1
Fetch	D1		D2	EX		MOV Reg2, (Reg1)

(b) Pointer load delay

Fetch	D1	D2	EX	WB		CMP Reg1, Imm		
Fetch	D1	D2	EX			Jcc Target		
				Fetch	D1	D2	EX	Target

(c) Branch instruction timing

Figure 16.21 80486 Instruction Pipeline Examples

Figure 16.21c illustrates the timing of a branch instruction, assuming that the branch is taken. The compare instruction updates condition codes in the WB stage, and bypass paths make this available to the EX stage of the jump instruction at the same time. In parallel, the processor runs a speculative fetch cycle to the target of the jump during the EX stage of the jump instruction. If the processor determines a false branch condition, it discards this prefetch and continues execution with the next sequential instruction (already fetched and decoded).

16.5 Processor Organization for Pipelining

This section looks at some of the enhancements to a simple pipeline that can be used to improve performance. Consider a five-stage pipeline:

- **Instruction fetch (IF):** Load instruction from cache.
- **Instruction decode (ID):** Determine the opcode and the operand specifiers.
- **Operand fetch (OF):** Read and buffer any register operands.
- **Execute (EX):** Perform the indicated operation. For a memory load or store, this involves memory access through the cache.
- **Write back (WB):** Write back instruction result to its destination register.

Figure 16.22a indicates a simple organization for this pipeline. Two contention problems are apparent. The WB and OF stages both need access to the register file, and the IF and EX stages both need access to the cache. **Figure 16.22b** shows modifications to the organization to alleviate these conflicts. Increasing the number of register ports and busses enables simultaneous read and write. Separating the L1 cache into an I-cache and a D-cache removes the conflict between the IF and EX stages.

Figure 16.23 shows a more complex organization that further enhances performance. The following are the changes:

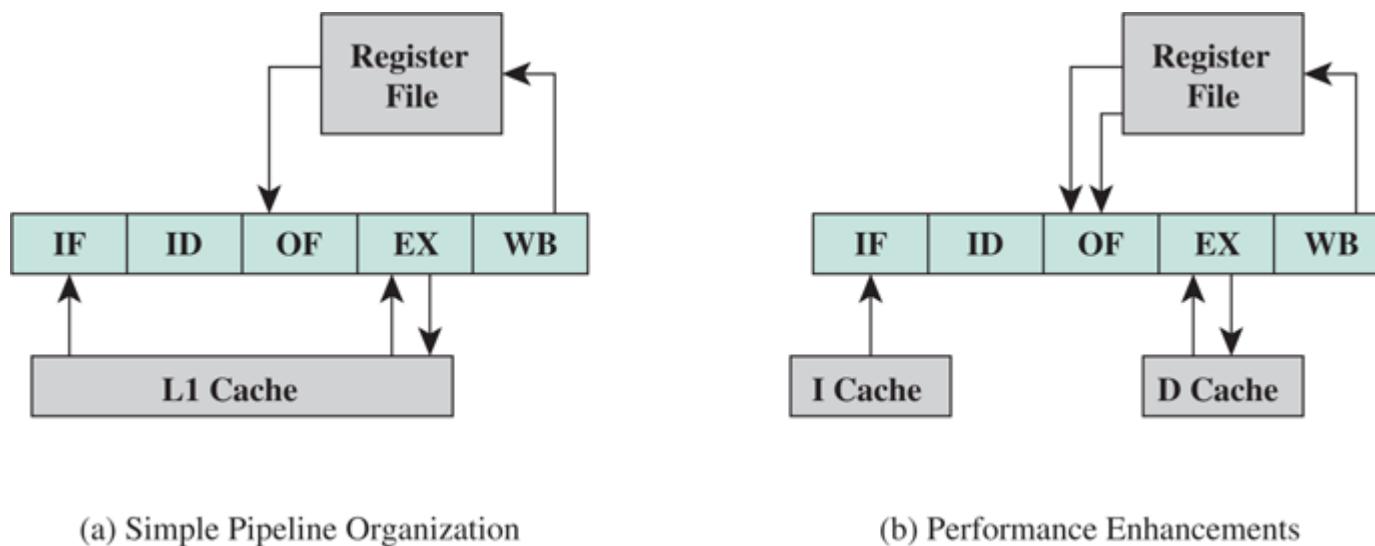

Figure 16.22 Approaches to Pipeline Organization

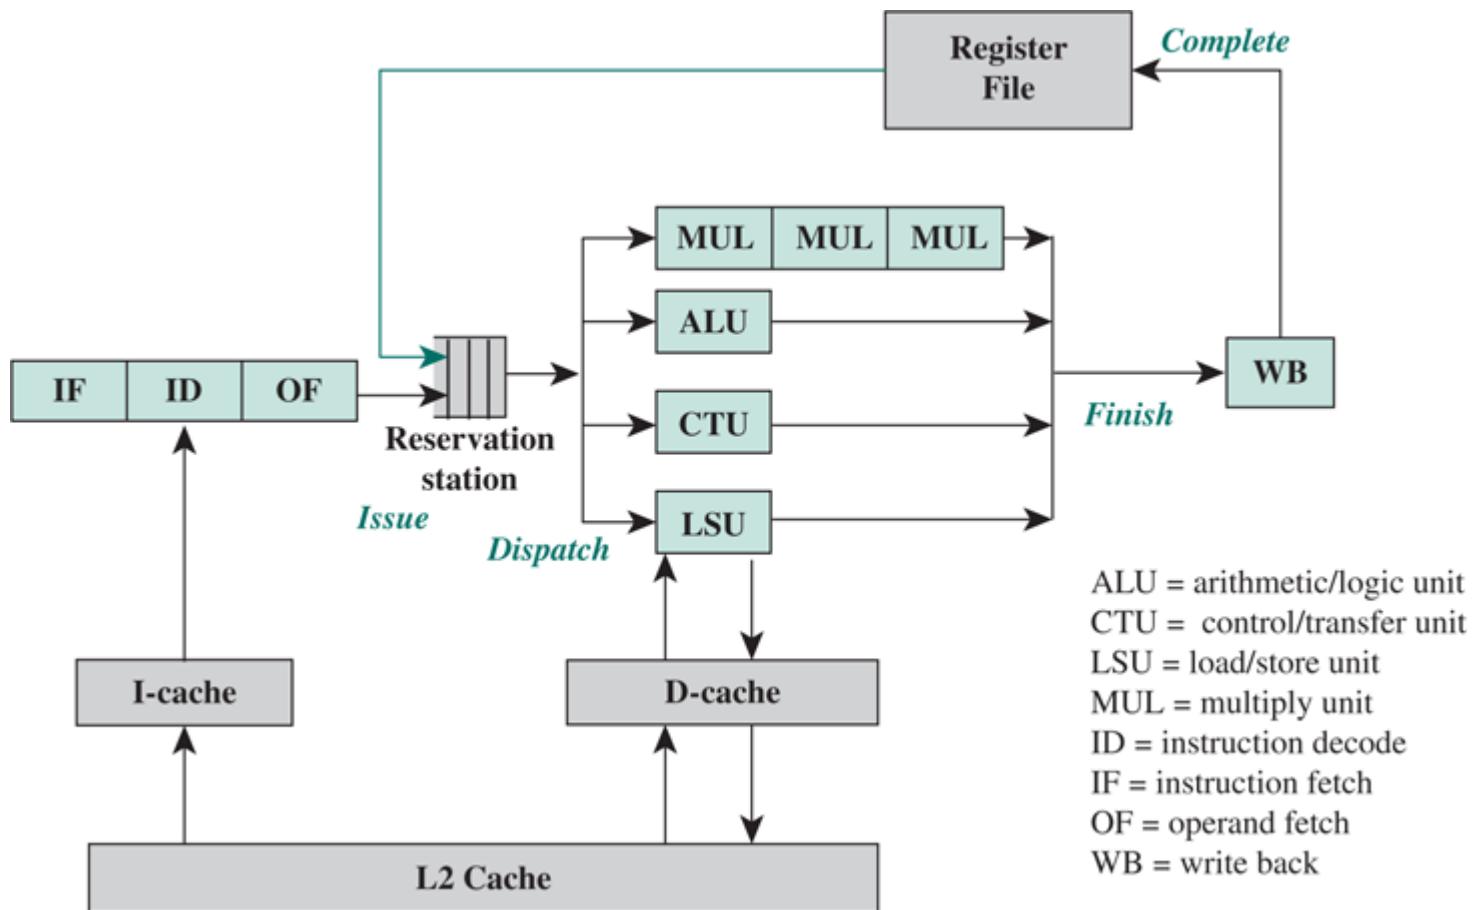

Figure 16.23 Improved Pipeline Organization

- **Dedicated execution units for each function:** Different units can have different time delays, allowing for more flexible pipelining.
- **Pipelining a functional unit:** Because different functional (EX) units have different time delays, it is possible to pipeline executions in a longer unit. For example, an integer multiply unit may take multiple clock cycles, compared to only one clock cycle for add/subtract and control transfer. Instead of having to stall the pipeline until the entire multiply operation is complete, a new EX stage can be started as soon as the first EX stage of the multiply is complete.
- **Reservation station:** A buffer used to hold operations and operands for an EX unit until the operands are available.

The purpose of the reservation station is to relieve a bottleneck at the OF stage. The OF can issue an instruction as soon as a functional unit is available and hazards are resolved. The problem this creates is that the OF stage cannot receive a new instruction until the previous instruction has been issued. The reservation stations provide a buffer that enables the OF stage to issue instructions as soon as possible. Then, the reservation station will dispatch each instruction to its functional unit when the latter is available.

Figure 16.24 shows the typical contents of a reservation station for a machine that has up to two operands per instruction. Each slot (shown vertically in the figure) holds information for one instruction consisting of one or more tag/value pairs and an OP field. The OP field is the instruction operation command for a functional unit. The Tag field indicates “valid” if the corresponding Value field contains an operand. Otherwise the Tag field indicates the identity of the desired operand, such as by using a register number. If the desired operand is available, it is copied from a register to the Value field; otherwise, the slot is in a waiting state until the operand is available.

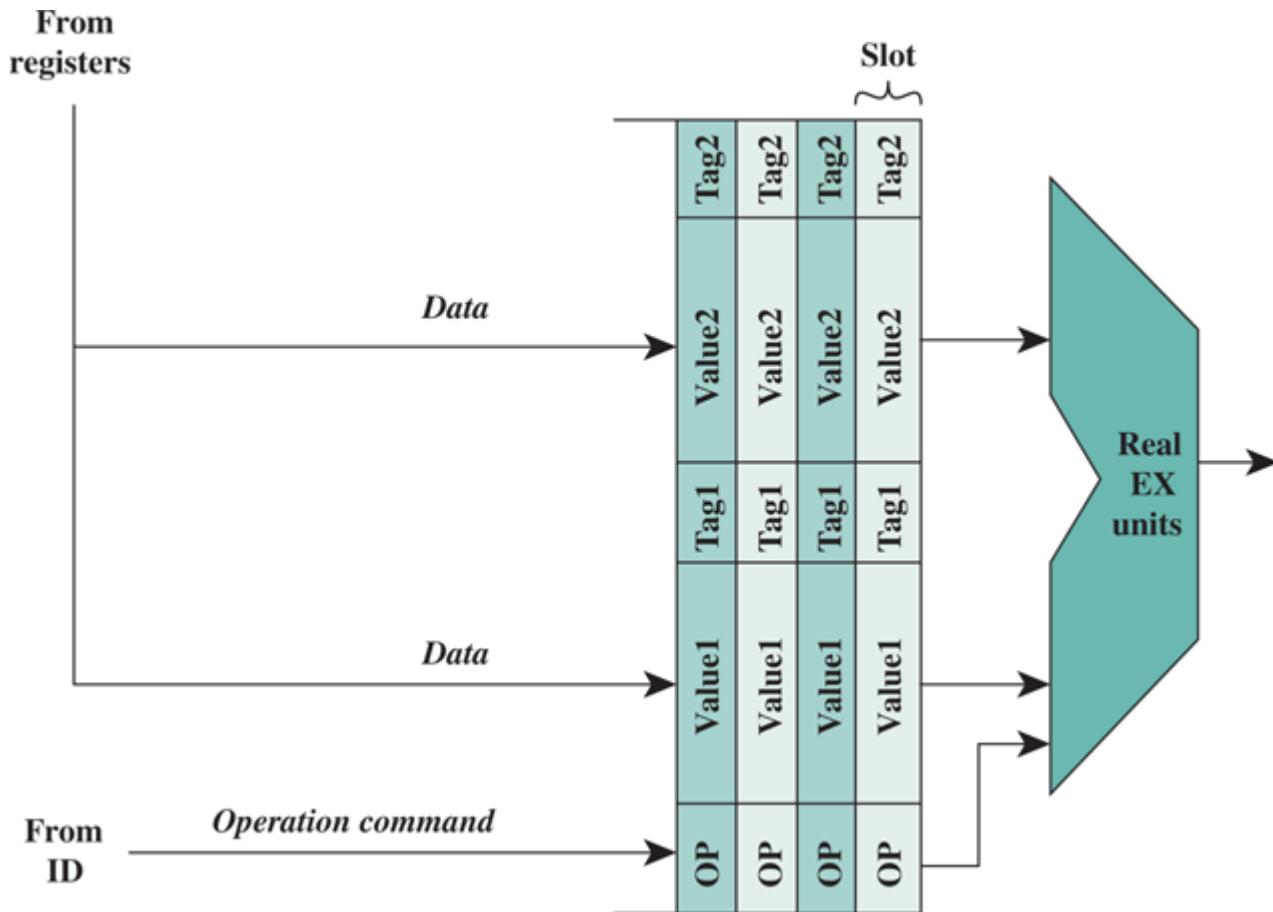

Figure 16.24 Reservation Station Contents

16.6 The x86 Processor Family

The x86 organization has evolved dramatically over the years. In this section we examine some of the details of the most recent processor organizations, concentrating on common elements in single processors. [Chapter 18](#) looks at superscalar aspects of the x86, and [Chapter 20](#) examines the multicore organization. An overview of the Pentium 4 processor organization is depicted in [Figure 5.17](#).

Register Organization

The register organization includes the following types of registers ([Table 16.2](#)):

Table 16.2 x86 Processor Registers

(a) Integer Unit in 32-bit Mode			
Type	Number	Length (bits)	Purpose
General	8	32	General-purpose user registers
Segment	6	16	Contain segment selectors
EFLAGS	1	32	Status and control bits
Instruction Pointer	1	32	Instruction pointer

(b) Integer Unit in 64-bit Mode			
Type	Number	Length (bits)	Purpose
General	16	32	General-purpose user registers
Segment	6	16	Contain segment selectors
RFLAGS	1	64	Status and control bits
Instruction Pointer	1	64	Instruction pointer

(c) Floating-Point Unit			
Type	Number	Length (bits)	Purpose
Numeric	8	80	Hold floating-point numbers
Control	1	16	Control bits

Status	1	16	Status bits
Tag Word	1	16	Specifies contents of numeric registers
Instruction Pointer	1	48	Points to instruction interrupted by exception
Data Pointer	1	48	Points to operand interrupted by exception

- **General:** There are eight 32-bit general-purpose registers (see [Figure 16.3c](#)). These may be used for all types of x86 instructions; they can also hold operands for address calculations. In addition, some of these registers also serve special purposes. For example, string instructions use the contents of the ECX, ESI, and EDI registers as operands without having to reference these registers explicitly in the instruction. As a result, a number of instructions can be encoded more compactly. In 64-bit mode, there are sixteen 64-bit general-purpose registers.
- **Segment:** The six 16-bit segment registers contain segment selectors, which index into segment tables, as discussed in [Chapter 9](#). The code segment (CS) register references the segment containing the instruction being executed. The stack segment (SS) register references the segment containing a user-visible stack. The remaining segment registers (DS, ES, FS, GS) enable the user to reference up to four separate data segments at a time.
- **Flags:** The 32-bit EFLAGS register contains condition codes and various mode bits. In 64-bit mode, this register is extended to 64 bits and referred to as RFLAGS. In the current architecture definition, the upper 32 bits of RFLAGS are unused.
- **Instruction pointer:** Contains the address of the current instruction.

There are also registers specifically devoted to the floating-point unit:

- **Numeric:** Each register holds an extended-precision 80-bit floating-point number. There are eight registers that function as a stack, with push and pop operations available in the instruction set.
- **Control:** The 16-bit control register contains bits that control the operation of the floating-point unit, including the type of rounding control; single, double, or extended precision; and bits to enable or disable various exception conditions.
- **Status:** The 16-bit status register contains bits that reflect the current state of the floating-point unit, including a 3-bit pointer to the top of the stack; condition codes reporting the outcome of the last operation; and exception flags.
- **Tag word:** This 16-bit register contains a 2-bit tag for each floating-point numeric register, which indicates the nature of the contents of the corresponding register. The four possible values are valid, zero, special (NaN, infinity, denormalized), and empty. These tags enable programs to check the contents of a numeric register without performing complex decoding of the actual data in the register. For example, when a context switch is made, the processor need not save any floating-point registers that are empty.

The use of most of the aforementioned registers is easily understood. Let us elaborate briefly on several of the registers.

EFLAGS REGISTER

The EFLAGS register ([Figure 16.25](#)) indicates the condition of the processor and helps to control its operation. It includes the six condition codes defined in [Table 13.8](#) (carry, parity, auxiliary, zero, sign, overflow), which report the results of an integer operation. In addition, there are bits in the register that may be referred to as control bits:

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	0	0	0	0	0	0	0	0	I D	V I P	V I F	A C	V M	R F	0	N T	I O P L	O F	D F	I F	T F	S F	Z F	0	A F	0	P F	1	C F	

X ID = Identification flag
X VIP = Virtual interrupt pending
X VIF = Virtual interrupt flag
X AC = Alignment check
X VM = Virtual 8086 mode
X RF = Resume flag
X NT = Nested task flag
X IOPL = I/O privilege level
S OF = Overflow flag

C DF = Direction flag
X IF = Interrupt enable flag
X TF = Trap flag
S SF = Sign flag
S ZF = Zero flag
S AF = Auxiliary carry flag
S PF = Parity flag
S CF = Carry flag

S indicates a status flag.
C indicates a control flag.
X indicates a system flag.
 Shaded bits are reserved.

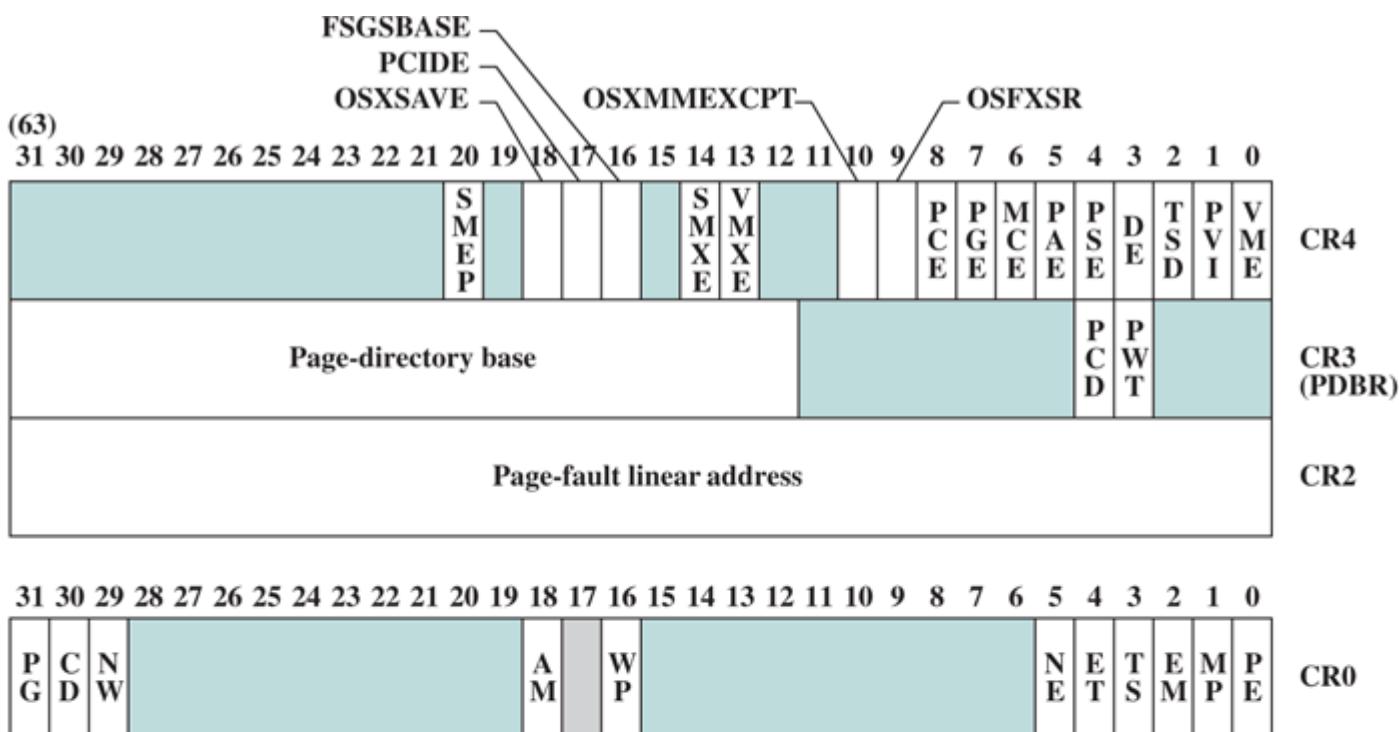

Figure 16.25 x86 EFLAGS Register

- **Trap flag (TF):** When set, causes an interrupt after the execution of each instruction. This is used for debugging.
- **Interrupt enable flag (IF):** When set, the processor will recognize external interrupts.
- **Direction flag (DF):** Determines whether string processing instructions increment or decrement the 16-bit half-registers SI and DI (for 16-bit operations) or the 32-bit registers ESI and EDI (for 32-bit operations).
- **I/O privilege flag (IOPL):** When set, causes the processor to generate an exception on all accesses to I/O devices during protected-mode operation.
- **Resume flag (RF):** Allows the programmer to disable debug exceptions so that the instruction can be restarted after a debug exception without immediately causing another debug exception.
- **Alignment check (AC):** Activates if a word or doubleword is addressed on a nonword or nondoubleword boundary.
- **Identification flag (ID):** If this bit can be set and cleared, then this processor supports the processorID instruction. This instruction provides information about the vendor, family, and model. In addition, there are 4 bits that relate to operating mode. The Nested Task (NT) flag indicates that the current task is nested within another task in protected-mode operation. The Virtual Mode (VM) bit allows the programmer to enable or disable virtual 8086 mode, which determines whether the processor runs as an 8086 machine. The Virtual Interrupt Flag (VIF) and Virtual Interrupt Pending (VIP) flag are used in a multitasking environment.

CONTROL REGISTERS

The x86 employs four control registers (register CR1 is unused) to control various aspects of processor operation ([Figure 16.26](#)). All of the registers except CR0 are either 32 bits or 64 bits long, depending on whether the implementation supports the x86 64-bit architecture. The CR0 register contains system control flags, which control modes or indicate states that apply generally to the

processor rather than to the execution of an individual task. The flags are as follows:

Shaded area indicates reserved bits.

OSXSAVE	= XSAVE enable bit	VME	= Virtual 8086 mode extensions
PCIDE	= Enables process-context identifiers	PCD	= Page-level cache disable
FSGSBASE	= Enables segment base instructions	PWT	= Page-level writes transparent
SMXE	= Enable safer mode extensions	PG	= Paging
VMXE	= Enable virtual machine extensions	CD	= Cache disable
OSXMMEXCPT	= Support unmasked SIMD FP exceptions	NW	= Not write through
OSFXSR	= Support FXSAVE, FXSTOR	AM	= Alignment mask
PCE	= Performance counter enable	WP	= Write protect
PGE	= Page global enable	NE	= Numeric error
MCE	= Machine check enable	ET	= Extension type
PAE	= Physical address extension	TS	= Task switched
PSE	= Page size extensions	EM	= Emulation
DE	= Debug extensions	MP	= Monitor coprocessor
TSD	= Time stamp disable	PE	= Protection enable
PVI	= Protected mode virtual interrupt		

Figure 16.26 x86 Control Registers

- **Protection Enable (PE):** Enable/disable protected mode of operation.
- **Monitor Coprocessor (MP):** Only of interest when running programs from earlier machines on the x86; it relates to the presence of an arithmetic coprocessor.
- **Emulation (EM):** Set when the processor does not have a floating-point unit, and causes an interrupt when an attempt is made to execute floating-point instructions.
- **Task Switched (TS):** Indicates that the processor has switched tasks.
- **Extension Type (ET):** Not used on the Pentium and later machines; used to indicate support of math coprocessor instructions on earlier machines.
- **Numeric Error (NE):** Enables the standard mechanism for reporting floating-point errors on external bus lines.

Write Protect (WP): When this bit is clear, read-only user-level pages can be written by a supervisor process. This feature is useful for supporting process creation in some operating systems.

- **Alignment Mask (AM):** Enables/disables alignment checking.
- **Not Write Through (NW):** Selects mode of operation of the data cache. When this bit is set, the data cache is inhibited from cache write-through operations.
- **Cache Disable (CD):** Enables/disables the internal cache fill mechanism.
- **Paging (PG):** Enables/disables paging.

When paging is enabled, the CR2 and CR3 registers are valid. The CR2 register holds the 32-bit linear address of the last page accessed before a page fault interrupt. The leftmost 20 bits of CR3 hold the 20 most significant bits of the base address of the page directory; the remainder of the address contains zeros. Two bits of CR3 are used to drive pins that control the operation of an external cache. The page-level cache disable (PCD) enables or disables the external cache, and the page-level writes transparent (PWT) bit controls write through in the external cache. CR4 contains additional control bits.

MMX REGISTERS

Recall from [Section 13.3](#) that the x86 MMX capability makes use of several 64-bit data types. The MMX instructions make use of 3-bit register address fields, so that eight MMX registers are supported. In fact, the processor does not include specific MMX registers. Rather, the processor uses an aliasing technique ([Figure 16.27](#)). The existing floating-point registers are used to store MMX values. Specifically, the low-order 64 bits (mantissa) of each floating-point register are used to form the eight MMX registers. Thus, the older 32-bit x86 architecture is easily extended to support the MMX capability. Some key characteristics of the MMX use of these registers are as follows:

Floating-point tag

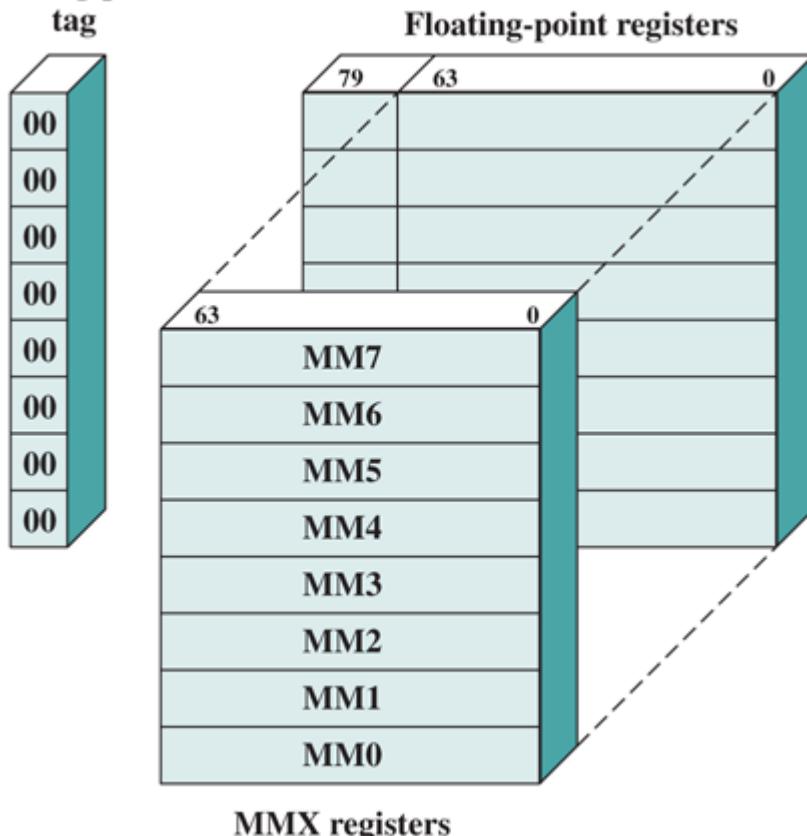

Figure 16.27 Mapping of MMX Registers to Floating-Point Registers

- Recall that the floating-point registers are treated as a stack for floating-point operations. For MMX

operations, these same registers are accessed directly.

- The first time that an MMX instruction is executed after any floating-point operations, the FP tag word is marked valid. This reflects the change from stack operation to direct register addressing.
- The EMMS (Empty MMX State) instruction sets bits of the FP tag word to indicate that all registers are empty. It is important that the programmer insert this instruction at the end of an MMX code block so that subsequent floating-point operations function properly.
- When a value is written to an MMX register, bits [79:64] of the corresponding FP register (sign and exponent bits) are set to all ones. This sets the value in the FP register to NaN (not a number) or infinity when viewed as a floating-point value. This ensures that an MMX data value will not look like a valid floating-point value.

Interrupt Processing

Interrupt processing within a processor is a facility provided to support the operating system. It allows an application program to be suspended, in order that a variety of interrupt conditions can be serviced and later resumed.

INTERRUPTS AND EXCEPTIONS

Two classes of events cause the x86 to suspend execution of the current instruction stream and respond to the event: interrupts and exceptions. In both cases, the processor saves the context of the current process and transfers to a predefined routine to service the condition. An *interrupt* is generated by a signal from hardware, and it may occur at random times during the execution of a program. An *exception* is generated from software, and it is provoked by the execution of an instruction. There are two sources of interrupts and two sources of exceptions:

1. Interrupts

- **Maskable interrupts:** Received on the processor's INTR pin. The processor does not recognize a maskable interrupt unless the interrupt enable flag (IF) is set.
- **Nonmaskable interrupts:** Received on the processor's NMI pin. Recognition of such interrupts cannot be prevented.

2. Exceptions

- **Processor-detected exceptions:** Results when the processor encounters an error while attempting to execute an instruction.
- **Programmed exceptions:** These are instructions that generate an exception (e.g., INTO, INT3, INT, and BOUND).

INTERRUPT VECTOR TABLE

Interrupt processing on the x86 uses the interrupt vector table. Every type of interrupt is assigned a number, and this number is used to index into the interrupt vector table. This table contains 256 32-bit interrupt vectors, which is the address (segment and offset) of the interrupt service routine for that interrupt number.

Table 16.3 shows the assignment of numbers in the interrupt vector table; shaded entries represent interrupts, while nonshaded entries are exceptions. The NMI hardware interrupt is type 2. INTR hardware interrupts are assigned numbers in the range of 32 to 255; when an INTR interrupt is generated, it must be accompanied on the bus with the interrupt vector number for this interrupt. The remaining vector numbers are used for exceptions.

Table 16.3 x86 Exception and Interrupt Vector Table

Unshaded: exceptions

Shaded: interrupts

Vector Number	Description
0	Divide error; division overflow or division by zero
1	Debug exception; includes various faults and traps related to debugging
2	NMI pin interrupt; signal on NMI pin
3	Breakpoint; caused by INT 3 instruction, which is a 1-byte instruction useful for debugging
4	INTO-detected overflow; occurs when the processor executes INTO with the OF flag set
5	BOUND range exceeded; the BOUND instruction compares a register with boundaries stored in memory and generates an interrupt if the contents of the register is out of bounds
6	Undefined opcode
7	Device not available; attempt to use ESC or WAIT instruction fails due to lack of external device
8	Double fault; two interrupts occur during the same instruction and cannot be handled serially
9	Reserved
10	Invalid task state segment; segment describing a requested task is not initialized or not valid
11	Segment not present; required segment not present
12	Stack fault; limit of stack segment exceeded or stack segment not present
13	General protection; protection violation that does not cause another exception (e.g., writing to a read-only segment)
14	Page fault
15	Reserved
16	Floating-point error; generated by a floating-point arithmetic instruction

17	Alignment check; access to a word stored at an odd byte address or a doubleword stored at an address not a multiple of 4
18	Machine check; model specific
19–31	Reserved
32–255	User interrupt vectors; provided when INTR signal is activated

If more than one exception or interrupt is pending, the processor services them in a predictable order. The location of vector numbers within the table does not reflect priority. Instead, priority among exceptions and interrupts is organized into five classes. In descending order of priority, these are

- **Class 1:** Traps on the previous instruction (vector number 1)
- **Class 2:** External interrupts (2, 32–255)
- **Class 3:** Faults from fetching next instruction (3, 14)
- **Class 4:** Faults from decoding the next instruction (6, 7)
- **Class 5:** Faults on executing an instruction (0, 4, 5, 8, 10–14, 16, 17)

INTERRUPT HANDLING

Just as with a transfer of execution using a CALL instruction, a transfer to an interrupt-handling routine uses the system stack to store the processor state. When an interrupt occurs and is recognized by the processor, a sequence of events takes place:

1. If the transfer involves a change of privilege level, then the current stack segment register and the current extended stack pointer (ESP) register are pushed onto the stack.
 2. The current value of the EFLAGS register is pushed onto the stack.
 3. Both the interrupt (IF) and trap (TF) flags are cleared. This disables INTR interrupts and the trap or single-step feature.
 4. The current code segment (CS) pointer and the current instruction pointer (IP or EIP) are pushed onto the stack.
 5. If the interrupt is accompanied by an error code, then the error code is pushed onto the stack.
 6. The interrupt vector contents are fetched and loaded into the CS and IP or EIP registers.
- Execution continues from the interrupt service routine.

To return from an interrupt, the interrupt service routine executes an IRET instruction. This causes all of the values saved on the stack to be restored; execution resumes from the point of the interrupt.

16.7 The ARM Processor

In this section, we look at some of the key elements of the ARM architecture and organization. We defer a discussion of more complex aspects of organization and pipelining until [Chapter 18](#). For the discussion in this section and in [Chapter 18](#), it is useful to keep in mind key characteristics of the ARM architecture. ARM is primarily a RISC system with the following notable attributes:

- A moderate array of uniform registers, more than are found on some CISC systems but fewer than are found on many RISC systems.
- A load/store model of data processing, in which operations only perform on operands in registers and not directly in memory. All data must be loaded into registers before an operation can be performed; the result can then be used for further processing or stored into memory.
- A uniform fixed-length instruction of 32 bits for the standard set and 16 bits for the Thumb instruction set.
- To make each data processing instruction more flexible, either a shift or rotation can preprocess one of the source registers. To efficiently support this feature, there are separate arithmetic logic unit (ALU) and shifter units.
- A small number of addressing modes with all load/store addressees determined from registers and instruction fields. Indirect or indexed addressing involving values in memory are not used.
- Auto-increment and auto-decrement addressing modes are used to improve the operation of program loops.
- Conditional execution of instructions minimizes the need for conditional branch instructions, thereby improving pipeline efficiency, because pipeline flushing is reduced.

Processor Organization

The ARM processor organization varies substantially from one implementation to the next, particularly when based on different versions of the ARM architecture. However, it is useful for the discussion in this section to present a simplified, generic ARM organization, which is illustrated in [Figure 16.28](#). In this figure, the arrows indicate the flow of data. Each box represents a functional hardware unit or a storage unit.

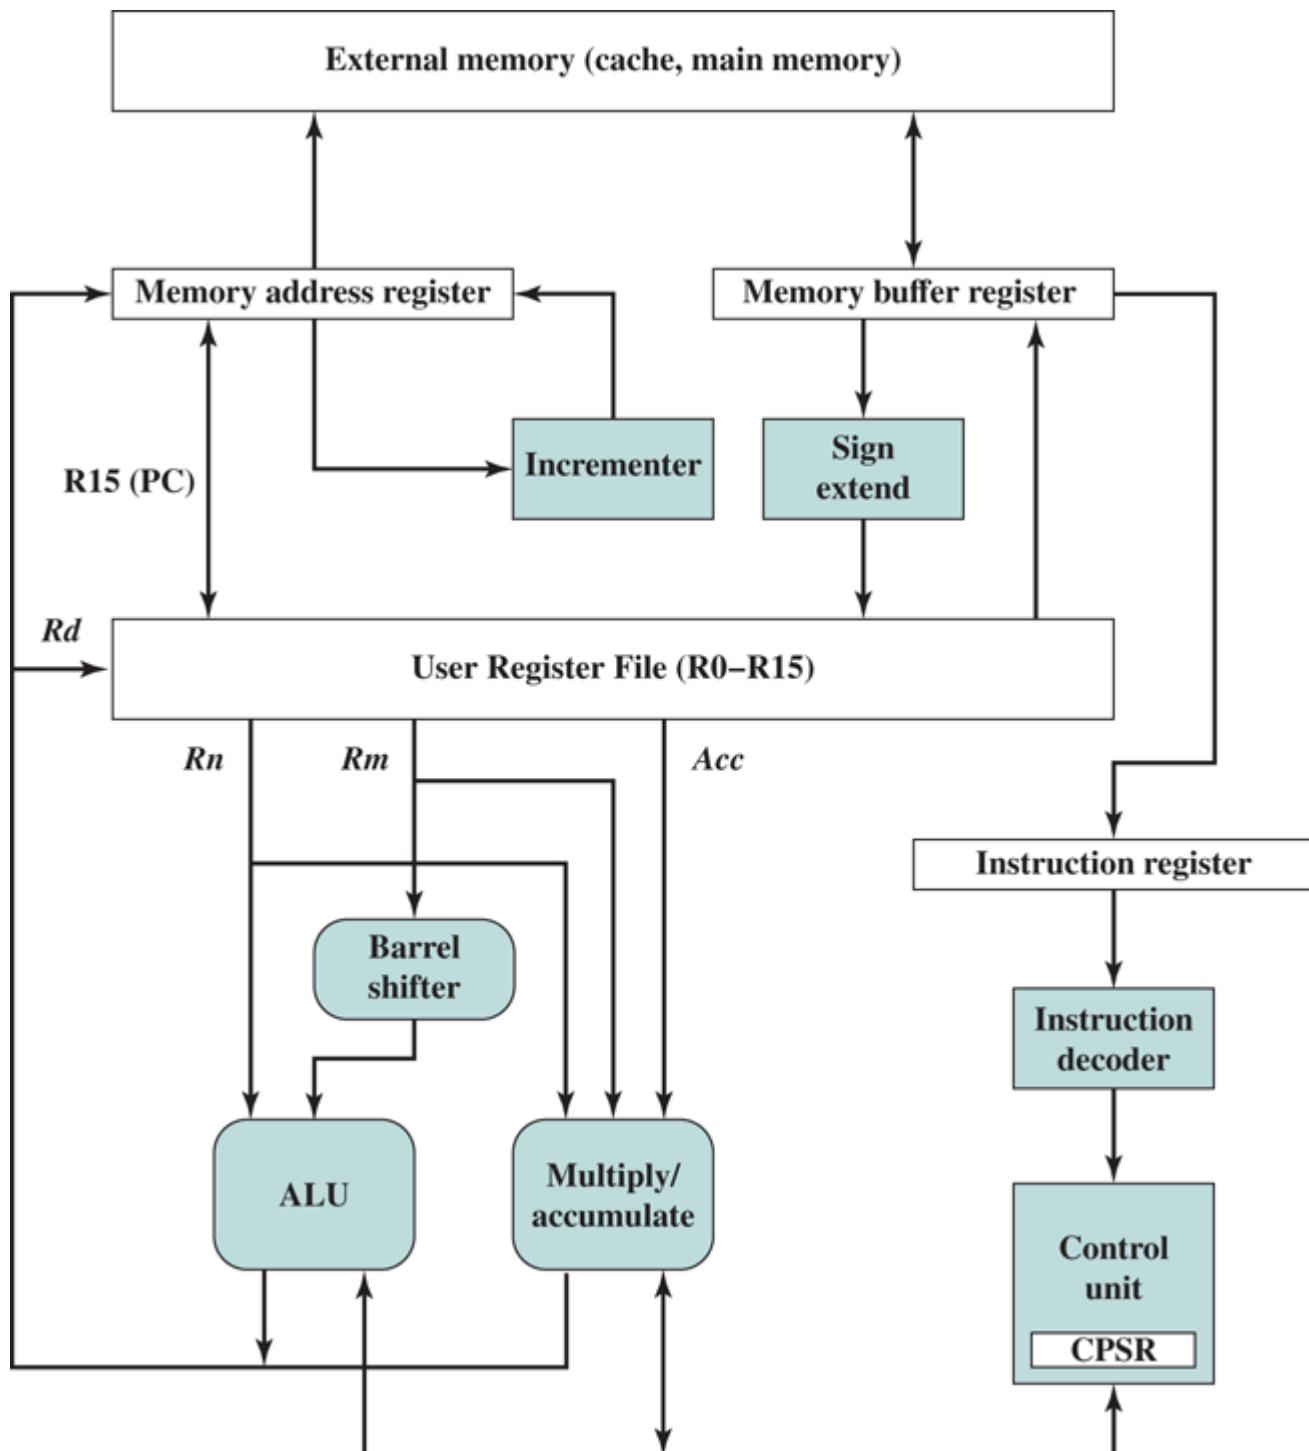

Figure 16.28 Simplified ARM Organization

Data are exchanged with the processor from external memory through a data bus. The value transferred is either a data item, as a result of a load or store instruction, or an instruction fetch. Fetched instructions pass through an instruction decoder before execution, under control of a control unit. The latter includes pipeline logic and provides control signals (not shown) to all the hardware elements of the processor. Data items are placed in the register file, consisting of a set of 32-bit registers. Byte or halfword items treated as two's-complement numbers are sign-extended to 32 bits.

ARM data processing instructions typically have two source registers, Rn and Rm , and a single result or destination register, Rd . The source register values feed into the ALU or a separate multiply unit that makes use of an additional register to accumulate partial results. The ARM processor also includes a hardware unit that can shift or rotate the Rm value before it enters the ALU. This shift or rotate occurs within the cycle time of the instruction and increases the power and flexibility of many data processing operations.

The results of an operation are fed back to the destination register. Load/store instructions may also use the output of the arithmetic units to generate the memory address for a load or store.

Processor Modes

It is quite common for a processor to support only a small number of processor modes. For example, many operating systems make use of just two modes: a user mode and a kernel mode, with the latter mode used to execute privileged system software. In contrast, the ARM architecture provides a flexible foundation for operating systems to enforce a variety of protection policies.

The ARM architecture supports seven execution modes. Most application programs execute in **user mode**. While the processor is in user mode, the program being executed is unable to access protected system resources or to change mode, other than by causing an exception to occur.

The remaining six execution modes are referred to as privileged modes. These modes are used to run system software. There are two principal advantages to defining so many different privileged modes: (1) The OS can tailor the use of system software to a variety of circumstances, and (2) certain registers are dedicated for use for each of the privileged modes, allowing swifter changes in context.

The exception modes have full access to system resources and can change modes freely. Five of these modes are known as exception modes. These are entered when specific exceptions occur. Each of these modes has some dedicated registers that substitute for some of the user mode registers, and which are used to avoid corrupting user mode state information when the exception occurs. The exception modes are as follows:

- **Supervisor mode:** Usually what the OS runs in. It is entered when the processor encounters a software interrupt instruction. Software interrupts are a standard way to invoke operating system services on ARM.
- **Abort mode:** Entered in response to memory faults.
- **Undefined mode:** Entered when the processor attempts to execute an instruction that is supported neither by the main integer core nor by one of the coprocessors.
- **Fast interrupt mode:** Entered whenever the processor receives an interrupt signal from the designated fast interrupt source. A fast interrupt cannot be interrupted, but a fast interrupt may interrupt a normal interrupt.
- **Interrupt mode:** Entered whenever the processor receives an interrupt signal from any other interrupt source (other than fast interrupt). An interrupt may only be interrupted by a fast interrupt.

The remaining privileged mode is the **System mode**. This mode is not entered by any exception and uses the same registers available in User mode. The System mode is used for running certain privileged operating system tasks. System mode tasks may be interrupted by any of the five exception categories.

Register Organization

Figure 16.29 depicts the user-visible registers for the ARM. The ARM processor has a total of 37 32-bit registers, classified as follows:

- Thirty-one registers referred to in the ARM manual as general-purpose registers. In fact, some of these, such as the program counters, have special purposes.
- Six program status registers.

Registers are arranged in partially overlapping banks, with the current processor mode determining which bank is available. At any time, sixteen numbered registers and one or two program status

registers are visible, for a total of 17 or 18 software-visible registers. **Figure 16.29** is interpreted as follows:

- Registers R0 through R7, register R15 (the program counter) and the current program status register (CPSR) are visible in and shared by all modes.
- Registers R8 through R12 are shared by all modes except fast interrupt, which has its own dedicated registers R8_fiq through R12_fiq.
- All the exception modes have their own versions of registers R13 and R16.
- All the exception modes have a dedicated saved program status register (SPSR).

Modes						
Privileged modes						
Exception modes						
User	System	Supervisor	Abort	Undefined	Interrupt	Fast interrupt
R0	R0	R0	R0	R0	R0	R0
R1	R1	R1	R1	R1	R1	R1
R2	R2	R2	R2	R2	R2	R2
R3	R3	R3	R3	R3	R3	R3
R4	R4	R4	R4	R4	R4	R4
R5	R5	R5	R5	R5	R5	R5
R6	R6	R6	R6	R6	R6	R6
R7	R7	R7	R7	R7	R7	R7
R8	R8	R8	R8	R8	R8	R8_fiq
R9	R9	R9	R9	R9	R9	R9_fiq
R10	R10	R10	R10	R10	R10	R10_fiq
R11	R11	R11	R11	R11	R11	R11_fiq
R12	R12	R12	R12	R12	R12	R12_fiq
R13(SP)	R13(SP)	R13_svc	R13_abt	R13_und	R13_irq	R13_fiq
R14(LR)	R14(LR)	R14_svc	R14_abt	R14_und	R14_irq	R14_fiq
R15(PC)	R15(PC)	R15(PC)	R15(PC)	R15(PC)	R15(PC)	R15(PC)

CPSR	CPSR	CPSR	CPSR	CPSR	CPSR	CPSR
		SPSR_svc	SPSR_abt	SPSR_und	SPSR_irq	SPSR_fiq

Shading indicates that the normal register used by User or System mode has been replaced by an alternative register specific to the exception mode.

SP = stack pointer

CPSR = current program status register

LR = link register

SPSR = saved program status register

PC = program counter

Figure 16.29 ARM Register Organization

GENERAL-PURPOSE REGISTERS

Register R13 is normally used as a stack pointer and is also known as the SP. Because each exception mode has a separate R13, each exception mode can have its own dedicated program stack. R14 is known as the link register (LR) and is used to hold subroutine return addresses and exception mode returns. Register R15 is the program counter (PC).

PROGRAM STATUS REGISTERS

The CPSR is accessible in all processor modes. Each exception mode also has a dedicated SPSR that is used to preserve the value of the CPSR when the associated exception occurs.

The 16 most significant bits of the CPSR contain user flags visible in user mode, and which can be used to affect the operation of a program ([Figure 16.30](#)). These are as follows:

- **Condition code flags:** The N, Z, C, and V flags, They are the N, Z, C, and V flags which are discussed in [Chapter 13](#).
 - **Q flag:** used to indicate whether overflow and/or saturation has occurred in some SIMD-oriented instructions.
 - **J bit:** indicates the use of special 8-bit instructions, known as Jazelle instructions, which are beyond the scope of our discussion.
 - **GE[3:0] bits:** SIMD instructions use bits [19:16] as Greater than or Equal (GE) flags for individual bytes or halfwords of the result.

The 16 least significant bits of the CPSR contain system control flags that can only be altered when the processor is in a privileged mode. The fields are as follows:

- **E bit:** Controls load and store endianness for data; ignored for instruction fetches.
 - **Interrupt disable bits:** The A bit disables imprecise data aborts when set; the I bit disables IRQ interrupts when set; and the F bit disables FIQ interrupts when set.
 - **T bit:** Indicates whether instructions should be interpreted as normal ARM instructions or Thumb instructions.
 - **Mode bits:** Indicates the processor mode.

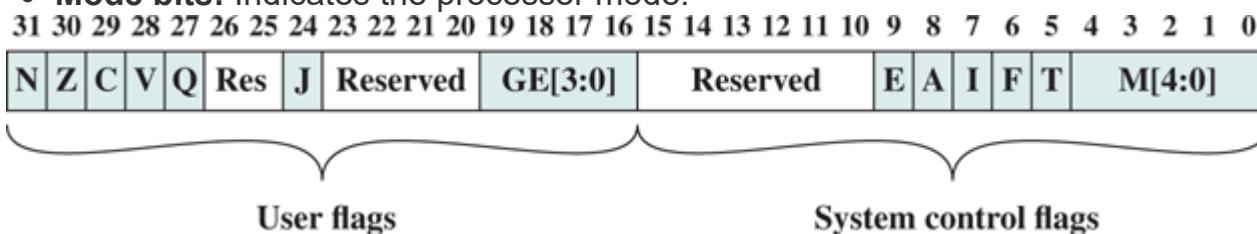

Figure 16.30 Format of ARM CPSR and SPSR

Interrupt Processing

As with any processor, the ARM includes a facility that enables the processor to interrupt the currently executing program to deal with exception conditions. Exceptions are generated by internal and external sources to cause the processor to handle an event. The processor state just before handling the exception is normally preserved so that the original program can be resumed when the exception routine has completed. More than one exception can arise at the same time. The ARM architecture supports seven types of exceptions. **Table 16.4** lists the types of exception and the processor mode that is used to process each type. When an exception occurs, execution is forced from a fixed memory address corresponding to the type of exception. These fixed addresses are called the exception vectors.

Table 16.4 ARM Interrupt Vector

Exception type	Mode	Normal entry address	Description
Reset	Supervisor	0x00000000	Occurs when the system is initialized.
Data abort	Abort	0x00000010	Occurs when an invalid memory address has been accessed, such as if there is no physical memory for an address or the correct access permission is lacking.
FIQ (fast interrupt)	FIQ	0x0000001C	Occurs when an external device asserts the FIQ pin on the processor. An interrupt cannot be interrupted except by an FIQ. FIQ is designed to support a data transfer or channel process, and has sufficient private registers to remove the need for register saving in such applications, therefore minimizing the overhead of context switching. A fast interrupt cannot be interrupted.
IRQ (interrupt)	IRQ	0x00000018	Occurs when an external device asserts the IRQ pin on the processor. An interrupt cannot be interrupted except by an FIQ.
Prefetch abort	Abort	0x0000000C	Occurs when an attempt to fetch an instruction results in a memory fault. The exception is raised when the instruction enters the execute stage of the pipeline.
Undefined instructions	Undefined	0x00000004	Occurs when an instruction not in the instruction set reaches the execute stage of the pipeline.
Software interrupt	Supervisor	0x00000008	Generally used to allow user mode programs to call the OS. The user program executes a SWI instruction with an argument that identifies the function the user wishes to perform.

If more than one interrupt is outstanding, they are handled in priority order. **Table 16.4** lists the exceptions in priority order from highest to lowest.

When an exception occurs, the processor halts execution after the current instruction. The state of the processor is preserved in the SPSR that corresponds to the type of exception, so that the original program can be resumed when the exception routine has completed. The address of the instruction the processor was just about to execute is placed in the link register of the appropriate processor mode. To return after handling the exception, the SPSR is moved into the CPSR and R14 is moved

into the PC.

Review Questions

16.1 What general roles are performed by processor registers?

16.2 What categories of data are commonly supported by user-visible registers?

16.3 What is the function of condition codes?

16.4 What is a program status word?

16.5 Why is a two-stage instruction pipeline unlikely to cut the instruction cycle time in half, compared with the use of no pipeline?

16.6 List and briefly explain various ways in which an instruction pipeline can deal with conditional branch instructions.

16.7 How are history bits used for branch prediction?

Problems

16.1

- a. If the last operation performed on a computer with an 8-bit word was an addition in which the two operands were 00000010 and 00000011, what would be the value of the following flags?
 - Carry
 - Zero
 - Overflow
 - Sign
 - Even Parity
 - Half-Carry
- b. Repeat for the addition of -1 (twos complement) and $+1$.

16.2 Repeat Problem 16.1 for the operation $A - B$, where A contains 11110000 and B contains 0010100.

16.3 A microprocessor is clocked at a rate of 5 GHz.

- How long is a clock cycle?
- What is the duration of a particular type of machine instruction consisting of three clock cycles?

16.4 A microprocessor provides an instruction capable of moving a string of bytes from one area of memory to another. The fetching and initial decoding of the instruction takes 10 clock cycles. Thereafter, it takes 15 clock cycles to transfer each byte. The microprocessor is clocked at a rate of 10 GHz.

- Determine the length of the instruction cycle for the case of a string of 64 bytes.
- What is the worst-case delay for acknowledging an interrupt if the instruction is noninterruptible?
- Repeat part (b) assuming the instruction can be interrupted at the beginning of each byte transfer.

16.5 The Intel 8088 consists of a bus interface unit (BIU) and an execution unit (EU), which form a 2-stage pipeline. The BIU fetches instructions into a 4-byte instruction queue. The BIU also participates in address calculations, fetches operands, and writes results in memory as requested by the EU. If no such requests are outstanding and the bus is free, the BIU fills any vacancies in the instruction queue. When the EU completes execution of an instruction, it passes any results to the BIU (destined for memory or I/O) and proceeds to the next instruction.

- Suppose the tasks performed by the BIU and EU take about equal time. By what factor does pipelining improve the performance of the 8088? Ignore the effect of branch instructions.
- Repeat the calculation assuming that the EU takes twice as long as the BIU.

16.6 Assume an 8088 is executing a program in which the probability of a program jump is 0.1. For simplicity, assume that all instructions are 2 bytes long.

- What fraction of instruction fetch bus cycles is wasted?
- Repeat if the instruction queue is 8 bytes long.

16.7 Consider the timing diagram of [Figures 16.10](#). Assume that there is only a two-stage pipeline (fetch, execute). Redraw the diagram to show how many time units are now needed for four instructions.

16.8 Assume a pipeline with four stages: fetch instruction (FI), decode instruction and calculate addresses (DA), fetch operand (FO), and execute (EX). Draw a diagram similar to [Figure 16.10](#) for a sequence of 7 instructions, in which the third instruction is a branch that is taken and in which there are no data dependencies.

16.9 A pipelined processor has a clock rate of 2.5 GHz and executes a program with 1.5 million instructions. The pipeline has five stages, and instructions are issued at a rate of one per clock cycle. Ignore penalties due to branch instructions and out-of-sequence executions.

- What is the speedup of this processor for this program compared to a nonpipelined processor, making the same assumptions used in [Section 16.4](#)?
- What is throughput (in MIPS) of the pipelined processor?

16.10 A nonpipelined processor has a clock rate of 2.5 GHz and an average CPI (cycles per instruction) of 4. An upgrade to the processor introduces a five-stage pipeline. However, due to internal pipeline delays, such as latch delay, the clock rate of the new processor has to be reduced to 2 GHz.

- What is the speedup achieved for a typical program?
- What is the MIPS rate for each processor?

16.11 Consider an instruction sequence of length n that is streaming through the instruction pipeline. Let p be the probability of encountering a conditional or unconditional branch instruction, and let q be the probability that execution of a branch instruction I causes a jump to a nonconsecutive address. Assume that each such jump requires the pipeline to be cleared, destroying all ongoing instruction processing, when I emerges from the last stage. Revise [Equations \(16.1\)](#) and [\(16.2\)](#) to take these probabilities into account.

16.12 One limitation of the multiple-stream approach to dealing with branches in a pipeline is that additional branches will be encountered before the first branch is resolved. Suggest two additional limitations or drawbacks.

16.13 Consider the state diagrams of [Figure 16.31](#).

- Describe the behavior of each.
- Compare these with the branch prediction state diagram in [Section 16.4](#). Discuss the relative merits of each of the three approaches to branch prediction.

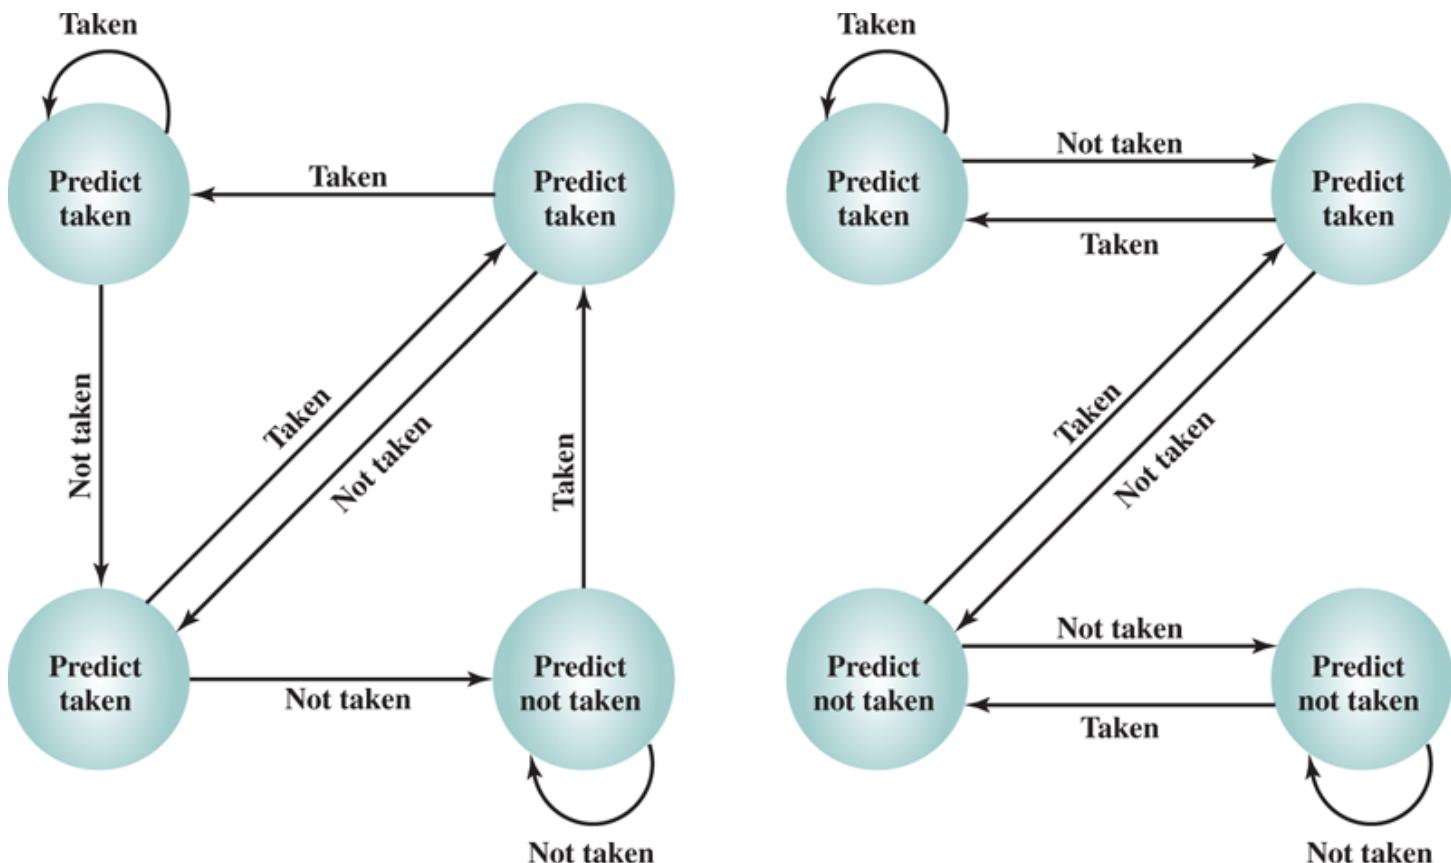

Figure 16.31 Two Branch Prediction State Diagrams

16.14 The Motorola 680x0 machines include the instruction Decrement and Branch According to Condition, which has the following form:

DBcc Dn, displacement

where cc is one of the testable conditions, Dn is a general-purpose register, and displacement specifies the target address relative to the current address. The instruction can be defined as follows:

```

if (cc = False)
then begin
    Dn: = (Dn) -1;
    if Dn Z -1 then PC: = (PC) + displacement end
else PC: = (PC) + 2;

```

When the instruction is executed, the condition is first tested to determine whether the termination condition for the loop is satisfied. If so, no operation is performed and execution continues at the next instruction in sequence. If the condition is false, the specified data register is decremented and checked to see if it is less than zero. If it is less than zero, the loop is terminated and execution continues at the next instruction in sequence. Otherwise, the program branches to the specified location. Now consider the following assembly-language program fragment:

AGAIN	CMPM.L	(A0) + , (A1) +
	DBNE	D1, AGAIN
	NOP	

Two strings addressed by A0 and A1 are compared for equality; the string pointers are incremented with each reference. D1 initially contains the number of longwords (4 bytes) to be compared.

- a. The initial contents of the registers are A0 = \$00004000, A1 = \$00005000 and D1 = \$000000FF (the \$ indicates hexadecimal notation). Memory between \$4000 and \$6000 is loaded with words \$AAAA. If the foregoing program is run, specify the number of times the DBNE loop is executed and the contents of the three registers when the NOP instruction is reached.
- b. Repeat (a), but now assume that memory between \$4000 and \$4FEE is loaded with \$0000 and between \$5000 and \$6000 is loaded with \$AAA.

16.15 Redraw [Figure 16.19c](#), assuming that the conditional branch is not taken.

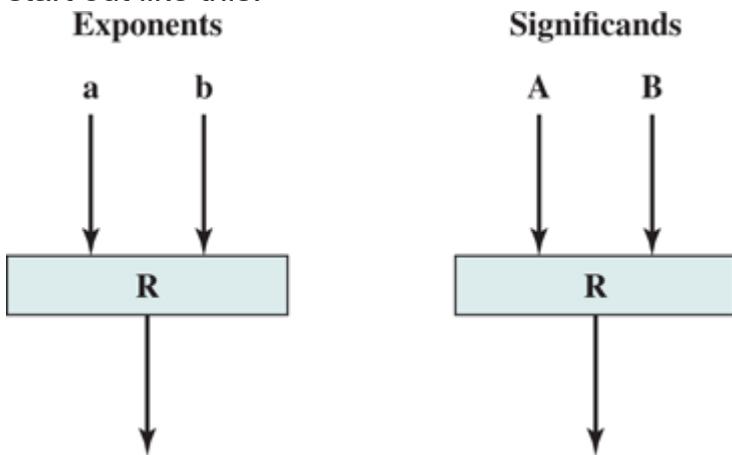

16.16 [Table 16.5](#) summarizes statistics from [MACD84] concerning branch behavior for various classes of applications. With the exception of type 1 branch behavior, there is no noticeable difference among the application classes. Determine the fraction of all branches that go to the branch target address for the scientific environment. Repeat for commercial and systems environments.

Table 16.5 Branch Behavior in Sample Applications

Occurrence of branch classes:				
Type 1: Branch	72.5%			
Type 2: Loop control	9.8%			
Type 3: Procedure call, return	17.7%			
Type 1 branch: where it goes		Scientific	Commercial	Systems
Unconditional—100% go to target		20%	40%	35%
Conditional—went to target		43.2%	24.3%	32.5%

Conditional—did not go to target (inline)	36.8%	35.7%	32.5%
Type 2 branch (all environments)			
That go to target	91%		
That go inline	9%		
Type 3 branch			
100% go to target			

16.17 Pipelining can be applied within the ALU to speed up floating-point operations. Consider the case of floating-point addition and subtraction. In simplified terms, the pipeline could have four stages: (1) Compare the exponents; (2) Choose the exponent and align the significands; (3) Add or subtract significands; (4) Normalize the results. The pipeline can be considered to have two parallel threads, one handling exponents and one handling significands, and could start out like this:

In this figure, the boxes labeled R refer to a set of registers used to hold temporary results. Complete the block diagram that shows at a top level the structure of the pipeline.

Learning Objectives

After studying this chapter, you should be able to:

- Provide an overview of the research results on instruction execution characteristics that motivated

the development of the RISC approach.

- Summarize the key characteristics of RISC machines.
- Understand the design and performance implications of using a large register file.
- Understand the use of compiler-based register optimization to improve performance.
- Discuss the implication of a RISC architecture for pipeline design and performance.
- List and explain key approaches to pipeline optimization on a RISC machine.

Since the development of the stored-program computer around 1950, there have been remarkably few true innovations in the areas of computer organization and architecture. The following are some of the major advances since the birth of the computer:

- **The family concept:** Introduced by IBM with its System/360 in 1964, followed shortly thereafter by DEC, with its PDP-8. The family concept decouples the architecture of a machine from its implementation. A set of computers is offered, with different price/performance characteristics, that presents the same architecture to the user. The differences in price and performance are due to different implementations of the same architecture.
- **Microprogrammed control unit:** Suggested by Wilkes in 1951 and introduced by IBM on the S/360 line in 1964. Microprogramming eases the task of designing and implementing the control unit and provides support for the family concept.
- **Cache memory:** First introduced commercially on IBM S/360 Model 85 in 1968. The insertion of this element into the memory hierarchy dramatically improves performance.
- **Pipelining:** A means of introducing parallelism into the essentially sequential nature of a machine-instruction program. Examples are instruction pipelining and vector processing.
- **Multiple processors:** This category covers a number of different organizations and objectives.
- **Reduced instruction set computer (RISC) architecture:** This is the focus of this chapter.

When it appeared, RISC architecture was a dramatic departure from the historical trend in processor architecture. An analysis of the RISC architecture brings into focus many of the important issues in computer organization and architecture.

Although RISC architectures have been defined and designed in a variety of ways by different groups, the key elements shared by most designs are these:

- A large number of general-purpose registers, and/or the use of compiler technology to optimize register usage.
- A limited and simple instruction set.
- An emphasis on optimizing the instruction pipeline.

Table 17.1 compares several RISC and non-RISC systems.

Table 17.1 Characteristics of Some CISCs, RISCs, and Superscalar Processors

	Complex Instruction Set (CISC) Computer	Reduced Instruction Set (RISC) Computer
--	--	--

Characteristic	<i>IBM 370/168</i>	<i>VAX 11/780</i>	<i>Intel 80486</i>	<i>SPARC</i>	<i>MIPS R4000</i>

Number of general-purpose registers	32	40–520	32
Control memory size (kbits)	—	—	—
Cache size (kB)	16–32	32	64

We begin this chapter with a brief survey of some results on instruction sets, and then examine each of the three topics just listed. This is followed by a description of two of the best-documented RISC designs.

17.1 Instruction Execution Characteristics

One of the most visible forms of evolution associated with computers is that of programming languages. As the cost of hardware has dropped, the relative cost of software has risen. Along with that, a chronic shortage of programmers has driven up software costs in absolute terms. Thus, the major cost in the life cycle of a system is software, not hardware. Adding to the cost, and to the inconvenience, is the element of unreliability: it is common for programs, both system and application, to continue to exhibit new bugs after years of operation.

The response from researchers and industry has been to develop ever more powerful and complex high-level programming languages. These **high-level languages (HLLs)**: (1) allow the programmer to express algorithms more concisely; (2) allow the compiler to take care of details that are not important in the programmer's expression of algorithms; and (3) often support naturally the use of structured programming and/or object-oriented design.

Alas, this solution gave rise to a perceived problem, known as the *semantic gap*, the difference between the operations provided in HLLs and those provided in computer architecture. Symptoms of this gap are alleged to include execution inefficiency, excessive machine program size, and compiler complexity. Designers responded with architectures intended to close this gap. Key features include large instruction sets, dozens of addressing modes, and various HLL statements implemented in hardware. An example of the latter is the CASE machine instruction on the VAX. Such complex instruction sets are intended to:

- Ease the task of the compiler writer.
- Improve execution efficiency, because complex sequences of operations can be implemented in microcode.
- Provide support for even more complex and sophisticated HLLs.

Meanwhile, a number of studies have been done over the years to determine the characteristics and patterns of execution of machine instructions generated from HLL programs. The results of these studies inspired some researchers to look for a different approach: namely, to make the architecture that supports the HLL simpler, rather than more complex.

To understand the line of reasoning of the RISC advocates, we begin with a brief review of instruction execution characteristics. The aspects of computation of interest are as follows:

- **Operations performed:** These determine the functions to be performed by the processor and its interaction with memory.
- **Operands used:** The types of operands and the frequency of their use determine the memory organization for storing them and the addressing modes for accessing them.
- **Execution sequencing:** This determines the control and pipeline organization.

In the remainder of this section, we summarize the results of a number of studies of high-level-language programs. All of the results are based on dynamic measurements. That is, measurements are collected by executing the program and counting the number of times some feature has appeared or a particular property has held true. In contrast, static measurements merely perform these counts on the source text of a program. They give no useful information on performance, because they are not weighted relative to the number of times each statement is executed.

Operations

A variety of studies have been made to analyze the behavior of HLL programs, with the following

general conclusions. There is quite good agreement in the results of this mixture of languages and applications. Assignment statements predominate, suggesting that the simple movement of data is of high importance. There is also a preponderance of conditional statements (IF, LOOP). These statements are implemented in machine language with some sort of compare and branch instruction. This suggests that the sequence control mechanism of the instruction set is important.

These results are instructive to the machine instruction set designer, indicating which types of statements occur most often and therefore should be supported in an “optimal” fashion. However, these results do not reveal which statements use the most time in the execution of a typical program. That is, we want to answer the question: Given a compiled machine-language program, which statements in the source language cause the execution of the most machine-language instructions and what is the execution time of these instructions?

To get at this underlying phenomenon, Patterson and Sequin [PATT82a] analyzed a set of measurements taken from compilers and programs for typesetting, computer-aided design (CAD), sorting, and file comparison. The programming languages C and Pascal compiled on the VAX, PDP-11, and Motorola 68000 to determine the average number of machine instructions and memory references per statement type. The second and third columns in **Table 17.2** show the relative frequency of occurrence of various HLL statements in a variety of programs; the data were obtained by observing the occurrences in running programs rather than just the number of times that statements occur in the source code. Hence these metrics capture dynamic behavior. To obtain the data in columns four and five (machine-instruction weighted), each value in the second and third columns is multiplied by the number of machine instructions produced by the compiler. These results are then normalized so that columns four and five show the relative frequency of occurrence, weighted by the number of machine instructions per HLL statement. Similarly, the sixth and seventh columns are obtained by multiplying the frequency of occurrence of each statement type by the relative number of memory references caused by each statement. The data in columns four through seven provide surrogate measures of the actual time spent executing the various statement types. The results suggest that the procedure call/return is the most time-consuming operation in typical HLL programs.

Table 17.2 Weighted Relative Dynamic Frequency of HLL Operations [PATT82a]

	Dynamic Occurrence		Machine-Instruction Weighted		Memory-Reference Weighted	
	Pascal	C	Pascal	C	Pascal	C
ASSIGN	45%	38%	13%	13%	14%	15%
LOOP	5%	3%	42%	32%	33%	26%
CALL	15%	12%	31%	33%	44%	45%
IF	29%	43%	11%	21%	7%	13%
GOTO	—	3%	—	—	—	—
OTHER	6%	1%	3%	1%	2%	1%

The reader should be clear on the significance of **Table 17.2**. This table indicates the relative

performance impact of various statement types in an HLL, when that HLL is compiled for a typical contemporary instruction set architecture. Some other architecture could conceivably produce different results. However, this study produces results that are representative for contemporary **complex instruction set computer (CISC) architectures**. Thus, they can provide guidance to those looking for more efficient ways to support HLLs.

Operands

Much less work has been done on the occurrence of types of operands, despite the importance of this topic. There are several aspects that are significant.

The Patterson study already referenced [PATT82a] also looked at the dynamic frequency of occurrence of classes of variables (**Table 17.3**). The results, consistent between Pascal and C programs, show that most references are to simple scalar variables. Further, more than 80% of the scalars were local (to the procedure) variables. In addition, each reference to an array or a structure requires a reference to an index or pointer, which again is usually a local scalar. Thus, there is a preponderance of references to scalars, and these are highly localized.

Table 17.3 Dynamic Percentage of Operands

	Pascal	C	Average
Integer constant	16%	23%	20%
Scalar variable	58%	53%	55%
Array/Structure	26%	24%	25%

The Patterson study examined the dynamic behavior of HLL programs, independent of the underlying architecture. As discussed before, it is necessary to deal with actual architectures to examine program behavior more deeply. One study, [LUND77], examined DEC-10 instructions dynamically and found that each instruction on the average references 0.5 operand in memory and 1.4 registers. Similar results are reported in [HUCK83] for C, Pascal, and FORTRAN programs on S/370, PDP-11, and VAX. Of course, these figures depend highly on both the architecture and the compiler, but they do illustrate the frequency of operand accessing.

These latter studies suggest the importance of an architecture that lends itself to fast operand accessing, because this operation is performed so frequently. The Patterson study suggests that a prime candidate for optimization is the mechanism for storing and accessing local scalar variables.

Procedure Calls

We have seen that procedure calls and returns are an important aspect of HLL programs. The evidence (**Table 17.2**) suggests that these are the most time-consuming operations in compiled HLL programs. Thus, it will be profitable to consider ways of implementing these operations efficiently. Two aspects are significant: the number of parameters and variables that a procedure deals with, and the depth of nesting.

A study by Tanenbaum [TANE78] found that 98% of dynamically called procedures were passed fewer than six arguments and that 92% of them used fewer than six local scalar variables. Similar

results were reported by the Berkeley RISC team [KATE83], as shown in **Table 17.4**. These results show that the number of words required per procedure activation is not large. The studies reported earlier indicated that a high proportion of operand references is to local scalar variables. These studies show that those references are in fact confined to relatively few variables.

Table 17.4 Procedure Arguments and Local Scalar Variables

Percentage of Executed Procedure Calls With	Compiler, Interpreter, and Typesetter	Small Nonnumeric Programs
>3 arguments	0–7%	0–5%
>5 arguments	0–3%	0%
>8 words of arguments and local scalars	1–20%	0–6%
>12 words of arguments and local scalars	1–6%	0–3%

The same Berkeley group also looked at the pattern of procedure calls and returns in HLL programs. They found that it is rare to have a long uninterrupted sequence of procedure calls followed by the corresponding sequence of returns. Rather, they found that a program remains confined to a rather narrow window of procedure-invocation depth. These results reinforce the conclusion that operand references are highly localized.

Implications

A number of groups have looked at results such as those just reported and have concluded that the attempt to make the instruction set architecture close to HLLs is not the most effective design strategy. Rather, the HLLs can best be supported by optimizing performance of the most time-consuming features of typical HLL programs.

Generalizing from the work of a number of researchers, three elements emerge that, by and large, characterize RISC architectures. First, use a large number of registers or use a compiler to optimize register usage. This is intended to optimize operand referencing. The studies just discussed show that there are several references per HLL statement and that there is a high proportion of move (assignment) statements. This, coupled with the locality and predominance of scalar references, suggests that performance can be improved by reducing memory references at the expense of more register references. Because of the locality of these references, an expanded register set seems practical.

Second, careful attention needs to be paid to the design of instruction pipelines. Because of the high proportion of conditional branch and procedure call instructions, a straightforward instruction pipeline will be inefficient. This manifests itself as a high proportion of instructions that are prefetched but never executed.

Finally, an instruction set consisting of high-performance primitives is indicated. Instructions should

have predictable costs (measured in execution time, code size, and increasingly, in energy dissipation) and be consistent with a high-performance implementation (which harmonizes with predictable execution-time cost).

17.2 The Use of a Large Register File

The results summarized in [Section 17.1](#) point out the desirability of quick access to operands. We have seen that there is a large proportion of assignment statements in HLL programs, and many of these are of the simple form $A \leftarrow B$. Also, there are a significant number of operand accesses per HLL statement. If we couple these results with the fact that most accesses are to local scalars, heavy reliance on register storage is suggested.

The reason that register storage is indicated is that it is the fastest available storage device, faster than both main memory and cache. The register file is physically small, on the same chip as the ALU and control unit, and employs much shorter addresses than addresses for cache and memory. Thus, a strategy is needed that will allow the most frequently accessed operands to be kept in registers and minimize register-memory operations.

Two basic approaches are possible, one based on software and the other on hardware. The software approach is to rely on the compiler to maximize register usage. The compiler will attempt to assign registers to those variables that will be used the most in a given time period. This approach requires the use of sophisticated program-analysis algorithms. The hardware approach is simply to use more registers so that more variables can be held in registers for longer periods of time.

In this section, we will discuss the hardware approach. This approach has been pioneered by the Berkeley RISC group [PATT82a]; was used in the first commercial RISC product, the Pyramid [RAGA83]; and is currently used in the popular [SPARC](#) architecture.

Register Windows

On the face of it, the use of a large set of registers should decrease the need to access memory. The design task is to organize the registers in such a fashion that this goal is realized.

Because most operand references are to local scalars, the obvious approach is to store these in registers, with perhaps a few registers reserved for global variables. The problem is that the definition of *local* changes with each procedure call and return, operations that occur frequently. On every call, local variables must be saved from the registers into memory, so that the registers can be reused by the called procedure. Furthermore, parameters must be passed. On return, the variables of the calling procedure must be restored (loaded back into registers) and results must be passed back to the calling procedure.

The solution is based on two other results reported in [Section 17.1](#). First, a typical procedure employs only a few passed parameters and local variables ([Table 17.4](#)). Second, the depth of procedure activation fluctuates within a relatively narrow range. To exploit these properties, multiple small sets of registers are used, each assigned to a different procedure. A procedure call automatically switches the processor to use a different fixed-size window of registers, rather than saving registers in memory. Windows for adjacent procedures are overlapped to allow parameter passing.

The concept is illustrated in [Figure 17.1](#). At any time, only one window of registers is visible and is addressable as if it were the only set of registers (e.g., addresses 0 through $N - 1$). The window is divided into three fixed-size areas. Parameter registers hold parameters passed down from the procedure that called the current procedure and hold results to be passed back up. Local registers are used for local variables, as assigned by the compiler. Temporary registers are used to exchange parameters and results with the next lower level (procedure called by current procedure). The temporary registers at one level are physically the same as the parameter registers at the next lower

level. This overlap permits parameters to be passed without the actual movement of data. Keep in mind that, except for the overlap, the registers at two different levels are physically distinct. That is, the parameter and local registers at level J are disjoint from the local and temporary registers at level $J + 1$.

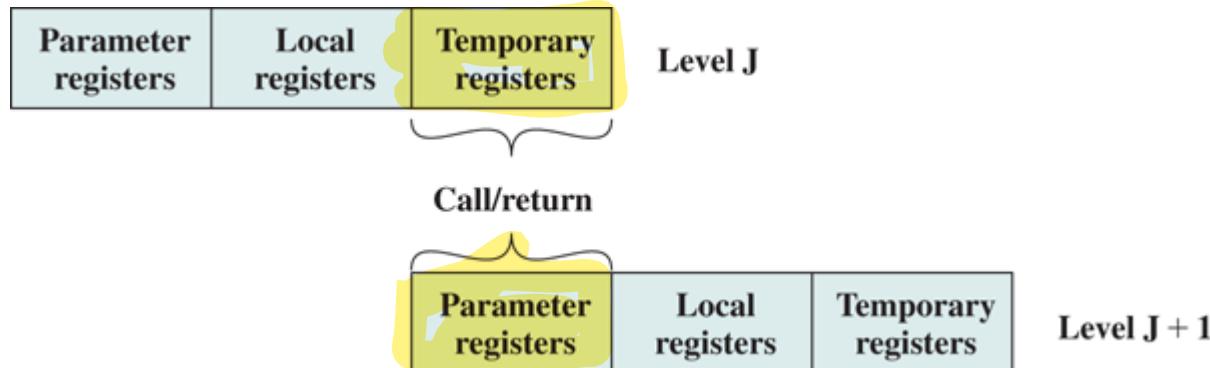

Figure 17.1 Overlapping Register Windows

To handle any possible pattern of calls and returns, the number of **register windows** would have to be unbounded. Instead, the register windows can be used to hold the few most recent procedure activations. Older activations must be saved in memory and later restored when the nesting depth decreases. Thus, the actual organization of the register file is as a circular buffer of overlapping windows. Two notable examples of this approach are Sun's SPARC architecture, described in [Section 17.7](#), and the IA-64 architecture used in Intel's Itanium processor.

The circular organization is shown in [Figure 17.2](#), which depicts a circular buffer of six windows. The buffer is filled to a depth of 4 (A called B; B called C; C called D) with procedure D active. The current-window pointer (CWP) points to the window of the currently active procedure. Register references by a machine instruction are offset by this pointer to determine the actual physical register. The saved-window pointer (SWP) identifies the window most recently saved in memory. If procedure D now calls procedure E, arguments for E are placed in D's temporary registers (the overlap between w3 and w4) and the CWP is advanced by one window.

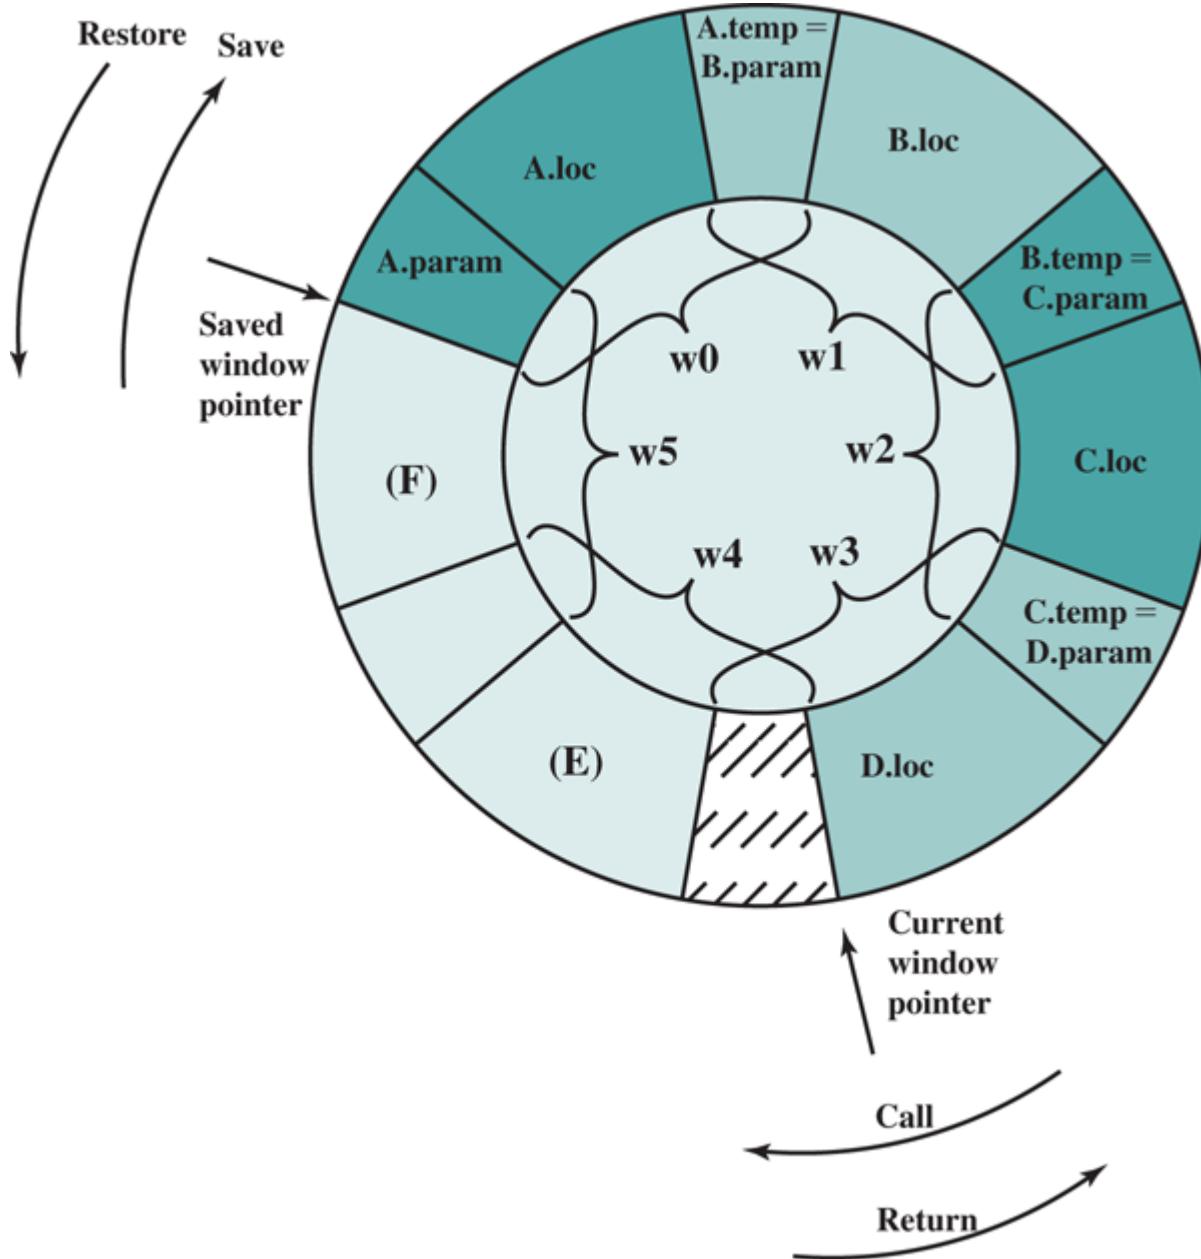

Figure 17.2 Circular-Buffer Organization of Overlapped Windows

If procedure E then makes a call to procedure F, the call cannot be made with the current status of the buffer. This is because F's window overlaps A's window. If F begins to load its temporary registers, preparatory to a call, it will overwrite the parameter registers of A (A.in). Thus, when CWP is incremented (modulo 6) so that it becomes equal to SWP, an interrupt occurs, and A's window is saved. Only the first two portions (A.in and A.loc) need be saved. Then, the SWP is incremented and the call to F proceeds. A similar interrupt can occur on returns. For example, subsequent to the activation of F, when B returns to A, CWP is decremented and becomes equal to SWP. This causes an interrupt that results in the restoration of A's window.

From the preceding, it can be seen that an N -window register file can hold only $N - 1$ procedure activations. The value of N need not be large. One study [TAMI83] found that, with 8 windows, a save or restore is needed on only 1% of the calls or returns. The Berkeley RISC computers use 8 windows of 16 registers each. The Pyramid computer employs 16 windows of 32 registers each.

Global Variables

The window scheme just described provides an efficient organization for storing local scalar variables

in registers. However, this scheme does not address the need to store global variables, those accessed by more than one procedure. Two options suggest themselves. First, variables declared as global in an HLL can be assigned memory locations by the compiler, and all machine instructions that reference these variables will use memory-reference operands. This is straightforward, from both the hardware and software (compiler) points of view. However, for frequently accessed global variables, this scheme is inefficient.

An alternative is to incorporate a set of global registers in the processor. These registers would be fixed in number and available to all procedures. A unified numbering scheme can be used to simplify the instruction format. For example, references to registers 0 through 7 could refer to unique global registers, and references to registers 8 through 31 could be offset to refer to physical registers in the current window. There is an increased hardware burden to accommodate the split in register addressing. In addition, the linker must decide which global variables should be assigned to registers.

Large Register File versus Cache

The register file, organized into windows, acts as a small, fast buffer for holding a subset of all variables that are likely to be used the most heavily. From this point of view, the register file acts much like a cache memory, although a much faster memory. The question therefore arises as to whether it would be simpler and better to use a cache and a small traditional register file.

Table 17.5 compares characteristics of the two approaches. The window-based register file holds all the local scalar variables (except in the rare case of window overflow) of the most recent $N - 1$ procedure activations. The cache holds a selection of recently used scalar variables. The register file should save time, because all local scalar variables are retained. On the other hand, the cache may make more efficient use of space, because it is reacting to the situation dynamically. Furthermore, caches generally treat all memory references alike, including instructions and other types of data. Thus, savings in these other areas are possible with a cache and not a register file.

Table 17.5 Characteristics of Large-Register-File and Cache Organizations

Large Register File	Cache
All local scalars	Recently-used local scalars
Individual variables	Blocks of memory
Compiler-assigned global variables	Recently-used global variables
Save/Restore based on procedure nesting depth	Save/Restore based on cache replacement algorithm
Register addressing	Memory addressing
Multiple operands addressed and accessed in one cycle	One operand addressed and accessed per cycle

A register file may make inefficient use of space, because not all procedures will need the full window

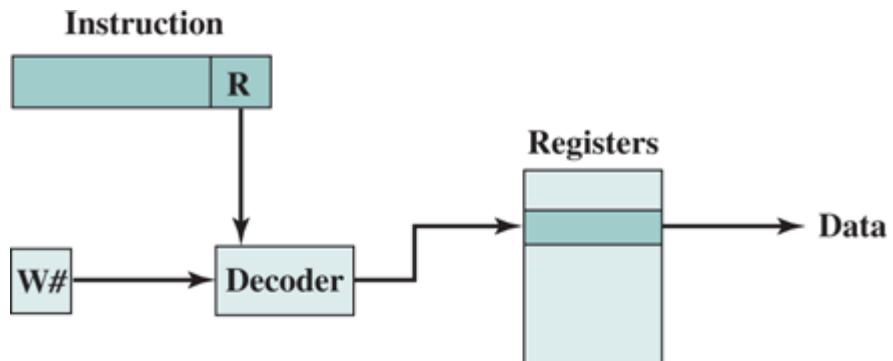

space allotted to them. On the other hand, the cache suffers from another sort of inefficiency: Data are read into the cache in blocks. Whereas the register file contains only those variables in use, the cache reads in a block of data, some or much of which will not be used.

The cache is capable of handling global as well as local variables. There are usually many global scalars, but only a few of them are heavily used [KATE83]. A cache will dynamically discover these variables and hold them. If the window-based register file is supplemented with global registers, it too can hold some global scalars. However, when program modules are separately compiled, it is impossible for the compiler to assign global values to registers; the linker must perform this task.

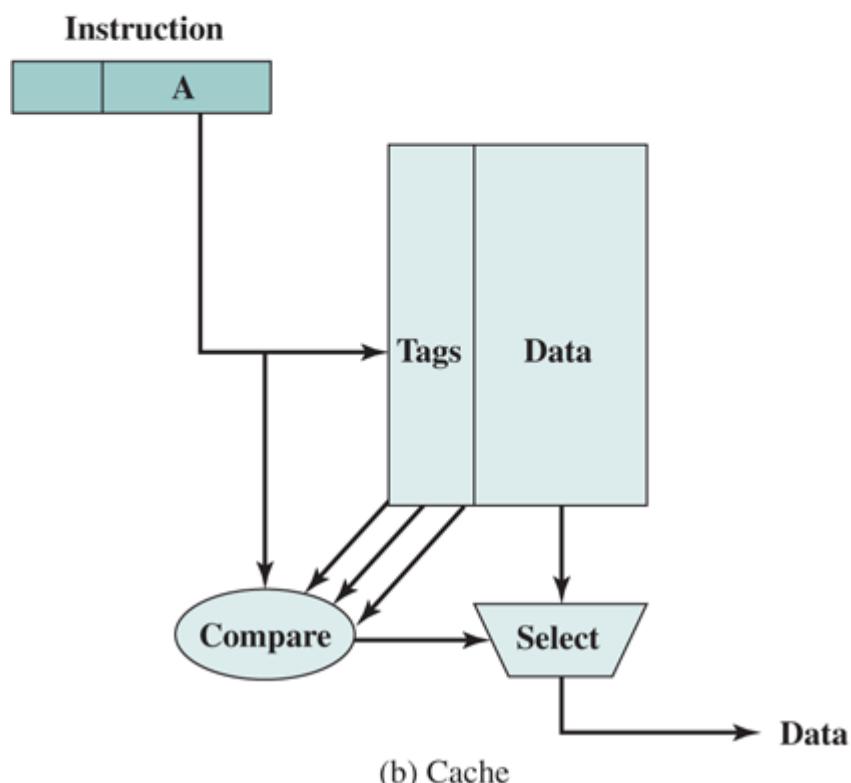

With the register file, the movement of data between registers and memory is determined by the procedure nesting depth. Because this depth usually fluctuates within a narrow range, the use of memory is relatively infrequent. Most cache memories are set associative with a small set size. Thus, there is the danger that other data or instructions will compete for cache residency.

Based on the discussion so far, the choice between a large window-based register file and a cache is not clear-cut. There is one characteristic, however, in which the register approach is clearly superior and which suggests that a cache-based system will be noticeably slower. This distinction shows up in the amount of addressing overhead experienced by the two approaches.

Figure 17.3 illustrates the difference. To reference a local scalar in a window-based register file, a “virtual” register number and a window number are used. These can pass through a relatively simple decoder to select one of the physical registers. To reference a memory location in cache, a full-width memory address must be generated. The complexity of this operation depends on the addressing mode. In a set associative cache, a portion of the address is used to read a number of words and tags equal to the set size. Another portion of the address is compared with the tags, and one of the words that were read is selected. It should be clear that even if the cache is as fast as the register file, the access time will be considerably longer. Thus, from the point of view of performance, the window-based register file is superior for local scalars. Further performance improvement could be achieved by the addition of a cache for instructions only.

(a) Window-based register file

(b) Cache

Figure 17.3 Referencing a Scalar

17.3 Compiler-Based Register Optimization

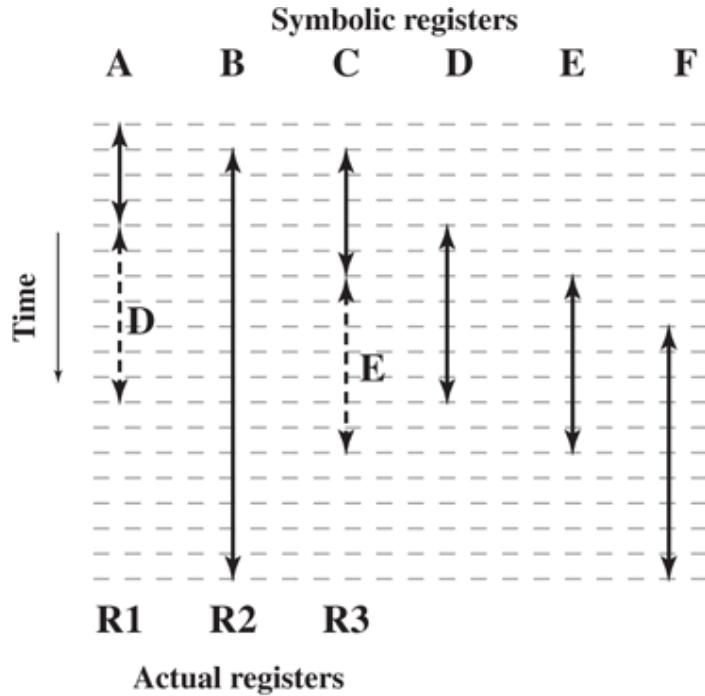

Let us assume now that only a small number (e.g., 16–32) of registers is available on the target RISC machine. In this case, optimized register usage is the responsibility of the compiler. A program written in a high-level language has, of course, no explicit references to registers (the C-language keyword `register` notwithstanding). Rather, program quantities are referred to symbolically. The objective of the compiler is to keep the operands for as many computations as possible in registers rather than main memory, and to minimize load-and-store operations.

In general, the approach taken is as follows. Each program quantity that is a candidate for residing in a register is assigned to a symbolic or virtual register. The compiler then maps the unlimited number of symbolic registers into a fixed number of real registers. Symbolic registers whose usage does not overlap can share the same real register. If, in a particular portion of the program, there are more quantities to deal with than real registers, then some of the quantities are assigned to memory locations. Load-and-store instructions are used to position quantities in registers temporarily for computational operations.

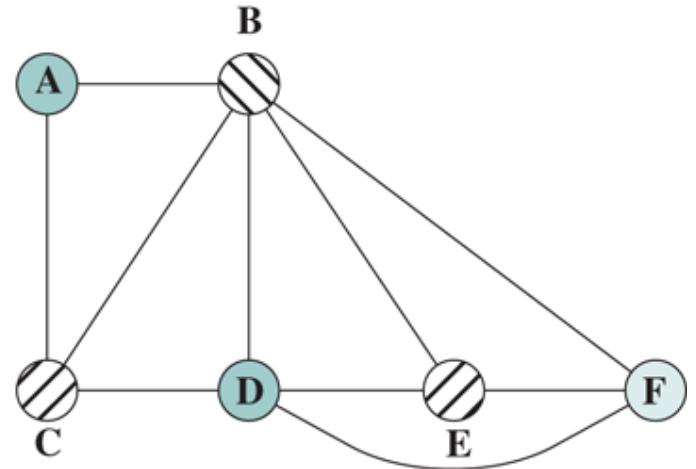

The essence of the optimization task is to decide which quantities are to be assigned to registers at any given point in the program. The technique most commonly used in RISC compilers is known as graph coloring, which is a technique borrowed from the discipline of topology [CHAI82, CHOW86, COUT86, CHOW90].

The graph coloring problem is this. Given a graph consisting of nodes and edges, assign colors to nodes such that adjacent nodes have different colors, and do this in such a way as to minimize the number of different colors. This problem is adapted to the compiler problem in the following way. First, the program is analyzed to build a register interference graph. The nodes of the graph are the symbolic registers. If two symbolic registers are “live” during the same program fragment, then they are joined by an edge to depict interference. An attempt is then made to color the graph with n colors, where n is the number of registers. Nodes that share the same color can be assigned to the same register. If this process does not fully succeed, then those nodes that cannot be colored must be placed in memory, and loads and stores must be used to make space for the affected quantities when they are needed.

Figure 17.4 is a simple example of the process. Assume a program with six symbolic registers to be compiled into three actual registers. **Figure 17.4a** shows the time sequence of active use of each symbolic register. The dashed horizontal lines indicate successive instruction executions. **Figure 17.4b** shows the register interference graph (shading and stripes are used instead of colors). A possible coloring with three colors is indicated. Because symbolic registers A and D do not interfere, the compiler can assign both of these to physical register R1. Similarly, symbolic registers C and E can be assigned to register R3. One symbolic register, F, is left uncolored and must be dealt with using loads and stores.

(a) Time sequence of active use of registers

(b) Register interference graph

Figure 17.4 Graph Coloring Approach

In general, there is a trade-off between the use of a large set of registers and compiler-based register optimization. For example, [BRAD91a] reports on a study that modeled a RISC architecture with features similar to the Motorola 88000 and the MIPS R2000. The researchers varied the number of registers from 16 to 128, and they considered both the use of all general-purpose registers and registers split between integer and floating-point use. Their study showed that with even simple register optimization, there is little benefit to the use of more than 64 registers. With reasonably sophisticated register optimization techniques, there is only marginal performance improvement with more than 32 registers. Finally, they noted that with a small number of registers (e.g., 16), a machine with a shared register organization executes faster than one with a split organization. Similar conclusions can be drawn from [HUGU91], which reports on a study that is primarily concerned with optimizing the use of a small number of registers rather than comparing the use of large register sets with optimization efforts.

17.4 Reduced Instruction Set Architecture

In this section, we look at some of the general characteristics of and the motivation for a reduced instruction set architecture. Specific examples will be seen later in this chapter. We begin with a discussion of motivations for contemporary complex instruction set architectures.

Why CISC

We have noted the trend to richer instruction sets, which include a larger number of instructions and more complex instructions. Two principal reasons have motivated this trend: a desire to simplify compilers and a desire to improve performance. Underlying both of these reasons was the shift to HLLs on the part of programmers; architects attempted to design machines that provided better support for HLLs.

It is not the intent of this chapter to say that the CISC designers took the wrong direction. Indeed, because technology continues to evolve and because architectures exist along a spectrum rather than in two neat categories, a black-and-white assessment is unlikely ever to emerge. Thus, the comments that follow are simply meant to point out some of the potential pitfalls in the CISC approach and to provide some understanding of the motivation of the RISC adherents.

The first of the reasons cited, compiler simplification, seems obvious, but it is not. The task of the compiler writer is to build a compiler that generates good (fast, small, fast and small) sequences of machine instructions for HLL programs (i.e., the compiler views individual HLL statements in the context of surrounding HLL statements). If there are machine instructions that resemble HLL statements, this task is simplified. This reasoning has been disputed by the RISC researchers ([HENN82], [RADI83], [PATT82b]). They have found that complex machine instructions are often hard to exploit because the compiler must find those cases that exactly fit the construct. The task of optimizing the generated code to minimize code size, reduce instruction execution count, and enhance pipelining is much more difficult with a complex instruction set. As evidence of this, studies cited earlier in this chapter indicate that most of the instructions in a compiled program are the relatively simple ones.

The other major reason cited is the expectation that a CISC will yield smaller, faster programs. Let us examine both aspects of this assertion: that programs will be smaller and that they will execute faster.

There are two advantages to smaller programs. Because the program takes up less memory, there is a savings in that resource. With memory today being so inexpensive, this potential advantage is no longer compelling. More importantly, smaller programs should improve performance, and this will happen in three ways. First, fewer instructions means fewer instruction bytes to be fetched. Second, in a paging environment, smaller programs occupy fewer pages, reducing page faults. Third, more instructions fit in cache(s).

The problem with this line of reasoning is that it is far from certain that a CISC program will be smaller than a corresponding RISC program. In many cases, the CISC program, expressed in symbolic machine language, may be *shorter* (i.e., fewer instructions), but the number of bits of memory occupied may not be noticeably *smaller*. **Table 17.6** shows results from three studies that compared the size of compiled C programs on a variety of machines, including RISC I, which has a reduced instruction set architecture. Note that there is little or no savings using a CISC over a RISC. It is also interesting to note that the VAX, which has a much more complex instruction set than the PDP-11, achieves very little savings over the latter. These results were confirmed by IBM researchers [RADI83], who found that the IBM 801 (a RISC) produced code that was 0.9 times the size of code on an IBM S/370. The study used a set of PL/I programs.

Table 17.6 Code Size Relative to RISC I

	[PATT82a] 11 C Programs	[KATE83] 12 C Programs	[HEAT84] 5 C Programs
RISC I	1.0	1.0	1.0
VAX-11/780	0.8	0.67	

M68000	0.9		0.9
Z8002	1.2		1.12
PDP-11/70	0.9	0.71	

There are several reasons for these rather surprising results. We have already noted that compilers on CISCs tend to favor simpler instructions, so that the conciseness of the complex instructions seldom comes into play. Also, because there are more instructions on a CISC, longer opcodes are required, producing longer instructions. Finally, RISCs tend to emphasize register rather than memory references, and the former require fewer bits. An example of this last effect is discussed presently.

So the expectation that a CISC will produce smaller programs, with the attendant advantages, may not be realized. The second motivating factor for increasingly complex instruction sets was that instruction execution would be faster. It seems to make sense that a complex HLL operation will execute more quickly as a single machine instruction rather than as a series of more primitive instructions. However, because of the bias toward the use of those simpler instructions, this may not be so. The entire control unit must be made more complex, and/or the microprogram control store must be made larger, to accommodate a richer instruction set. Either factor increases the execution time of the simple instructions.

In fact, some researchers have found that the speedup in the execution of complex functions is due not so much to the power of the complex machine instructions as to their residence in high-speed control store [RADI83]. In effect, the control store acts as an instruction cache. Thus, the hardware architect is in the position of trying to determine which subroutines or functions will be used most frequently and assigning those to the control store by implementing them in microcode. The results have been less than encouraging. On S/390 systems, instructions such as Translate and Extended-Precision-Floating-Point-Divide reside in high-speed storage, while the sequence involved in setting up procedure calls or initiating an interrupt handler are in slower main memory.

Thus, it is far from clear that a trend to increasingly complex instruction sets is appropriate. This has led a number of groups to pursue the opposite path.

Characteristics of Reduced Instruction Set Architectures

Although a variety of different approaches to reduced instruction set architecture have been taken, certain characteristics are common to all of them:

- One instruction per cycle
- Register-to-register operations
- Simple addressing modes
- Simple instruction formats

Here, we provide a brief discussion of these characteristics. Specific examples are explored later in this chapter.

The first characteristic listed is that there is **one machine instruction per machine cycle**. A *machine cycle* is defined to be the time it takes to fetch two operands from registers, perform an ALU operation, and store the result in a register. Thus, RISC machine instructions should be no more complicated than, and execute about as fast as, microinstructions on CISC machines (discussed in Part Four). With simple, one-cycle instructions, there is little or no need for microcode; the machine instructions can be hardwired. Such instructions should execute faster than comparable machine instructions on other machines, because it is not necessary to access a microprogram control store during instruction execution.

A second characteristic is that most operations should be **register to register**, with only simple LOAD and STORE operations accessing memory. This design feature simplifies the instruction set and therefore the control unit. For example, a RISC instruction set may include only one or two ADD instructions (e.g., integer add, add with carry); the VAX has 25 different ADD instructions. Another benefit is that such an architecture encourages the optimization of register use, so that frequently accessed operands remain in high-speed storage.

This emphasis on register-to-register operations is notable for RISC designs. Contemporary CISC machines provide such instructions, but also include memory-to-memory and mixed register/memory operations. Attempts to compare these approaches were made in the 1970s, before the appearance of RISCs. [Figure 17.5a](#) illustrates the approach taken. Hypothetical architectures were evaluated on program size and the number of bits of memory traffic. Results such as this one led one researcher to suggest that future architectures should contain no registers at all [MYER78]. One wonders what he would have thought, at the time, of the RISC machine once produced by Pyramid, which contained no less than 528 registers!

8	16	16	16		8	4	16

Register to memory
 $I = 60, D = 0, M = 60$

(b) $A \leftarrow B + C; B \leftarrow A + C; D \leftarrow D - B$

I = number of bytes occupied by executed instructions
D = number of bytes occupied by data
M = total memory traffic = $I + D$

Figure 17.5 Two Comparisons of Register-to-Register and Memory-to-Memory Approaches

What was missing from those studies was a recognition of the frequent access to a small number of local scalars and that, with a large bank of registers or an optimizing compiler, most operands could be kept in registers for long periods of time. Thus, [Figure 17.5b](#) may be a fairer comparison.

A third characteristic is the use of **simple addressing modes**. Almost all RISC instructions use simple register addressing. Several additional modes, such as displacement and PC-relative, may be included. Other, more complex modes can be synthesized in software from the simple ones. Again, this design feature simplifies the instruction set and the control unit.

A final common characteristic is the use of **simple instruction formats**. Generally, only one or a few formats are used. Instruction length is fixed and aligned on word boundaries. Field locations, especially the opcode, are fixed. This design feature has a number of benefits. With fixed fields, opcode decoding and register operand accessing can occur simultaneously. Simplified formats simplify the control unit. Instruction fetching is optimized because word-length units are fetched. Alignment on a word boundary also means that a single instruction does not cross page boundaries.

Taken together, these characteristics can be assessed to determine the potential performance benefits of the RISC approach. A certain amount of “circumstantial evidence” can be presented. First, more effective optimizing compilers can be developed. With more-primitive instructions, there are more opportunities for moving functions out of loops, reorganizing code for efficiency, maximizing register utilization, and so forth. It is even possible to compute parts of complex instructions at compile time. For example, the S/390

Move Characters (MVC) instruction moves a string of characters from one location to another. Each time it is executed, the move will depend on the length of the string, whether and in which direction the locations overlap, and what the alignment characteristics are. In most cases, these will all be known at compile time. Thus, the compiler could produce an optimized sequence of primitive instructions for this function.

A second point, already noted, is that most instructions generated by a compiler are relatively simple anyway. It would seem reasonable that a control unit built specifically for those instructions and using little or no microcode could execute them faster than a comparable CISC.

A third point relates to the use of instruction pipelining. RISC researchers feel that the instruction pipelining technique can be applied much more effectively with a reduced instruction set. We examine this point in some detail presently.

A final, and somewhat less significant, point is that RISC processors are more responsive to interrupts because interrupts are checked between rather elementary operations. Architectures with complex instructions either restrict interrupts to instruction boundaries or must define specific interruptible points and implement mechanisms for restarting an instruction.

The case for improved performance for a reduced instruction set architecture is strong, but one could perhaps still make an argument for CISC. A number of studies have been done, but not on machines of comparable technology and power. Further, most studies have not attempted to separate the effects of a reduced instruction set and the effects of a large register file. The “circumstantial evidence,” however, is suggestive.

CISC versus RISC Characteristics

After the initial enthusiasm for RISC machines, there has been a growing realization that (1) RISC designs may benefit from the inclusion of some CISC features and that (2) CISC designs may benefit from the inclusion of some RISC features. The result is that the more recent RISC designs, notably the PowerPC, are no longer “pure” RISC and the more recent CISC designs, notably the Pentium II and later Pentium models, do incorporate some RISC characteristics.

An interesting comparison in [MASH95] provides some insight into this issue. **Table 17.7** lists a number of processors and compares them across a number of characteristics. For purposes of this comparison, the following are considered typical of a classic RISC:

1. A single instruction size.
2. That size is typically 4 bytes.
3. A small number of data addressing modes, typically less than five. This parameter is difficult to pin down. In the table, register and literal modes are not counted and different formats with different offset sizes are counted separately.
4. No indirect addressing that requires you to make one memory access to get the address of another operand in memory.
5. No operations that combine load/store with arithmetic (e.g., add from memory, add to memory).
6. No more than one memory-addressed operand per instruction.
7. Does not support arbitrary alignment of data for load/store operations.
8. Maximum number of uses of the memory management unit (MMU) for a data address in an instruction.
9. Number of bits for integer register specifier equal to five or more. This means that at least 32 integer registers can be explicitly referenced at a time.
10. Number of bits for floating-point register specifier equal to four or more. This means that at least 16 floating-point registers can be explicitly referenced at a time.

Table 17.7 Characteristics of Some Processors

Notes:

^a RISC that does not conform to this characteristic.

^b CISC that does not conform to this characteristic.

Processor	Number of	Max instruction	Number of addressing	Indirect addressing	Load/store combined	Max number	Unaligned addressing	Max number	Number of bits	Number of bits

Items 1 through 3 are an indication of instruction decode complexity. Items 4 through 8 suggest the ease or difficulty of pipelining, especially in the presence of virtual memory requirements. Items 9 and 10 are related to the ability to take good advantage of compilers.

In the table, the first eight processors are clearly RISC architectures, the next five are clearly CISC, and the last two are processors often thought of as RISC that in fact have many CISC characteristics.

17.5 Risc Pipelining

Pipelining with Regular Instructions

As we discussed in **Section 16.4**, instruction pipelining is often used to enhance performance. Let us reconsider this in the context of a RISC architecture. Most instructions are register to register, and an instruction cycle has the following two stages:

- I: Instruction fetch.
- E: Execute. Performs an ALU operation with register input and output.

For load and store operations, three stages are required:

- I: Instruction fetch.
- E: Execute. Calculates memory address.
- D: Memory. Register-to-memory or memory-to-register operation.

Figure 17.6a depicts the timing of a sequence of instructions using no pipelining. Clearly, this is a wasteful process. Even very simple pipelining can substantially improve performance. **Figure 17.6b** shows a two-stage pipelining scheme, in which the I and E stages of two different instructions are performed simultaneously. The two stages of the pipeline are an instruction fetch stage, and an execute/memory stage that executes the instruction, including register-to-memory and memory-to-register operations. Thus we see that the instruction fetch stage of the second instruction can be performed in parallel with the first part of the execute/memory stage. However, the execute/memory stage of the second instruction must be delayed until the first instruction clears the second stage of the pipeline. This scheme can yield up to twice the execution rate of a serial scheme. Two problems prevent the maximum speedup from being achieved. First, we assume that a single-port memory is used and that only one memory access is possible per stage. This requires the insertion of a wait state in some instructions. Second, a branch instruction interrupts the sequential flow of execution. To accommodate this with minimum circuitry, a NOOP instruction can be inserted into the instruction stream by the compiler or assembler.

Load rA \leftarrow M

(d) Four-stage pipelined timing

Figure 17.6 The Effects of Pipelining

Single
Memory
Access so
need to delay

Pipelining can be improved further by permitting two memory accesses per stage. This yields the sequence shown in **Figure 17.6c**. Now, up to three instructions can be overlapped, and the improvement is as much as a factor of 3. Again, branch instructions cause the speedup to fall short of the maximum possible. Also, note that data dependencies have an effect. If an instruction needs an operand that is altered by the preceding instruction, a delay is required. Again, this can be accomplished by a NOOP.

The pipelining discussed so far works best if the three stages are of approximately equal duration. Because the E stage usually involves an ALU operation, it may be longer. In this case, we can divide into two substages:

- E_1 : Register file read
- E_2 : ALU operation and register write

Because of the simplicity and regularity of a RISC instruction set, the design of the phasing into three or four stages is easily accomplished. **Figure 17.6d** shows the result with a four-stage pipeline. Up to four instructions at a time can be under way, and the maximum potential speedup is a factor of 4. Note again the use of NOOPs to account for data and branch delays.

Optimization of Pipelining

Because of the simple and regular nature of RISC instructions, it is easier for a hardware designer to implement a simple, fast pipeline. There are few variations in instruction execution duration, and the pipeline can be tailored to reflect this. However, we have seen that data and branch dependencies reduce the overall execution rate.

DELAYED BRANCH

To compensate for these dependencies, code reorganization techniques have been developed. First, let us consider branching instructions. **Delayed branch**, a way of increasing the efficiency of the pipeline, makes use of a branch that does not take effect until after execution of the following instruction (hence the term *delayed*). The instruction location immediately following the branch is referred to as the *delay slot*. This strange procedure is illustrated in **Table 17.8**. In the column labeled “normal branch,” we see a normal symbolic instruction machine-language program. After 102 is executed, the next instruction to be executed is 105. To regularize the pipeline, a NOOP is inserted after this branch. However, increased performance is achieved if the instructions at 101 and 102 are interchanged.

Table 17.8 Normal and Delayed Branch

Address	Normal Branch		Delayed Branch		Optimized Delayed Branch	
100	LOAD	X, rA	LOAD	X, rA	LOAD	X, rA
101	ADD	1, rA	ADD	1, rA	JUMP	105
102	JUMP	105	JUMP	106	ADD	1, rA
103	ADD	rA, rB	NOOP		ADD	rA, rB

104	SUB	rC, rB	ADD	rA, rB	SUB	rC, rB
105	STORE	rA, Z	SUB	rC, rB	STORE	rA, Z
106			STORE	rA, Z		

Figure 17.7 shows the result. **Figure 17.7a** shows the traditional approach to pipelining, of the type discussed in **Chapter 16** (e.g., see **Figures 16.11** and **16.12**). The JUMP instruction is fetched at time 4. At time 5, the JUMP instruction is executed at the same time that instruction 103 (ADD instruction) is fetched. Because a JUMP occurs, which updates the program counter, the pipeline must be cleared of instruction 103; at time 6, instruction 105, which is the target of the JUMP, is loaded. **Figure 17.7b** shows the same pipeline handled by a typical RISC organization. The timing is the same. However, because of the insertion of the NOOP instruction, we do not need special circuitry to clear the pipeline; the NOOP simply executes with no effect. **Figure 17.7c** shows the use of the delayed branch. The JUMP instruction is fetched at time 2, before the ADD instruction, which is fetched at time 3. Note, however, that the ADD instruction is fetched before the execution of the JUMP instruction has a chance to alter the program counter. Therefore, during time 4, the ADD instruction is executed at the same time that instruction 105 is fetched. Thus, the original semantics of the program are retained but two fewer clock cycles are required for execution.

	Time →							
	1	2	3	4	5	6	7	8
100 LOAD X, rA	I	E	D					
101 ADD 1, rA		I		E				
102 JUMP 105				I	E			
103 ADD rA, rB					I	E		
105 STORE rA, Z						I	E	D

(a) Traditional pipeline

	1	2	3	4	5	6	7	8
100 LOAD X, rA	I	E	D					
101 ADD 1, rA		I		E				
102 JUMP 106				I	E			
103 NOOP					I	E		
106 STORE rA, Z						I	E	D

(b) RISC pipeline with inserted NOOP

	1	2	3	4	5	6
100 LOAD X, Ar	I	E	D			
101 JUMP 105		I	E			
102 ADD 1, rA			I	E		
105 STORE rA, Z				I	E	D

(c) Reversed instructions

Figure 17.7 Use of the Delayed Branch

This interchange of instructions will work successfully for unconditional branches, calls, and returns. For conditional branches, this procedure cannot be blindly applied. If the condition that is tested for the branch can be altered by the immediately preceding instruction, then the compiler must refrain from doing the interchange and instead insert a NOOP. Otherwise, the compiler can seek to insert a useful instruction after the branch. The experience with both the Berkeley RISC and IBM 801 systems is that the majority of conditional branch instructions can be optimized in this fashion ([PATT82a], [RAD183]).

DELAYED LOAD

A similar sort of tactic, called the **delayed load**, can be used on LOAD instructions. On LOAD instructions, the register that is to be the target of the load is locked by the processor. The processor then continues execution of the instruction stream until it reaches an instruction requiring that register, at which point it idles until the load is complete. If the compiler can rearrange instructions so that useful work can be done while the load is in the pipeline, efficiency is increased.

Aleksandr Lukin/123RF

Loop Unrolling Simulator

LOOP UNROLLING

Another compiler technique to improve instruction parallelism is loop unrolling [BACO94]. Unrolling replicates the body of a loop some number of times called the unrolling factor (u) and iterates by step u instead of step 1.

Unrolling can improve the performance by

- reducing loop overhead
- increasing instruction parallelism by improving pipeline performance
- improving register, data cache, or TLB locality

Figure 17.8 illustrates all three of these improvements in an example. Loop overhead is cut in half because two iterations are performed before the test and branch at the end of the loop. Instruction parallelism is increased because the second assignment can be performed while the results of the first are being stored and the loop variables are being updated. If array elements are assigned to registers, register locality will improve because $a[i]$ and $a[i + 1]$ are used twice in the loop body, reducing the number of loads per iteration from three to two.

```
do i=2, n-1
    a[i] = a[i] + a[i-1] * a[i+1]
end do
```

(a) Original loop

```
do i=2, n-2, 2
    a[i] = a[i] + a[i-1] * a[i+1]
    a[i+1] = a[i+1] + a[i] * a[i+2]
end do

if (mod(n-2, 2) = i) then
    a[n-1] = a[n-1] + a[n-2] * a[n]
end if
```

(b) Loop unrolled twice

Figure 17.8 Loop Unrolling

As a final note, we should point out that the design of the instruction pipeline should not be carried out in isolation from other optimization techniques applied to the system. For example, [BRAD91b] shows that the scheduling of instructions for the pipeline and the dynamic allocation of registers should be considered together to achieve the greatest efficiency.

17.6 MIPS R4000

One of the first commercially available RISC chip sets was developed by MIPS Technology Inc. The system was inspired by an experimental system, also using the name MIPS, developed at Stanford [HENN84]. In this section we look at the MIPS R4000. It has substantially the same architecture and instruction set of the earlier MIPS designs: the R2000 and R3000. The most significant difference is that the R4000 uses 64 rather than 32 bits for all internal and external data paths and for addresses, registers, and the ALU.

The use of 64 bits has a number of advantages over a 32-bit architecture. It allows a bigger address space—large enough for an operating system to map more than a terabyte of files directly into virtual memory for easy access. With 1-terabyte and larger disk drives now common, the 4-gigabyte address space of a 32-bit machine becomes limiting. Also, the 64-bit capacity allows the R4000 to process data such as IEEE double-precision floating-point numbers and character strings, up to eight characters in a single action.

The R4000 processor chip is partitioned into two sections, one containing the CPU and the other containing a coprocessor for memory management. The processor has a very simple architecture. The intent was to design a system in which the instruction execution logic was as simple as possible, leaving space available for logic to enhance performance (e.g., the entire memory-management unit).

The processor supports thirty-two 64-bit registers. It also provides for up to 128 Kbytes of high-speed cache, half each for instructions and data. The relatively large cache (the IBM 3090 provides 128 to 256 Kbytes of cache) enables the system to keep large sets of program code and data local to the processor, off-loading the main memory bus and avoiding the need for a large register file with the accompanying windowing logic.

Instruction Set

All MIPS R series instructions are encoded in a single 32-bit word format. All data operations are register to register; the only memory references are pure load/store operations.

The R4000 makes no use of condition codes. If an instruction generates a condition, the corresponding flags are stored in a general-purpose register. This avoids the need for special logic to deal with condition codes, as they affect the pipelining mechanism and the reordering of instructions by the compiler. Instead, the mechanisms already implemented to deal with register-value dependencies are employed. Further, conditions mapped onto the register files are subject to the same compile-time optimizations in allocation and reuse as other values stored in registers.

As with most RISC-based machines, the MIPS uses a single 32-bit instruction length. This single instruction length simplifies instruction fetch and decode, and it also simplifies the interaction of instruction fetch with the virtual memory management unit (i.e., instructions do not cross word or page boundaries). The three instruction formats ([Figure 17.9](#)) share common formatting of opcodes and register references, simplifying instruction decode. The effect of more complex instructions can be synthesized at compile time.

Operation	Operation code
rs	Source register specifier
rt	Source/destination register specifier
Immediate	Immediate, branch, or address displacement
Target	Jump target address
rd	Destination register specifier
Shift	Shift amount
Function	ALU/shift function specifier

Figure 17.9 MIPS Instruction Formats

Only the simplest and most frequently used memory-addressing mode is implemented in hardware. All memory references consist of a 16-bit offset from a 32-bit register. For example, the “load word” instruction is of the form

<pre>lw r2, 128(r3)</pre>	<pre>/* load word at address 128 offset from register 3 into register 2</pre>
---------------------------	---

Each of the 32 general-purpose registers can be used as the base register. One register, r0, always contains 0.

The compiler makes use of multiple machine instructions to synthesize typical addressing modes in conventional machines. Here is an example from [CHOW87], which uses the instruction lui (load upper immediate). This instruction loads the upper half of a register with a 16-bit immediate value, setting the lower half to zero. Consider an assembly-language instruction that uses a 32-bit immediate argument

<pre>lw r2, #imm(r4)</pre>	<pre>/* load word at address using a 32-bit immediate offset #imm</pre> <pre>/* offset from register 4 into register 2</pre>
----------------------------	---

This instruction can be compiled into the following MIPS instructions

--	--

<code>lui r1, #imm-hi</code>	/* where #imm-hi is the high-order 16 bits of #imm
<code>addu r1, r1, r4</code>	/* add unsigned #imm-hi to r4 and put in r1
<code>lw r2, #imm-lo(r1)</code>	/* where #imm-lo is the low-order 16 bits of #imm

Instruction Pipeline

With its simplified instruction architecture, the MIPS can achieve very efficient pipelining. It is instructive to look at the evolution of the MIPS pipeline, as it illustrates the evolution of RISC pipelining in general.

The initial experimental RISC systems and the first generation of commercial RISC processors achieve execution speeds that approach one instruction per system clock cycle. To improve on this performance, two classes of processors have evolved to offer execution of multiple instructions per clock cycle: superscalar and superpipelined architectures. In essence, a superscalar architecture replicates each of the pipeline stages so that two or more instructions at the same stage of the pipeline can be processed simultaneously. A superpipelined architecture is one that makes use of more, and more fine-grained, pipeline stages. With more stages, more instructions can be in the pipeline at the same time, increasing parallelism.

Both approaches have limitations. With superscalar pipelining, dependencies between instructions in different pipelines can slow down the system. Also, over-head logic is required to coordinate these dependencies. With superpipelining, there is overhead associated with transferring instructions from one stage to the next.

[Chapter 18](#) is devoted to a study of superscalar architecture. The MIPS R4000 is a good example of a RISC-based superpipeline architecture.

Aleksandr Lukin/123RF

MIPS R3000 Five-Stage Pipeline Simulator

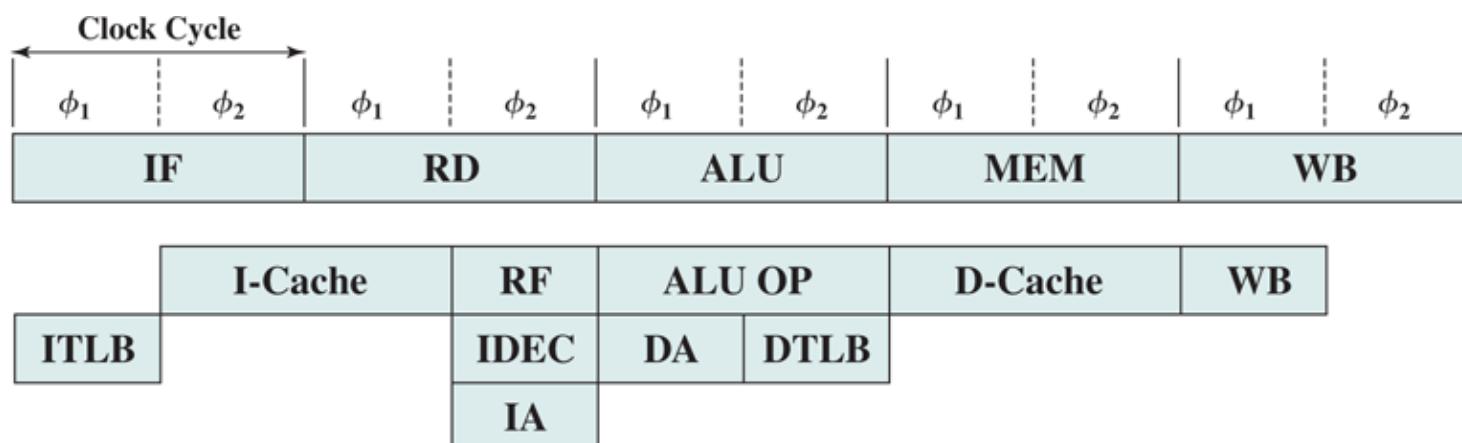

[Figure 17.10a](#) shows the instruction pipeline of the R3000. In the R3000, the pipeline advances once per clock cycle. The MIPS compiler is able to reorder instructions to fill delay slots with code 70 to 90% of the time. All instructions follow the same sequence of five pipeline stages:

-

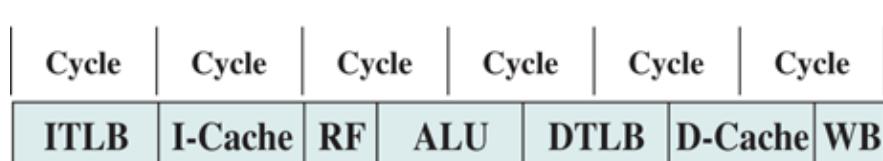

Instruction fetch;

- Source operand fetch from register file;
- ALU operation or data operand address generation;
- Data memory reference;
- Write back into register file.

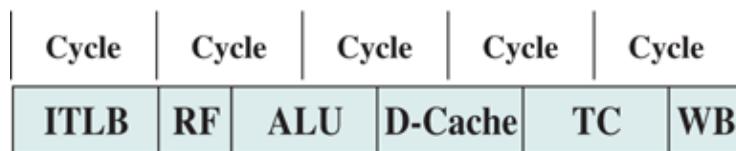

As illustrated in **Figure 17.10a**, there is not only parallelism due to pipelining, but also parallelism within the execution of a single instruction. The 60-ns clock cycle is divided into two 30-ns stages. The external instruction and data access operations to the cache each require 60 ns, as do the major internal operations (OP, DA, IA). Instruction decode is a simpler operation, requiring only a single 30-ns stage, overlapped with register fetch in the same instruction. Calculation of an address for a branch instruction also overlaps instruction decode and register fetch, so that a branch at instruction i can address the ICACHE access of instruction $i + 2$. Similarly, a load at instruction i fetches data that are immediately used by the OP of instruction $i + 1$, while an ALU/shift result gets passed directly into instruction $i + 1$ with no delay. This tight coupling between instructions makes for a highly efficient pipeline.

I-Cache	= Instruction cache access
RF	= Fetch operand from register
D-Cache	= Data cache access
ITLB	= Instruction address translation
IDECA	= Instruction decode
IA	= Compute instruction address
DA	= Calculate data virtual address
DTLB	= Data address translation
TC	= Data cache tag check

Figure 17.10 Enhancing the R3000 Pipeline

In detail, then, each clock cycle is divided into separate stages, denoted as ϕ_1 and ϕ_2 . The functions performed in each stage are summarized in **Table 17.9**.

Table 17.9 R3000 Pipeline Stages

Pipeline	Phase	Function

Stage		
IF	$\phi 1$	Using the TLB, translate an instruction virtual address to a physical address (after a branching decision).
IF	$\phi 2$	Send the physical address to the instruction address.
RD	$\phi 1$	Return instruction from instruction cache.
		Compare tags and validity of fetched instruction.
RD	$\phi 2$	Decode instruction.
		Read register file.
		If branch, calculate branch target address.
ALU	$\phi 1 + \phi 2$	If register-to-register operation, the arithmetic or logical operation is performed.
ALU	$\phi 1$	If a branch, decide whether the branch is to be taken or not.
		If a memory reference (load or store), calculate data virtual address.
ALU	$\phi 2$	If a memory reference, translate data virtual address to physical using TLB.
MEM	$\phi 1$	If a memory reference, send physical address to data cache.
MEM	$\phi 2$	If a memory reference, return data from data cache, and check tags.
WB	$\phi 1$	Write to register file.

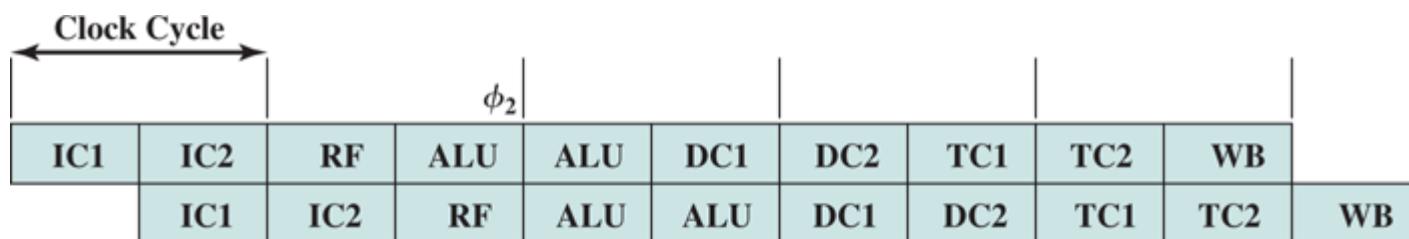

The R4000 incorporates a number of technical advances over the R3000. The use of more advanced technology allows the clock cycle time to be cut in half, to 30 ns, and for the access time to the register file to be cut in half. In addition, there is greater density on the chip, which enables the instruction and data caches to be incorporated on the chip. Before looking at the final R4000 pipeline, let us consider how the R3000 pipeline can be modified to improve performance using R4000 technology.

[Figure 17.10b](#) shows a first step. Remember that the cycles in this figure are half as long as those in [Figure 17.10a](#). Because they are on the same chip, the instruction and data cache stages take only half as long; so they still occupy only one clock cycle. Again, because of the speedup of the register file access, register read and write still occupy only half of a clock cycle.

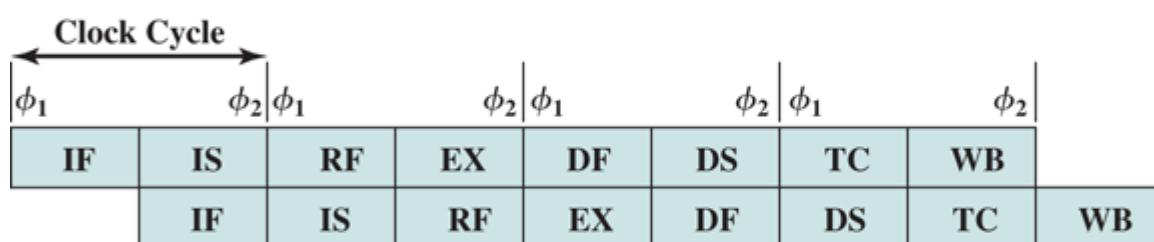

Because the R4000 caches are on-chip, the virtual-to-physical address translation can delay the cache access. This delay is reduced by implementing virtually indexed caches and going to a parallel cache access and address translation. [Figure 17.10c](#) shows the optimized R3000 pipeline with this

improvement. Because of the compression of events, the data cache tag check is performed separately on the next cycle after cache access. This check determines whether the data item is in the cache.

In a superpipelined system, existing hardware is used several times per cycle by inserting pipeline registers to split up each pipe stage. Essentially, each superpipeline stage operates at a multiple of the base clock frequency, the multiple depending on the degree of superpipelining. The R4000 technology has the speed and density to permit superpipelining of degree 2. [Figure 17.11a](#) shows the optimized R3000 pipeline using this superpipelining. Note that this is essentially the same dynamic structure as [Figure 17.10c](#).

(a) Superpipelined implementation of the optimized R3000 pipeline

(b) R4000 pipeline

IF = Instruction fetch first half	DC = Data cache
IS = Instruction fetch second half	DF = Data cache first half
RF = Fetch operands from register	DS = Data cache second half
EX = Instruction execute	TC = Tag check
IC = Instruction cache	WB = Write back to register file

Figure 17.11 Theoretical R3000 and Actual R4000 Superpipelines

Further improvements can be made. For the R4000, a much larger and specialized adder was designed. This makes it possible to execute ALU operations at twice the rate. Other improvements allow the execution of loads and stores at twice the rate. The resulting pipeline is shown in [Figure 17.11b](#).

The R4000 has eight pipeline stages, meaning that as many as eight instructions can be in the pipeline at the same time. The pipeline advances at the rate of two stages per clock cycle. The eight pipeline stages are as follows:

- **Instruction fetch first half:** Virtual address is presented to the instruction cache and the translation lookaside buffer.
- **Instruction fetch second half:** Instruction cache outputs the instruction and the TLB generates the physical address.
- **Register file:** Three activities occur in parallel:
 - Instruction is decoded and check made for interlock conditions (i.e., this instruction depends on

the result of a preceding instruction).

—Instruction cache tag check is made.

—Operands are fetched from the register file.

- **Instruction execute:** One of three activities can occur:

—If the instruction is a register-to-register operation, the ALU performs the arithmetic or logical operation.

—If the instruction is a load or store, the data virtual address is calculated.

—If the instruction is a branch, the branch target virtual address is calculated and branch conditions are checked.

- **Data cache first:** Virtual address is presented to the data cache and TLB.
- **Data cache second:** The TLB generates the physical address, and the data cache outputs the data.
- **Tag check:** Cache tag checks are performed for loads and stores.
- **Write back:** Instruction result is written back to register file.

17.7 SPARC

SPARC (Scalable Processor Architecture) refers to an architecture defined by Sun Microsystems. Sun developed its own SPARC implementation but also licenses the architecture to other vendors to produce SPARC-compatible machines. The SPARC architecture is inspired by the Berkeley RISC I machine, and its instruction set and register organization is based closely on the Berkeley RISC model.

SPARC Register Set

As with the Berkeley RISC, the SPARC makes use of register windows. Each window gives addressability to 24 registers, and the total number of windows is implementation dependent and ranges from 2 to 32 windows. [Figure 17.12](#) illustrates an implementation that supports 8 windows, using a total of 136 physical registers; as the discussion in [Section 17.2](#) indicates, this seems a reasonable number of windows. Physical registers 0 through 7 are global registers shared by all procedures. Each procedure sees logical registers 0 through 31. Logical registers 24 through 31, referred to as *ins*, are shared with the calling (parent) procedure; and logical registers 8 through 15, referred to as *outs*, are shared with any called (child) procedure. These two portions overlap with other windows. Logical registers 16 through 23, referred to as *locals*, are not shared and do not overlap with other windows. Again, as the discussion of [Section 16.1](#) indicates, the availability of 8 registers for parameter passing should be adequate in most cases (e.g., see [Table 17.4](#)).

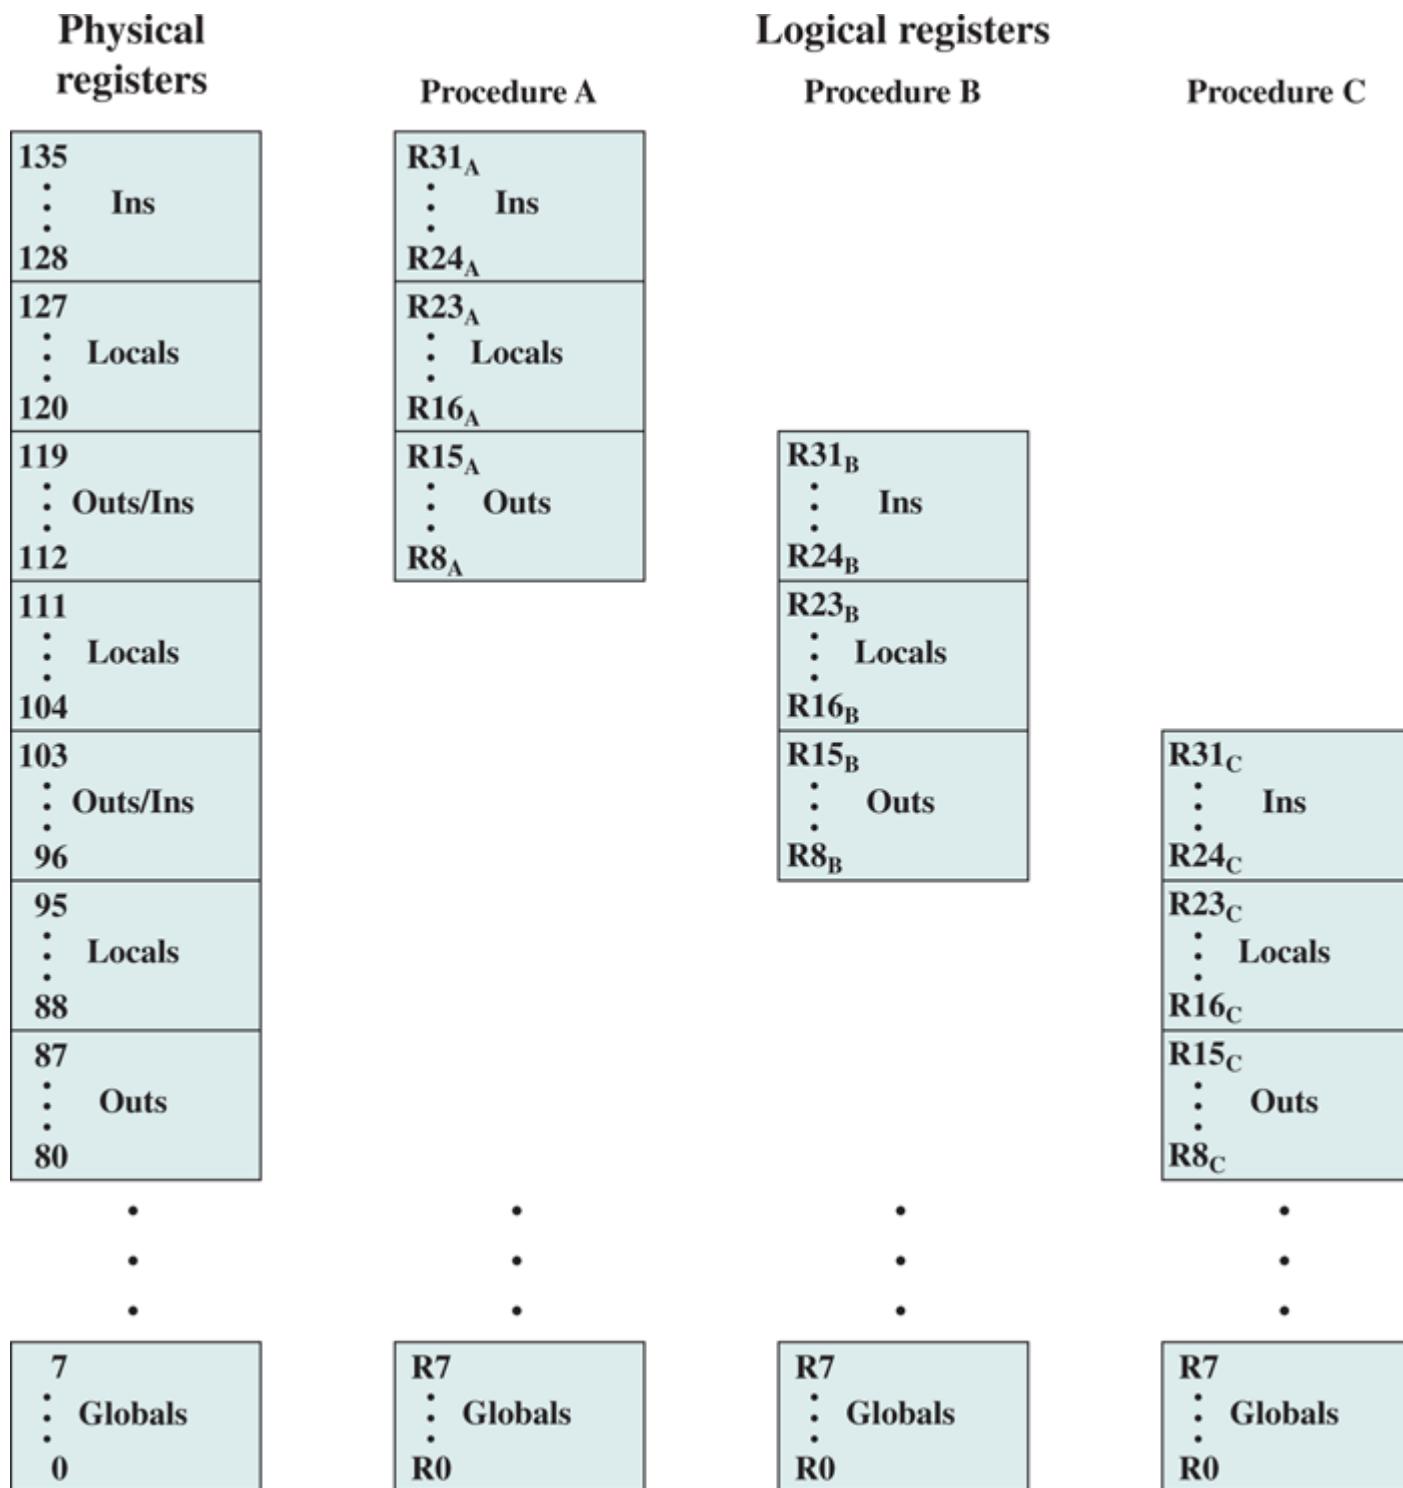

Figure 17.12 SPARC Register Window Layout with Three Procedures

Figure 17.13 is another view of the register overlap. The calling procedure places any parameters to be passed in its *outs* registers; the called procedure treats these same physical registers as its *ins* registers. The processor maintains a current window pointer (CWP), located in the processor status register (PSR), that points to the window of the currently executing procedure. The window invalid mask (WIM), also in the PSR, indicates which windows are invalid.

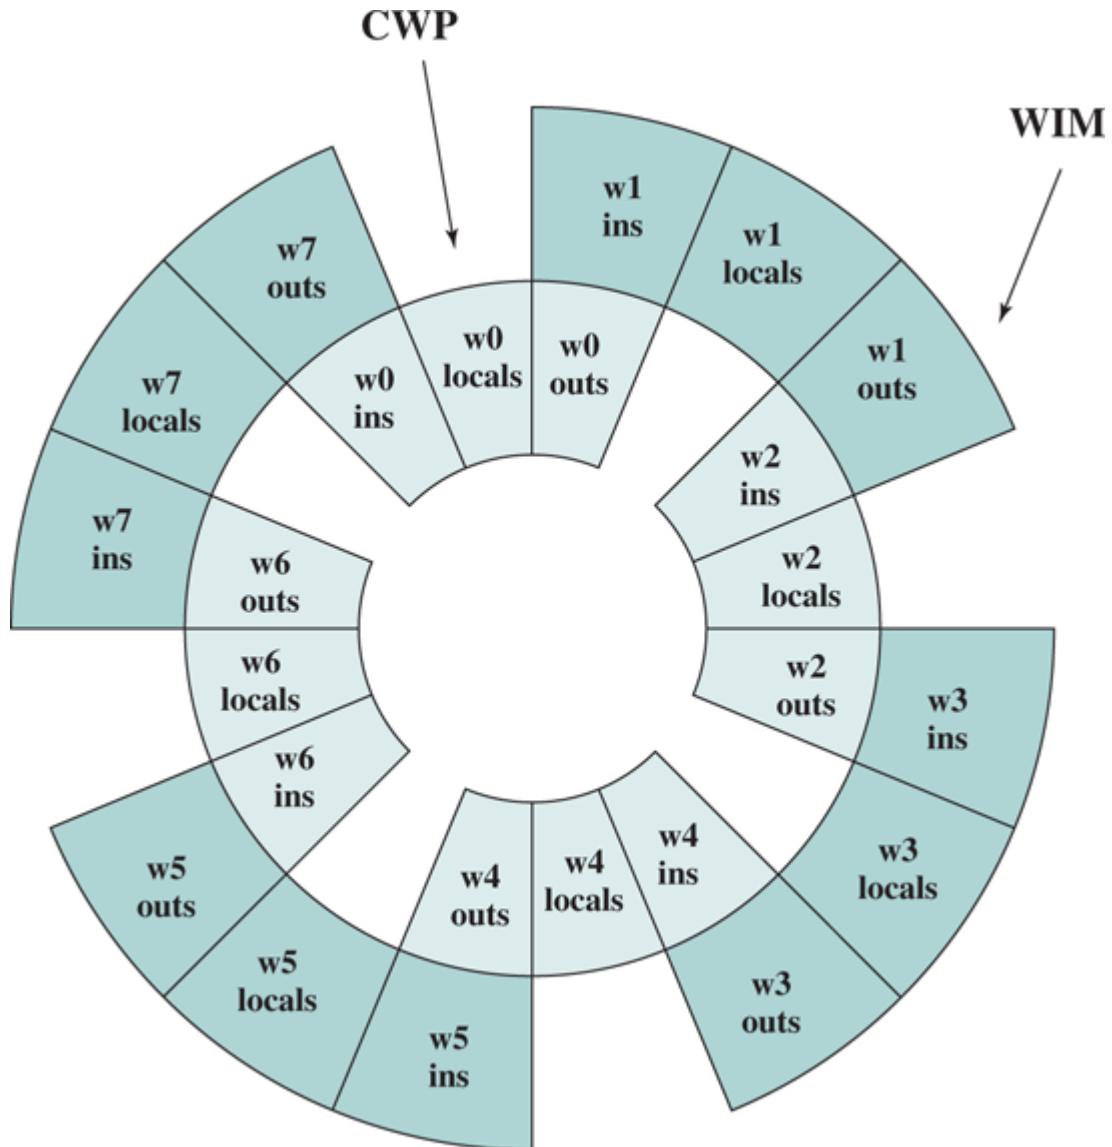

Figure 17.13 Eight Register Windows Forming a Circular Stack in SPARC

With the SPARC register architecture, it is usually not necessary to save and restore registers for a procedure call. The compiler is simplified because the compiler need be concerned only with allocating the local registers for a procedure in an efficient manner, and need not be concerned with register allocation between procedures.

Instruction Set

Most of the SPARC instructions reference only register operands. Register-to-register instructions have three operands and can be expressed in the form

$$R_d \rightarrow R_{S1} op S2$$

where R_d and R_{S1} are register references; $S2$ can refer either to a register or to a 13-bit immediate operand. Register zero (R_0) is hardwired with the value 0. This form is well suited to typical programs, which have a high proportion of local scalars and constants.

The available ALU operations can be grouped as follows:

- Integer addition (with or without carry).

Integer subtraction (with or without carry).

- Bitwise Boolean AND, OR, XOR and their negations.
- Shift left logical, right logical, or right arithmetic.

All of these instructions, except the shifts, can optionally set the four condition codes (ZERO, NEGATIVE, OVERFLOW, CARRY). Signed integers are represented in 32-bit two's complement form.

Only simple load and store instructions reference memory. There are separate load and store instructions for word (32 bits), doubleword, halfword, and byte. For the latter two cases, there are instructions for loading these quantities as signed or unsigned numbers. Signed numbers are sign extended to fill out the 32-bit destination register. Unsigned numbers are padded with zeros.

The only available addressing mode, other than register, is a displacement mode. That is, the effective address (EA) of an operand consists of a displacement from an address contained in a register:

$$\begin{aligned} EA &= (R_{S1}) + S2 \\ \text{or } EA &= (R_{S1}) + (R_{S2}) \end{aligned}$$

depending on whether the second operand is immediate or a register reference. To perform a load or store, an extra stage is added to the instruction cycle. During the second stage, the memory address is calculated using the ALU; the load or store occurs in a third stage. This single addressing mode is quite versatile and can be used to synthesize other addressing modes, as indicated in [Table 17.10](#).

Table 17.10 Synthesizing Other Addressing Modes with SPARC Addressing Modes

Note: S2 = either a register operand or a 13-bit immediate operand.

Instruction Type	Addressing Mode	Algorithm	SPARC Equivalent
Register-to-register	Immediate	operand = A	S2
Load, store	Direct	EA = A	R ₀ + S ₂
Register-to-register	Register	EA = R	R _{S1} , S _{S2}
Load, store	Register Indirect	EA = (R)	R _{S1} + 0
Load, store	Displacement	EA = (R) + A	R _{S1} + S ₂

It is instructive to compare the SPARC addressing capability with that of the MIPS. The MIPS makes use of a 16-bit offset, compared with a 13-bit offset on the SPARC. On the other hand, the MIPS does not permit an address to be constructed from the contents of two registers.

Instruction Format

As with the MIPS R4000, SPARC uses a simple set of 32-bit instruction formats ([Figure 17.14](#)). All instructions begin with a 2-bit opcode. For most instructions, this is extended with additional opcode bits elsewhere in the format. For the Call instruction, a 30-bit immediate operand is extended with two zero bits to the right to form a 32-bit PC-relative address in two's complement form. Instructions are aligned on a 32-bit boundary so that this form of addressing suffices.

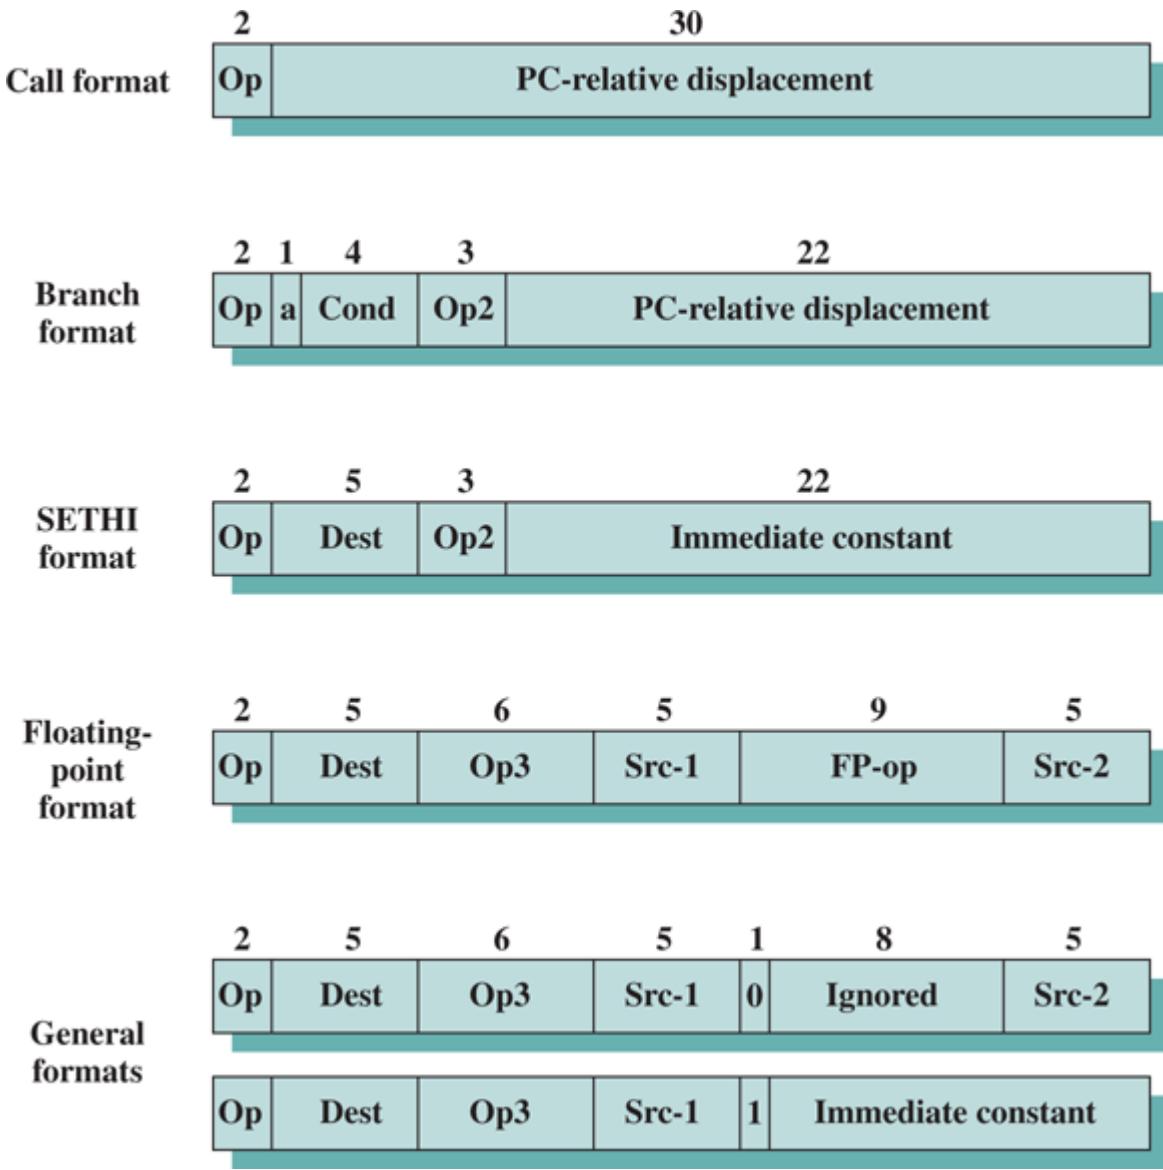

Figure 17.14 SPARC Instruction Formats

The Branch instruction includes a 4-bit condition field that corresponds to the four standard condition code bits, so that any combination of conditions can be tested. The 22-bit PC-relative address is extended with two zero bits on the right to form a 24-bit two's complement relative address. An unusual feature of the Branch instruction is the annul bit. When the annul bit is not set, the instruction after the branch is always executed, regardless of whether the branch is taken. This is the typical delayed branch operation found on many RISC machines and described in [Section 17.5](#) (see [Figure 17.7](#)). However, when the annul bit is set, the instruction following the branch is executed only if the branch is taken. The processor suppresses the effect of that instruction even though it is already in the pipeline. This annul bit is useful because it makes it easier for the compiler to fill the delay slot following a conditional branch. The instruction that is the target of the branch can always be put in the delay slot, because if the branch is not taken, the instruction can be annulled. The reason this technique is desirable is that conditional branches are generally taken more than half the time.

The SETHI instruction is a special instruction used to form a 32-bit constant. This feature is needed to form large data constants; for example, it can be used to form a large offset for a load or store instruction. The SETHI instruction sets the 22 high-order bits of a register with its 22-bit immediate operand, and zeros out the low-order 10 bits. An immediate constant of up to 13 bits can be specified in one of the general formats, and such an instruction could be used to fill in the remaining 10 bits of the register. A load or store instruction can also be used to achieve a direct addressing mode. To load a value from location K in memory, we could use the following SPARC instructions:

sethi	%hi(K), %r8	;load high-order 22 bits of address of location
		;K into register r8
Ld	[%r8 + %lo(K)], %r8	;load contents of location K into r8

The macros %hi and %lo are used to define immediate operands consisting of the appropriate address bits of a location. This use of SETHI is similar to the use of the lui instruction on the MIPS.

The floating-point format is used for floating-point operations. Two source and one destination registers are designated.

Finally, all other operations, including loads, stores, arithmetic, and logical operations use one of the last two formats shown in [Figure 17.14](#). One of the formats makes use of two source registers and a destination register, while the other uses one source register, one 13-bit immediate operand, and one destination register.

17.8 Processor Organization For Pipelining

This section looks at some of the enhancements to the pipeline illustrated in Figure 16.23 that can be used to improve performance. To begin, we merge the instruction decode (ID) and operand fetch (OF) stages into a single ID stage, with the ID stage responsible for instruction decode and register operand fetch. This is appropriate for a RISC machine, in which most operands are register. It can also be used in CISC machines. In either case, memory operand fetch is deferred to the load/store unit (LSU).

Figure 17.15 shows the addition of three enhancements: the instruction buffer, the store buffer, and the predecoder. All are designed to smooth out and enhance the flow of instructions through the pipeline. The **instruction buffer** supports the function of instruction prefetching. The objective is to prevent, or at least minimize, delays in issuing instructions due to L1 instruction cache misses. Without instruction prefetching, when a cache miss occurs in the L1 instruction cache, the pipeline freezes until new instructions are brought from the L2 cache into the L1 cache. To counter this, the IF stage can fetch multiple instructions to keep the instruction buffer full, so that when a miss occurs, the ID stage still has instructions to draw upon from the instruction buffer. Occasionally, when branches occur, instructions will need to be flushed from the instruction buffer. But overall performance is improved.

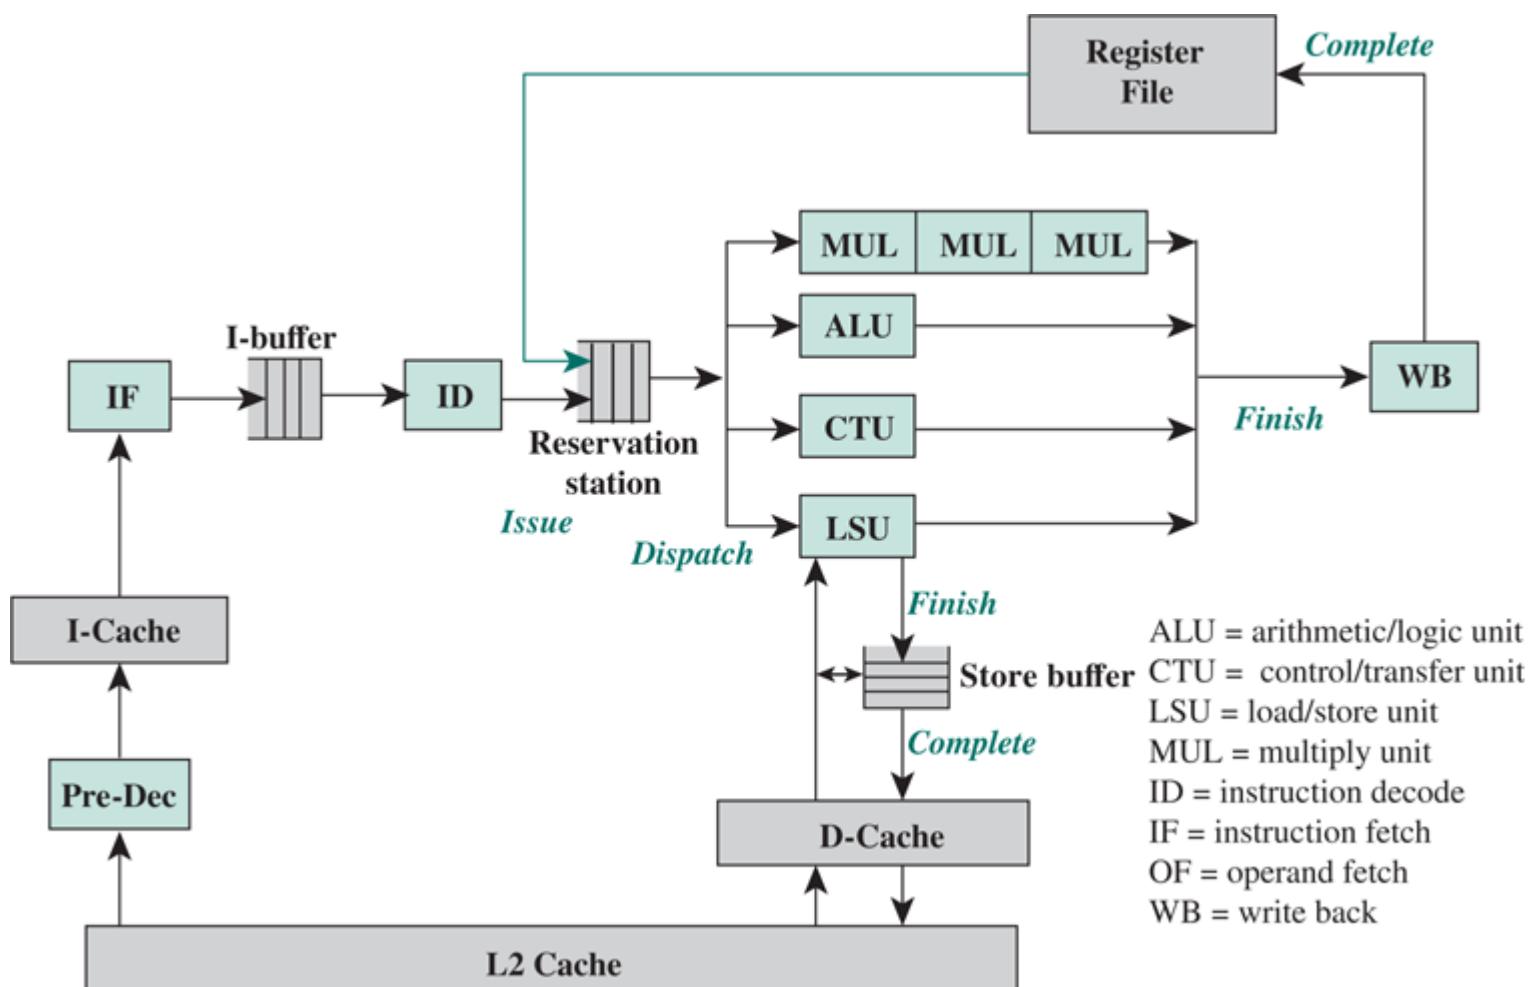

Figure 17.15 Pipeline Organization with Buffers and Pre-Decoding

The **predecoder (PD)** off-loads some of the tasks of the instruction decode (ID) stage to avoid the ID stage becoming a bottleneck. As previously discussed, the functions of the instruction decoder include decoding the opcode and operand fields and evaluating dependencies and hazards. As the pipeline

structure becomes more complex, these functions take more time, especially for a CISC machine such as the x86 architecture. However, as we move to a superscalar architecture in the next chapter, in which multiple instructions are decoded in parallel, even RISC architectures require substantial decoding time. The objective with the predecoder is to perform some of the decoding ahead of time to reduce the burden on the ID stage. The PD stage is inserted between the L2 cache and the L1 instruction cache. Because of the relatively slow L2 cache time, there is spare time here to perform the PD function. The PD may add a few bits to the instruction to designate the type of instruction and the resources required. For a CISC instruction architecture the PD may also determine instruction length and decode instruction prefixes.

Another buffer, the **store buffer**, improves performance on store operations. In essence, the store buffer allows a load to bypass the completion of a store to access a memory location. Thus, the load instruction can make use of a data item as soon as it is created (finished) and does not have to wait for the data item to be stored in the data cache (completed). This feature is especially useful for loop instructions, in which data created in one iteration is used immediately in the next iteration. On loads, the LSU examines the store buffer as a lookaside buffer and extracts the data from there if available; otherwise, it queries the data cache as normal.

Figure 17.15 shows the pipeline structure with the addition of the instruction buffer, the store buffer, and the predecoder to the organization shown in Figure 16.23. Next, we consider three more features to enhance performance: multiple reservation stations, forwarding, and the reorder buffer.

The reservation station was described in [Section 16.5](#) (see [Figure 16.24](#)). It overcomes the bottleneck problem that the ID cannot receive a new instruction until the preceding instruction is issued. If the corresponding functional unit (ALU, CTU, LSU, etc.) is not available, then the ID stage stalls. The reservation station allows the ID to issue the instruction into the reservation station, which can buffer multiple instructions pending their dispatch to the appropriate functional unit (FU). Figure 16.23 shows a single reservation station that serves all the FUs. The control of such an arrangement is relatively complex and is rarely used. The Pentium is an example of a system that used a single reservation station. An improvement both in performance and simplicity is the use of a **dedicated reservation station** for each individual FU. The process of dispatching an instruction to a functional unit proceeds in two parts:

- **Issue from ID to reservation station:** Each slot in the reservation station serves the role of a virtual FU, to which the ID issues an instruction. There is no stall unless all the slots in the reservation station for a given FU are in use (buffer full).
- **Dispatch from reservation station to FU:** Dispatch occurs when the corresponding FU is available and all operand values are available. However, dispatch does not have to be FIFO, but rather different priorities can be assigned to different instructions.

The reservation station is also referred to as an **instruction window**, particularly in the superscalar literature, and we use this latter term in [Chapter 18](#).

Data forwarding addresses the problem of read-after-write (RAW) delays due to WB delays. As with the store buffer, data forwarding makes data available as soon as it is created. The forwarded data becomes input to the reservation stations, going to an operand field.

The **reorder buffer** supports out-of-order execution. Out-of-order execution (OoOE) is an approach to processing that allows instructions for high-performance microprocessors to begin execution as soon as their operands are ready. Although instructions are issued in order, they can proceed out-of-order (OoO) with respect to each other. The goal of OoO processing is to allow the processor to avoid a class of stalls that occur when the data needed to perform an operation are unavailable. OoOE is discussed in [Chapter 18](#). The reorder buffer ensures that instructions complete in order. Reorder buffers are discussed in [Appendix G](#).

Figure 17.16 adds multiple reservation stations, forwarding, and the reorder buffer to the organization shown in **Figure 17.15**. Note that the forwarding function occurs at finishing time, prior to the reorder buffer and completion of write back.

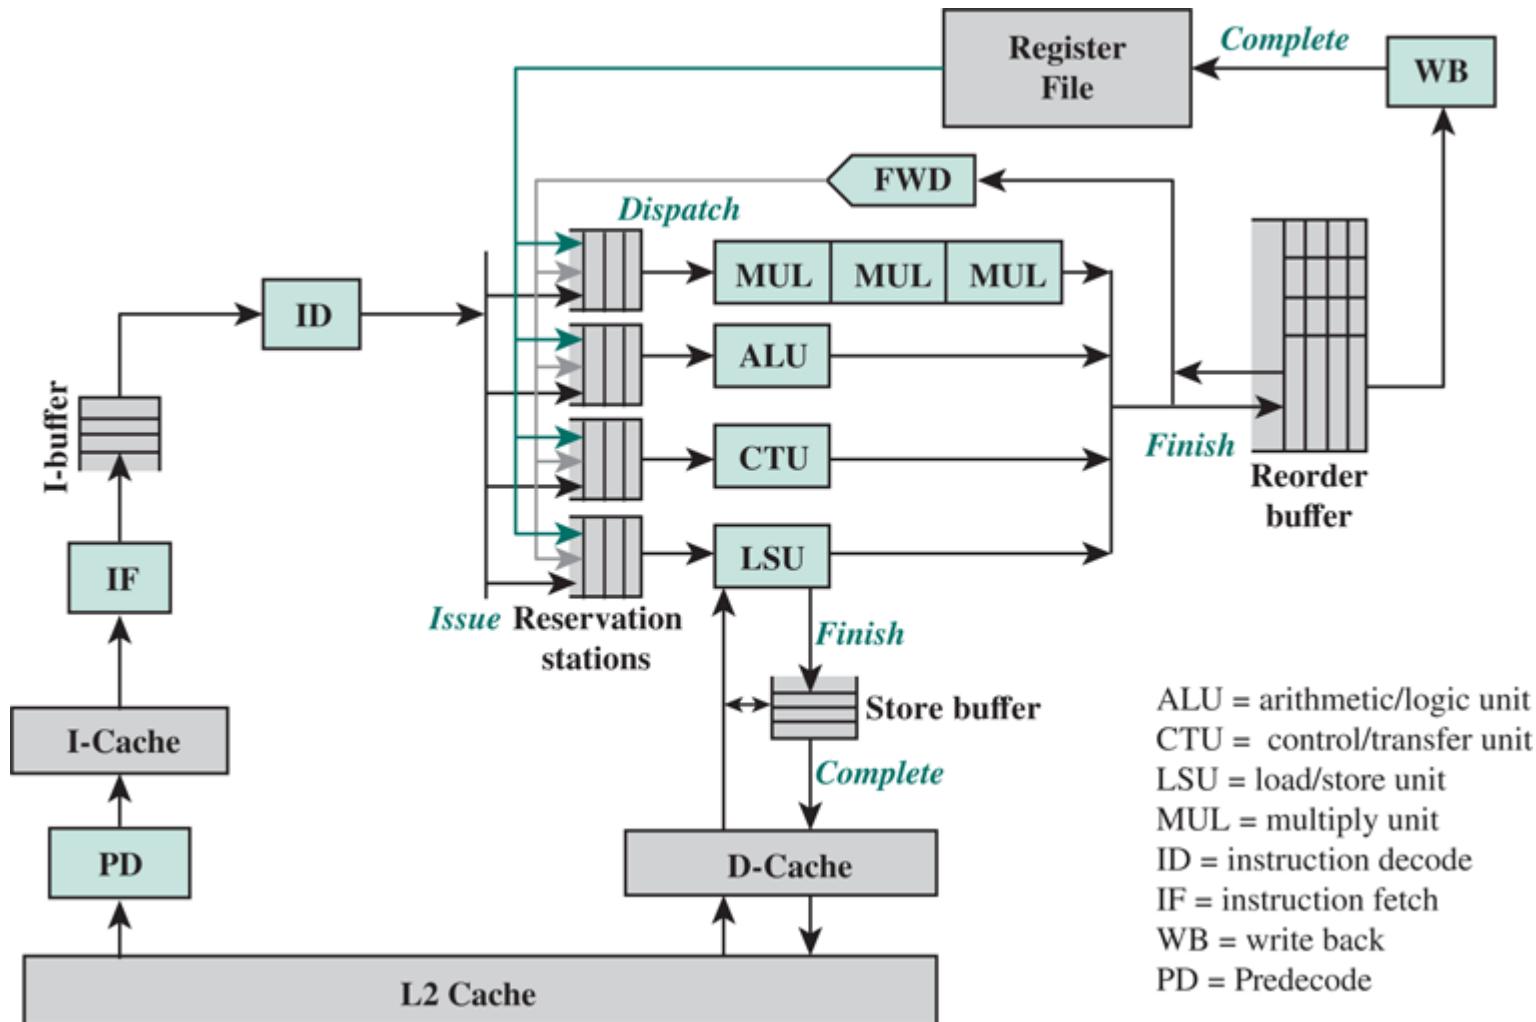

Figure 17.16 Pipeline Organization with Forwarding, Reorder Buffer, and Multiple Reservation Stations

17.9 CISC, RISC, And Contemporary Systems

During the 1980s, there was quite a RISC versus CISC controversy concerning the relative performance of each approach, with no clear-cut resolution of the issue. In more recent years, the RISC versus CISC controversy has died down to a great extent. This is because there has been a gradual convergence of the technologies. As chip densities and raw hardware speeds increase, RISC systems have become more complex. At the same time, in an effort to squeeze out maximum performance, CISC designs have focused on issues traditionally associated with RISC, such as an increased number of general-purpose registers and increased emphasis on instruction pipeline design.

At the time of the introduction of RISC, the focus of computer architecture design were desktops and servers, the primary design objective was performance, and the primary design constraints were chip area and processor design complexity. This situation has dramatically changed with the proliferation of embedded devices built on ARM, primarily a RISC-based architecture, while the primarily CISC x86 continues to dominate larger systems, including laptops, desktops, and servers. There is much more emphasis on power consumption as a design constraint. A study reported in [BLEM15] found that the details of implementation plus the presence or absence of specializations such as floating point and SIMD support were major factors in both performance and power consumption, but that the use of a CISC or RISC instruction set architecture was not a significant factor.

A major conclusion that can be deduced is that differences in the instruction set architecture (RISC vs. CISC) do affect implementation choices, but because of modern microarchitecture techniques, these differences do not drive performance or power consumption. An example of modern microarchitecture techniques is the translation of machine instructions into microinstructions on contemporary x86 implementations.

Review Questions

17.1 What are some typical distinguishing characteristics of RISC organization?

17.2 Briefly explain the two basic approaches used to minimize register-memory operations on RISC machines.

17.3 If a circular register buffer is used to handle local variables for nested procedures, describe two approaches for handling global variables.

17.4 What are some typical characteristics of a RISC instruction set architecture?

17.5 What is a delayed branch?

Problems

17.1 In the discussion of [Figure 17.2](#), it was stated that only the first two portions of a window are saved or restored. Why is it not necessary to save the temporary registers?

17.2 We wish to determine the execution time for a given program using the various pipelining schemes discussed in [Section 17.5](#). Let

N = number of executed instructions

D = number of memory accesses

J = number of jump instructions

For the simple sequential scheme ([Figure 17.6a](#)), the execution time is $2N + D$ stages. Derive formulas for two-stage, three-stage, and four-stage pipelining.

17.3 Reorganize the code sequence in [Figure 17.6d](#) to reduce the number of NOOPs.

17.4 Consider the following code fragment in a high-level language:

```
for I in 1...100 loop
    S ← S + Q(I). VAL
end loop;
```

Assume that Q is an array of 32-byte records and the VAL field is in the first 4 bytes of each record. Using x86 code, we can compile this program fragment as follows:

	MOV	ECX,1	;use register ECX to hold I
LP:	IMUL	EAX, ECX, 32	;get offset in EAX
	MOV	EBX, Q[EAX]	;load VAL field
	ADD	S, EBX	;add to S
	INC	ECX	;increment I
	CMP	ECX, 101	;compare to 101
	JNE	LP	;loop until $I = 100$

This program makes use of the IMUL instruction, which multiplies the second operand by the immediate value in the third operand and places the result in the first operand (see Problem 10.13). A RISC advocate would like to demonstrate that a clever compiler can eliminate unnecessarily complex instructions such as IMUL. Provide the demonstration by rewriting the above x86 program without using the IMUL instruction.

17.5 Consider the following loop:

```
S := 0;
for K:=1 to 100 do
    S:=S - K;
```

A straightforward translation of this into a generic assembly language would look something like this:

	LD	R1, 0	;keep value of S in R1
	LD	R2,1	;keep value of K in R2
LP	SUB	R1, R1, R2	;S := S - K
	BEQ	R2, 100, EXIT	;done if K = 100
	ADD	R2, R2, 1	;else increment K

JMP

LP

;back to start of loop

A compiler for a RISC machine will introduce delay slots into this code so that the processor can employ the delayed branch mechanism. The JMP instruction is easy to deal with, because this instruction is always followed by the SUB instruction; therefore, we can simply place a copy of the SUB instruction in the delay slot after the JMP. The BEQ presents a difficulty. We can't leave the code as is, because the ADD instruction would then be executed one too many times. Therefore, a NOP instruction is needed. Show the resulting code.

17.6 A RISC machine's compiler may do both a mapping of symbolic registers to actual registers and a rearrangement of instructions for pipeline efficiency. An interesting question arises as to the order in which these two operations should be done. Consider the following program fragment:

LD	SR1, A	;load A into symbolic register 1
LD	SR2, B	;load B into symbolic register 2
ADD	SR3, SR1, SR2	;add contents of SR1 and SR2 and store in SR3
LD	SR4, C	
LD	SR5, D	
ADD	SR6, SR4, SR5	

- a. First do the register mapping and then any possible instruction reordering. How many machine registers are used? Has there been any pipeline improvement?
- b. Starting with the original program, now do instruction reordering and then any possible mapping. How many machine registers are used? Has there been any pipeline improvement?

17.7 Add entries for the following processors to **Table 17.7** :

- a. Pentium II
- b. ARM

17.8 In many cases, common machine instructions that are not listed as part of the MIPS instruction set can be synthesized with a single MIPS instruction. Show this for the following:

- a. Register-to-register move
- b. Increment, decrement
- c. Complement
- d. Negate
- e. Clear

17.9 A SPARC implementation has K register windows. What is the number N of physical registers?

17.10 SPARC is lacking a number of instructions commonly found on CISC machines. Some of these are easily simulated using either register R0, which is always set to 0, or a constant operand. These simulated instructions are called pseudoinstructions and are recognized by the SPARC assembler. Show how to simulate the following pseudoinstructions, each with a single

SPARC instruction. In all of these, src and dst refer to registers. (*Hint*: A store to R0 has no effect.)

- a. MOV src, dst
- b. COMPARE src1, src2
- c. TEST src1
- d. NOT dst
- e. NEG dst
- f. INC dst
- g. DEC dst
- h. CLR dst
- i. NOP

17.11 Consider the following code fragment:

```
if K > 10
    L := K + 1
else
    L := K - 1
```

A straightforward translation of this statement into SPARC assembler could take the following form:

	sethi	%hi(K), %r8	;load high-order 22 bits of address of location
			;K into register r8
	ld	[%r8 + %lo(K)], %r8	;load contents of location K into r8
	cmp	%r8, 10	;compare contents of r8 with 10
	ble	L1	;branch if (r8) ≤ 10
	nop		
	sethi	%hi(K), %r9	
	ld	[%r9 + %lo(K)], %r9	;load contents of location K into r9
	inc	%r9	;add 1 to (r9)
	sethi	%hi(L), %r10	
	st	%r9, [%r10 + %lo(L)]	;store (r9) into location L
	b	L2	
	nop		

L1:	sethi	%hi(K), %r11	
	ld	[% r11 + % lo(K)], %r12	;load contents of location K into r12
	dec	%r12	;subtract 1 from (r12)
	sethi	%hi(L), %r13	
	st	%r12, [% r13 + % lo(L)]	;store (r12) into location L
L2:			

The code contains a nop after each branch instruction to permit delayed branch operation.

- a. Standard compiler optimizations that have nothing to do with RISC machines are generally effective in being able to perform two transformations on the foregoing code. Notice that two of the loads are unnecessary and that the two stores can be merged if the store is moved to a different place in the code. Show the program after making these two changes.
- b. It is now possible to perform some optimizations peculiar to SPARC. The nop after the ble can be replaced by moving another instruction into that delay slot and setting the annul bit on the ble instruction (expressed as ble,a L1). Show the program after this change.
- c. There are now two unnecessary instructions. Remove these and show the resulting program.

Learning Objectives

After studying this chapter, you should be able to:

- Explain the difference between superscalar and superpipelined approaches.
- Define instruction-level parallelism.
- Discuss dependencies and resource conflicts as limitations to instruction-level parallelism
- Present an overview of the design issues involved in instruction-level parallelism.
- Compare and contrast techniques of improving pipeline performance in RISC machines and

superscalar machines.

A *superscalar implementation of a processor architecture* is one in which common instructions—integer and floating-point arithmetic, loads, stores, and conditional branches—can be initiated simultaneously and executed independently. Such implementations raise a number of complex design issues related to the instruction pipeline.

Superscalar design arrived on the scene hard on the heels of RISC architecture. Although the simplified instruction set architecture of a RISC machine lends itself readily to superscalar techniques, the superscalar approach can be used on either a RISC or CISC architecture.

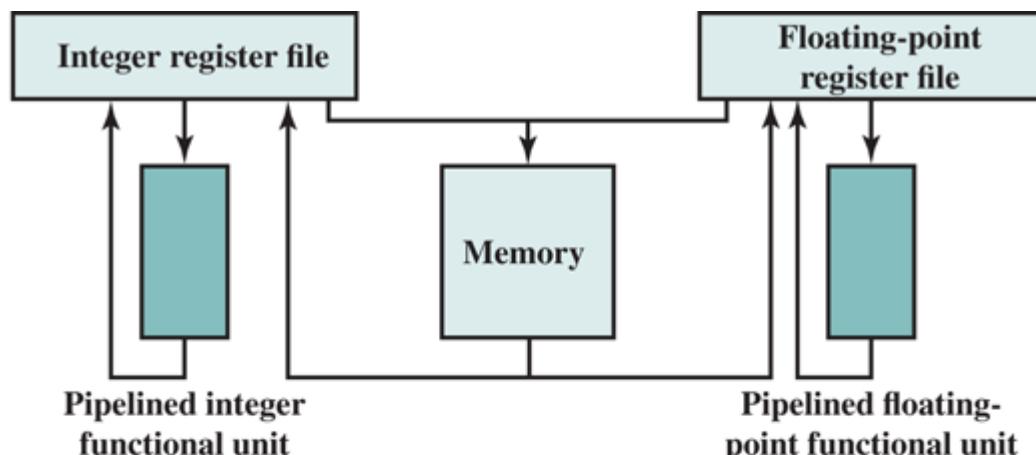

Whereas the gestation period for the arrival of commercial RISC machines from the beginning of true RISC research with the IBM 801 and the Berkeley RISC I was seven or eight years, the first superscalar machines became commercially available within just a year or two of the coining of the term **superscalar**. The superscalar approach has now become the standard method for implementing high-performance microprocessors.

In this chapter, we begin with an overview of the superscalar approach, contrasting it with superpipelining. Next, we present the key design issues associated with superscalar implementation. Then we look at several important examples of superscalar architecture.

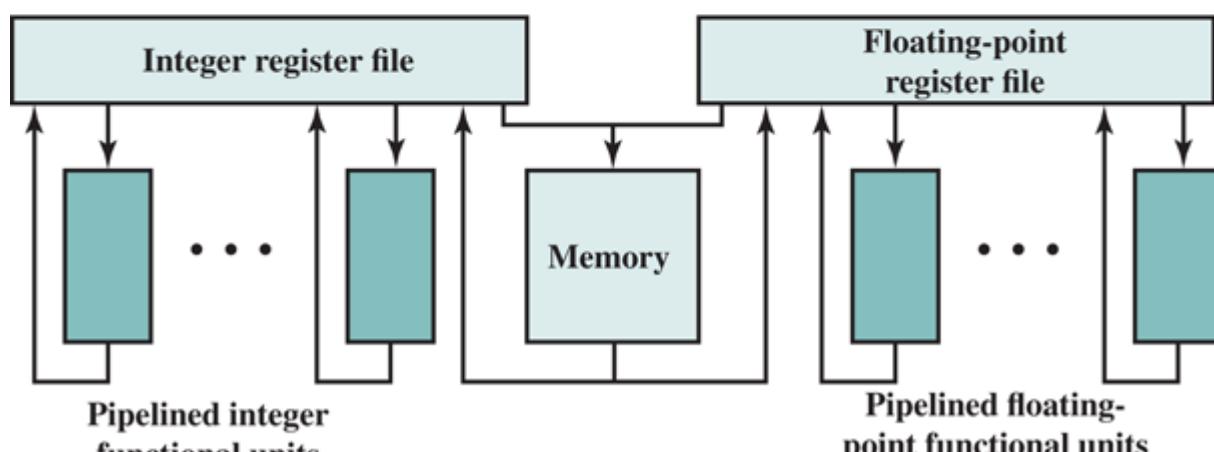

18.1 Overview

The term *superscalar*, first coined in 1987 [AGER87], refers to a machine that is designed to improve the performance of the execution of scalar instructions. In most applications, the bulk of the operations are on scalar quantities. Accordingly, the superscalar approach represents the next step in the evolution of high-performance general-purpose processors.

The essence of the superscalar approach is the ability to execute instructions independently and concurrently in different pipelines. The concept can be further exploited by allowing instructions to be executed in an order different from the program order. **Figure 18.1** compares, in general terms, the scalar and superscalar approaches. In a traditional scalar organization, there is a single pipelined functional unit for integer operations and one for floating-point operations. Parallelism is achieved by enabling multiple instructions to be at different stages of the pipeline at one time. In the superscalar organization, there are multiple functional units, each of which is implemented as a pipeline. Each individual functional unit provides a degree of parallelism by virtue of its pipelined structure. The use of multiple functional units enables the processor to execute streams of instructions in parallel, one stream for each pipeline. It is the responsibility of the hardware, in conjunction with the compiler, to assure that the parallel execution does not violate the intent of the program.

(a) Scalar organization

(b) Superscalar organization

Figure 18.1 Superscalar Organization Compared to Ordinary Scalar Organization

Figure 18.2 provides additional detail of a typical organization for a superscalar pipeline processor. Compare with **Figure 17.16**. The L1 cache is divided into instruction and data. Groups of instructions are fetched into an instruction buffer. The instruction decode stage involves, at minimum, determining the opcode and operand specifiers. This stage also usually involves detection of inter-instruction dependencies among the group of instructions that have been fetched but not yet dispatched. This stage selects instructions to be issued in the next instruction cycle and sends them to the issue window. The issue window holds all decoded instructions of issue in the next cycle. The width of the issue window corresponds to the degree of superscaling.

¹ Figure provided by Professor Roger Kieckhafer of Michigan Technological University.

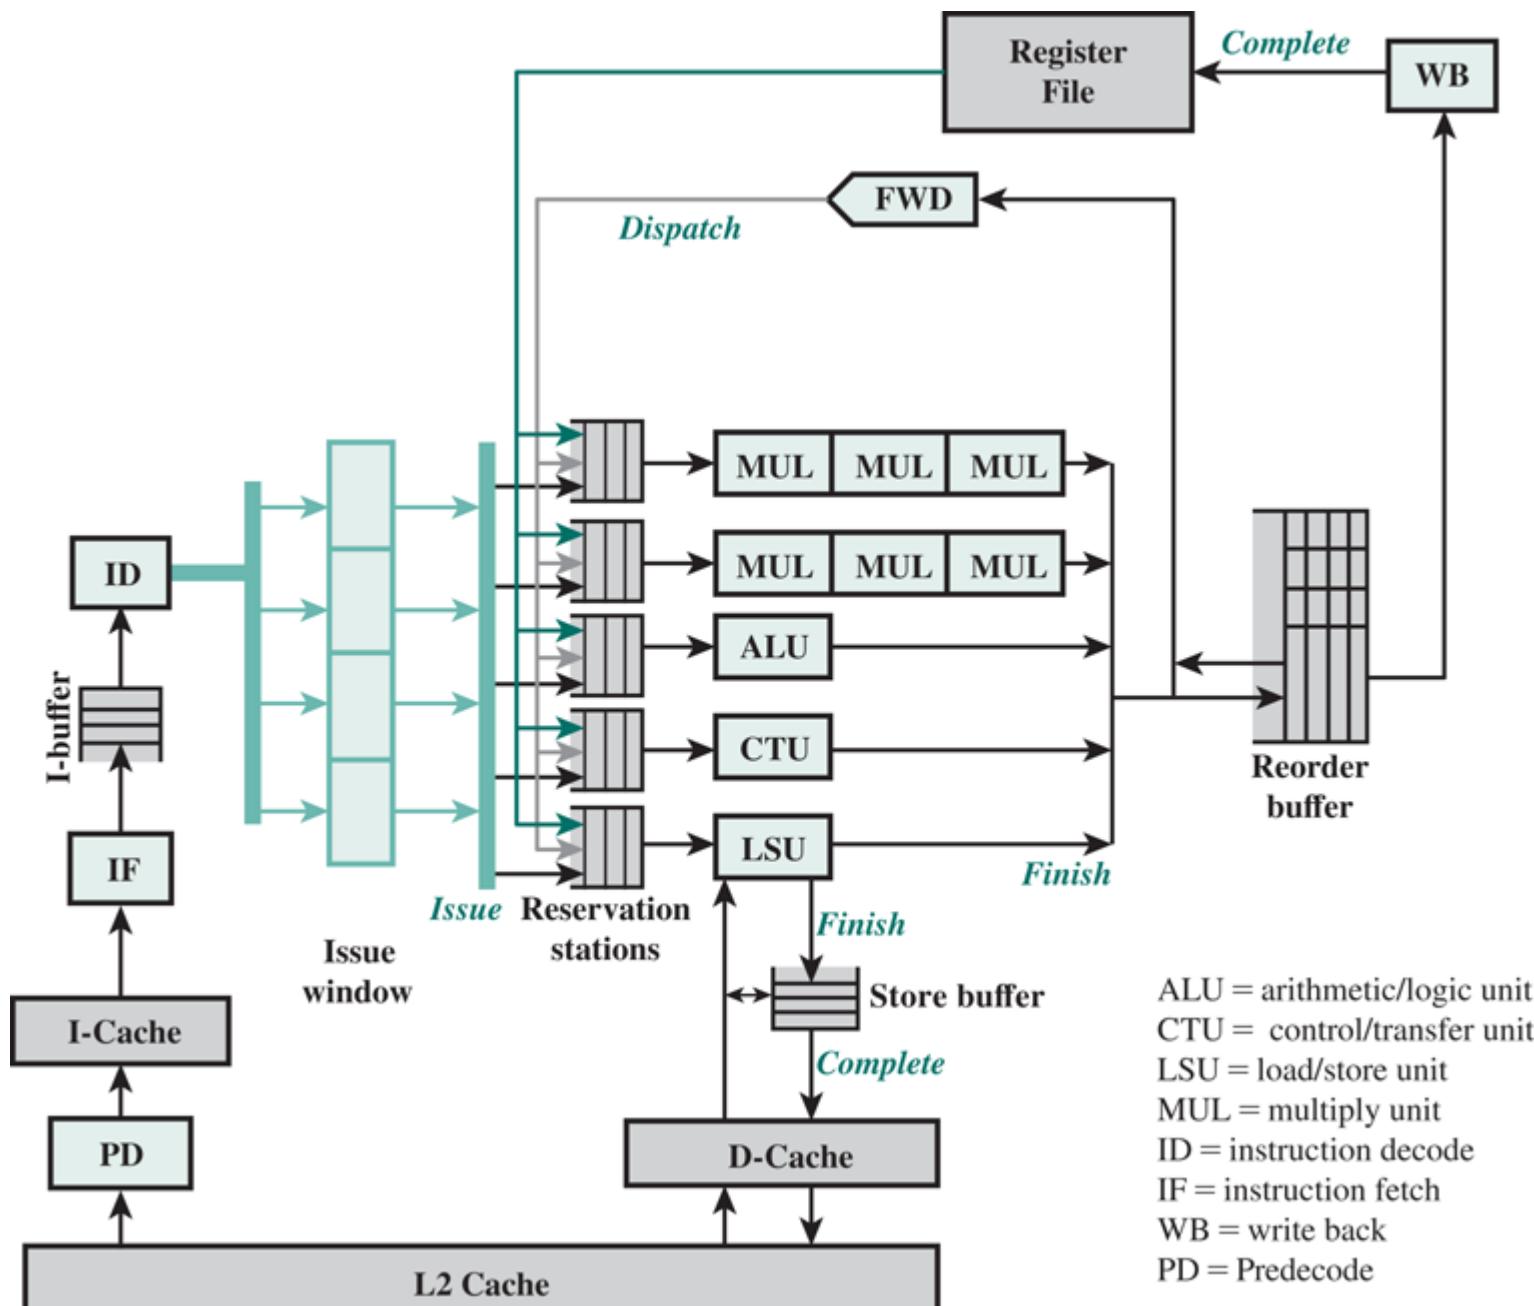

Figure 18.2 Generic Superscalar Organization (degree = 4)

Define **issue rate** as the number of instructions issued per instruction cycle. Then, for a superscalar machine, the maximum issue rate equals the width of the issue window. The mean issue rate depends

on the occurrence of pipeline hazards and constraints, and the issue policies that are based on these hazards and constraints. The design objective is to achieve an issue rate of well above one instruction per instruction cycle, and as close as is reasonable to the maximum issue rate.

The issue window is followed by a set of reservation stations, with instructions being issued from the issue window as reservation station capacity becomes available. The concept of a single reservation station was introduced in Chapter 16. With a superscalar architecture, there are multiple reservation stations, one for each pipeline. Each reservation station is essentially a set of input registers that are used to buffer operations and operands for a functional unit. The purpose of the reservation station is to relieve a bottleneck at the instruction decode (ID) stage. The ID can issue an instruction as soon as a functional unit is available and hazards are resolved. The problem this creates is that the ID stage cannot receive a new instruction until the previous instruction has been issued. The reservation stations provide a buffer that enables the ID stage to issue instructions as soon as possible. Then, the reservation station will dispatch each instruction to its functional unit when the latter is available.

The reorder buffer holds results until it is safe to store the results to memory or a register in program order. When an instruction is complete and can be finalized, it is either written back to the register file or the results forwarded to the reservation stations.

Many researchers have investigated superscalar-like processors, and their research indicates that some degree of performance improvement is possible. **Table 18.1** presents the reported performance advantages. The differences in the results arise from differences both in the hardware of the simulated machine and in the applications being simulated.

Table 18.1 Reported Speedups of Superscalar-Like Machines

Reference	Speedup
[TJAD70]	1.8
[KUCK77]	8
[WEIS84]	1.58

[JOUP89b]	2.2
[LEE91]	7

Superscalar versus Superpipelined

An alternative approach to achieving greater performance is referred to as superpipelining, a term first coined in 1988 [JOUP88]. Superpipelining divides the pipeline into a greater number of smaller stages in order to clock it at a higher frequency. There is still only one pipeline, but by increasing the number

of stages, we increase its *temporal parallelism*—it is working on more instructions at the same time. This use of a very deep, very high-speed pipeline for instruction processing is called superpipelining. We have seen one example of this approach with the MIPS R4000.

Figure 18.3 compares the two approaches. The upper part of the diagram illustrates an ordinary pipeline, used as a base for comparison. The base pipeline issues one instruction per clock cycle and can perform one pipeline stage per clock cycle. The pipeline has four stages: instruction fetch; operation decode; operation execution; and result write back. The execution stage is crosshatched for clarity. Note that although several instructions are executing concurrently, only one instruction is in its execution stage at any one time.

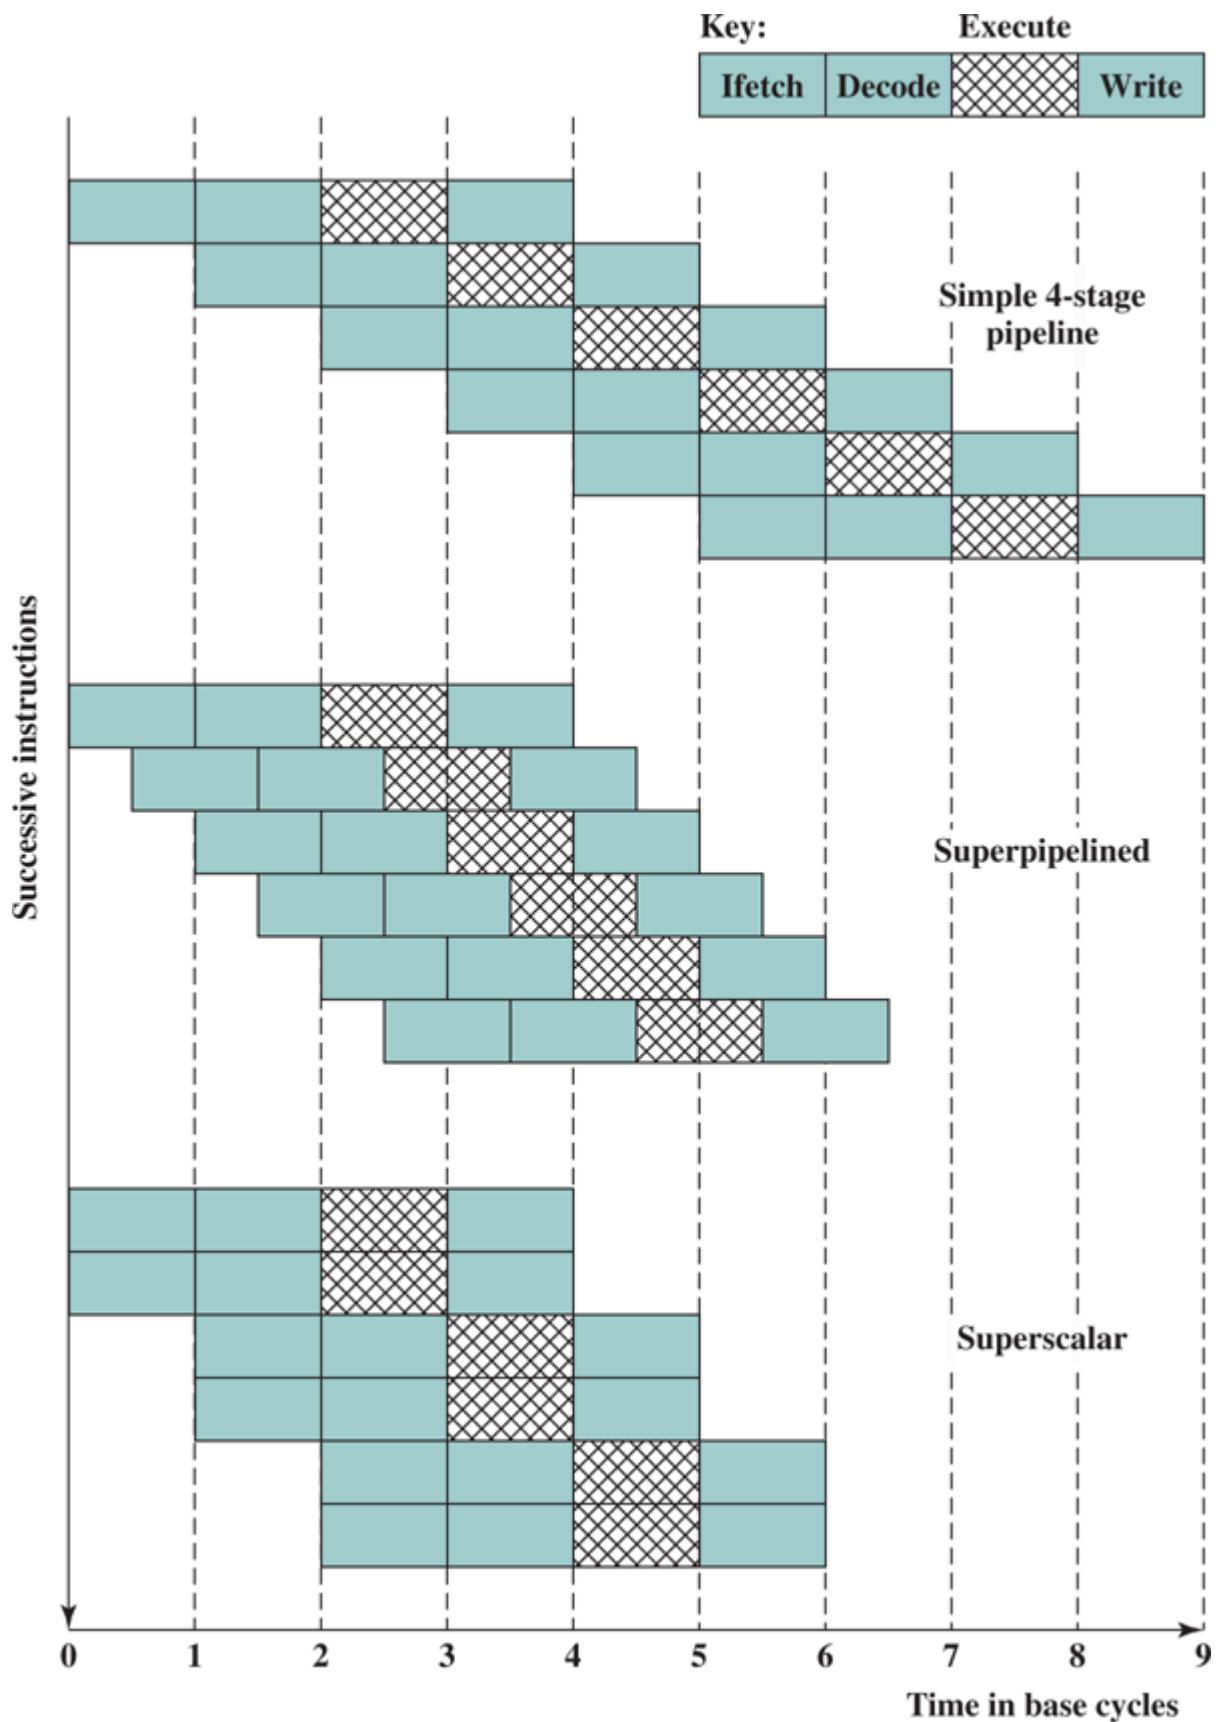

Figure 18.3 Comparison of Superscalar and Superpipeline Approaches

The next part of the diagram shows a **superpipelined** implementation that is capable of performing two pipeline stages per clock cycle. An alternative way of looking at this is that the functions performed in each stage can be split into two nonoverlapping parts, and each can execute in half a clock cycle. A superpipeline implementation that behaves in this fashion is said to be of degree 2. Finally, the lowest part of the diagram shows a superscalar implementation capable of executing two instances of each stage in parallel. Higher-degree superpipeline and superscalar implementations are

of course possible.

Both the superpipeline and the superscalar approaches depicted in [Figure 18.3](#) have the same number of instructions executing at the same time in the steady state. The superpipelined processor falls behind the superscalar processor at the start of the program and at each branch target.

Constraints

The superscalar approach depends on the ability to execute multiple instructions in parallel. The term **instruction-level parallelism** refers to the degree to which, on average, the instructions of a program can be executed in parallel. A combination of compiler-based optimization and hardware techniques can be used to maximize instruction-level parallelism. Before examining the design techniques used in superscalar machines to increase instruction-level parallelism, we need to look at the fundamental limitations to parallelism with which the system must cope. [JOHN91] lists five limitations:

- True data dependency;
- Procedural dependency;
- Resource conflicts;
- Output dependency;
- Antidependency.

We examine the first three of these limitations in the remainder of this section. A discussion of the last two must await some of the developments in the next section.

TRUE DATA DEPENDENCY

Consider the following sequence:²

² For the Intel x86 assembly language, a semicolon starts a comment field.

```
ADD EAX, ECX ;load register EAX with the con-
;tents of ECX plus the contents
;of EAX
MOV EBX, EAX ;load EBX with the contents of EAX
```

The second instruction can be fetched and decoded but cannot execute until the first instruction executes. The reason is that the second instruction needs data produced by the first instruction. This situation is referred to as a **true data dependency** (also called **flow dependency** or **read after write [RAW] dependency**).

[Figure 18.4](#) illustrates this **dependency** in a superscalar machine of degree 2. With no dependency, two instructions can be fetched and executed in parallel. If there is a data dependency between the first and second instructions, then the second instruction is delayed as many clock cycles as required to remove the dependency. In general, any instruction must be delayed until all of its input values have been produced.

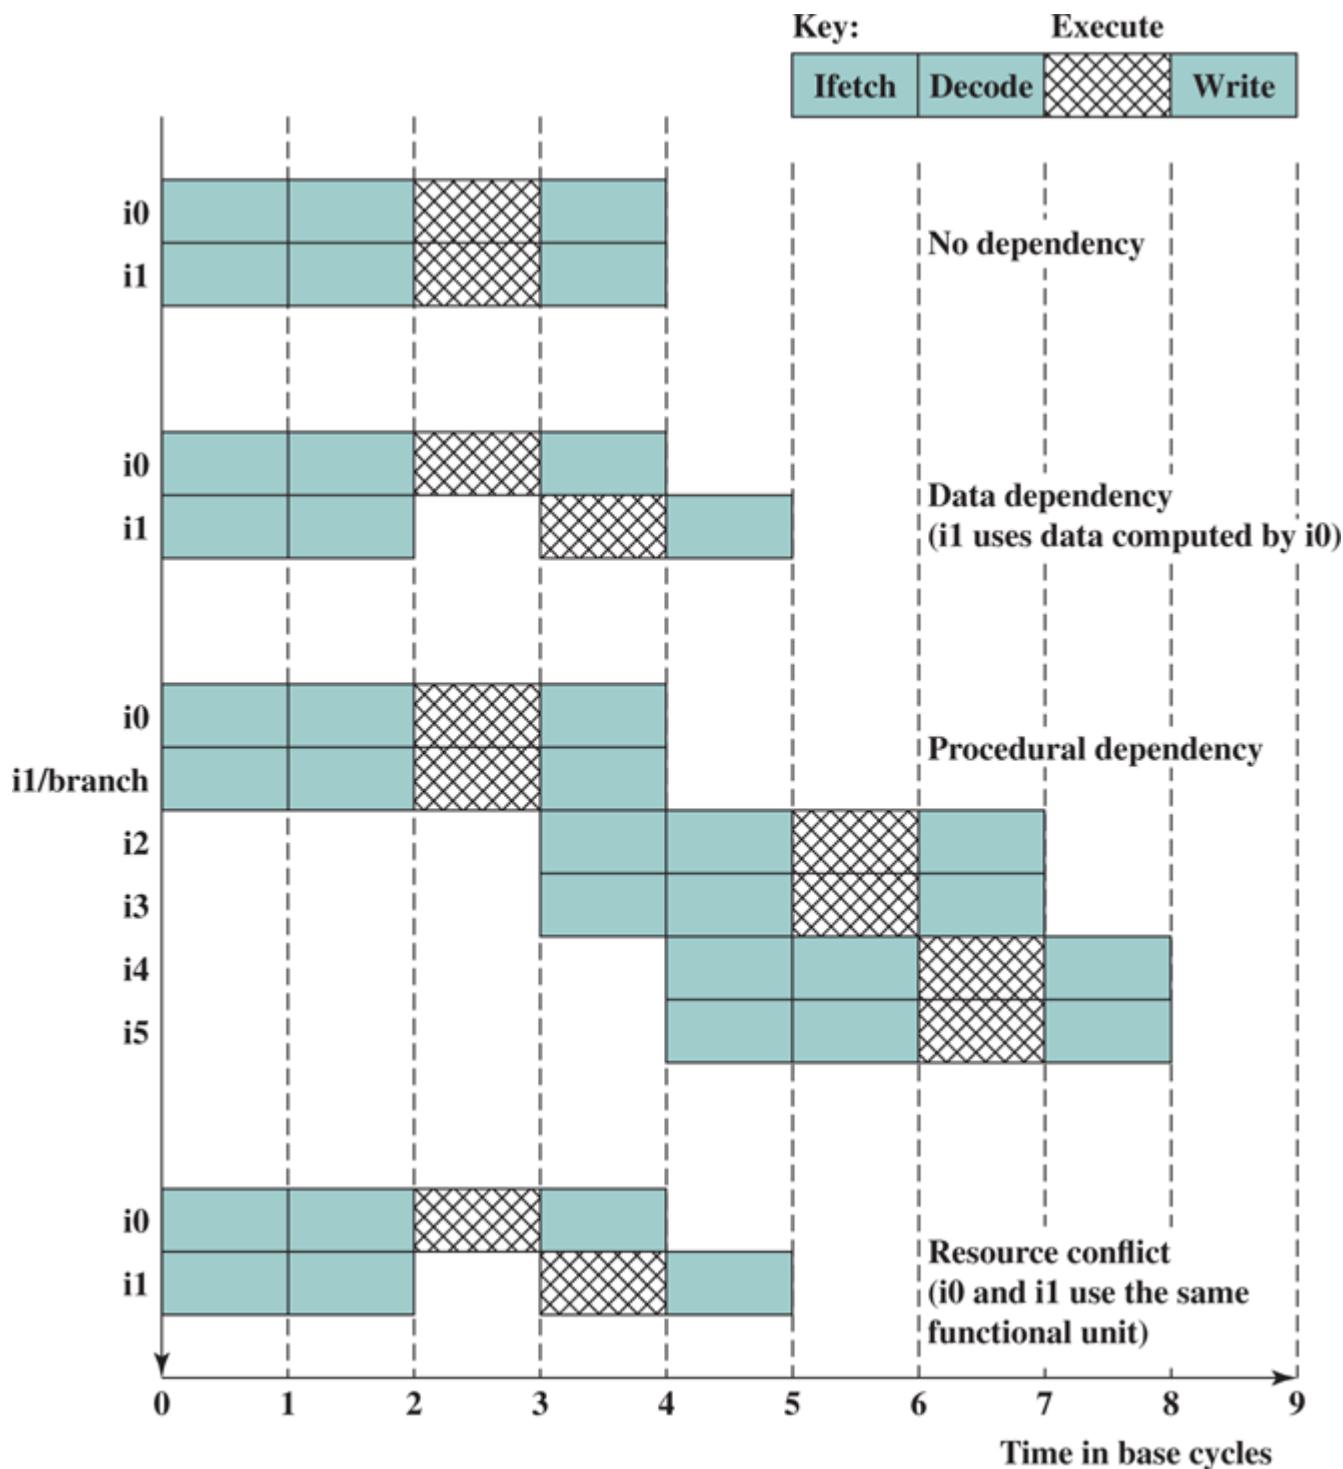

Figure 18.4 Effect of Dependencies

In a simple pipeline, such as illustrated in the upper part of [Figure 18.3](#), the aforementioned sequence of instructions would cause no delay. However, consider the following, in which one of the loads is from memory rather than from a register:

```

MOV EAX, eff ;load register EAX with the
               contents of effective memory
               address eff
MOV EBX, EAX ;load EBX with the contents of EAX

```

A typical RISC processor takes two or more cycles to perform a load from memory when the load is a cache hit. It can take tens or even hundreds of cycles for a cache miss on all cache levels, because of

the delay of an off-chip memory access. One way to compensate for this delay is for the compiler to reorder instructions so that one or more subsequent instructions that do not depend on the memory load can begin flowing through the pipeline. This scheme is less effective in the case of a superscalar pipeline: The independent instructions executed during the load are likely to be executed on the first cycle of the load, leaving the processor with nothing to do until the load completes.

PROCEDURAL DEPENDENCIES

As was discussed in [Chapter 14](#), the presence of branches in an instruction sequence complicates the pipeline operation. The instructions following a branch (taken or not taken) have a **procedural dependency** on the branch and cannot be executed until the branch is executed. [Figure 18.4](#) illustrates the effect of a branch on a superscalar pipeline of degree 2.

As we have seen, this type of procedural dependency also affects a scalar pipeline. The consequence for a superscalar pipeline is more severe, because a greater magnitude of opportunity is lost with each delay.

If variable-length instructions are used, then another sort of procedural dependency arises. Because the length of any particular instruction is not known, it must be at least partially decoded before the following instruction can be fetched. This prevents the simultaneous fetching required in a superscalar pipeline. This is one of the reasons that superscalar techniques are more readily applicable to a RISC or RISC-like architecture, with its fixed instruction length.

RESOURCE CONFLICT

A **resource conflict** is a competition of two or more instructions for the same resource at the same time. Examples of resources include memories, caches, buses, register-file ports, and functional units (e.g., ALU adder).

In terms of the pipeline, a resource conflict exhibits similar behavior to a data dependency ([Figure 18.4](#)). There are some differences, however. For one thing, resource conflicts can be overcome by duplication of resources, whereas a true data dependency cannot be eliminated. Also, when an operation takes a long time to complete, resource conflicts can be minimized by pipelining the appropriate functional unit.

18.2 Design Issues

Instruction-Level Parallelism and Machine Parallelism

[JOUP89a] makes an important distinction between the two related concepts of instruction-level parallelism and machine parallelism. **Instruction-level parallelism** exists when instructions in a sequence are independent and thus can be executed in parallel by overlapping.

As an example of the concept of instruction-level parallelism, consider the following two code fragments [JOUP89b]:

<i>Load R1 ← R2</i>	<i>Add R3 ← R3, "1"</i>
<i>Add R3 ← R3, "1"</i>	<i>Add R4 ← R3, R2</i>
<i>Add R4 ← R4, R2</i>	<i>Store [R4] ← R0</i>

The three instructions on the left are independent, and in theory all three could be executed in parallel. In contrast, the three instructions on the right cannot be executed in parallel because the second instruction uses the result of the first, and the third instruction uses the result of the second.

The degree of instruction-level parallelism is determined by the frequency of true data dependencies and procedural dependencies in the code. These factors, in turn, are dependent on the instruction set architecture and on the application. Instruction-level parallelism is also determined by what [JOUP89a] refers to as operation latency: the time until the result of an instruction is available for use as an operand in a subsequent instruction. The latency determines how much of a delay a data or procedural dependency will cause.

Machine parallelism is a measure of the ability of the processor to take advantage of instruction-level parallelism. Machine parallelism is determined by the number of instructions that can be fetched and executed at the same time (the number of parallel pipelines) and by the speed and sophistication of the mechanisms that the processor uses to find independent instructions.

Both instruction-level and machine parallelism are important factors in enhancing performance. A program may not have enough instruction-level parallelism to take full advantage of machine parallelism. The use of a fixed-length instruction set architecture, as in a RISC, enhances instruction-level parallelism. On the other hand, limited machine parallelism will limit performance no matter what the nature of the program.

Instruction Issue Policy

As was mentioned, machine parallelism is not simply a matter of having multiple instances of each pipeline stage. The processor must also be able to identify instruction-level parallelism and orchestrate the fetching, decoding, and execution of instructions in parallel. [JOHN91] uses the term **instruction issue** to refer to the process of initiating instruction execution in the processor's functional units, and the term **instruction issue policy** to refer to the protocol used to issue instructions. In general, we can say that instruction issue occurs when instruction moves from the decode stage of the pipeline to the first execute stage of the pipeline.

In essence, the processor is trying to look ahead of the current point of execution to locate instructions that can be brought into the pipeline and executed. Three types of orderings are important in this

regard:

- The order in which instructions are fetched;
- The order in which instructions are executed;
- The order in which instructions update the contents of register and memory locations.

The more sophisticated the processor, the less it is bound by a strict relationship between these orderings. To optimize utilization of the various pipeline elements, the processor will need to alter one or more of these orderings with respect to the ordering to be found in a strict sequential execution. The one constraint on the processor is that the result must be correct. Thus, the processor must accommodate the various dependencies and conflicts discussed earlier.

In general terms, we can group superscalar instruction issue policies into the following categories:

- In-order issue with in-order completion.
- In-order issue with **out-of-order completion**.
- Out-of-order issue with out-of-order completion.

IN-ORDER ISSUE WITH IN-ORDER COMPLETION

The simplest instruction issue policy is to issue instructions in the exact order that would be achieved by sequential execution (**in-order issue**) and to write results in that same order (**in-order completion**). Not even scalar pipelines follow such a simple-minded policy. However, it is useful to consider this policy as a baseline for comparing more sophisticated approaches.

Figure 18.5a gives an example of this policy. We assume a superscalar pipeline capable of fetching and decoding two instructions at a time, having three separate functional units (e.g., two integer arithmetic and one floating-point arithmetic), and having two instances of the write-back pipeline stage. The example assumes the following constraints on a six-instruction code fragment:

Decode		Execute		Write		Cycle
I1	I2					1
I3	I4	I1	I2			2
I3	I4	I1				3
	I4			I1	I2	4
I5	I6			I3	I4	5
	I6		I5			6
			I6			7
				I5	I6	8

(a) In-order issue and in-order completion

Decode		Execute		Write		Cycle
I1	I2					1
I3	I4	I1	I2			2
	I4	I1		I3		3
I5	I6			I4		4
	I6		I5			5
			I6			6
				I5		7
				I6		

(b) In-order issue and out-of-order completion

Decode		Window		Execute		Write		Cycle
I1	I2							1
I3	I4	I1,I2		I1	I2			2
I5	I6	I3,I4		I1		I3		3
		I4,I5,I6			I6	I4		4
		I5			I5			5
							I5	6

(c) Out-of-order issue and out-of-order completion

Figure 18.5 Superscalar Instruction Issue and Completion Policies

- I1 requires two cycles to execute.
- I3 and I4 conflict for the same functional unit.
- I5 depends on the value produced by I4.
- I5 and I6 conflict for a functional unit.

Instructions are fetched two at a time and passed to the decode unit. Because instructions are fetched in pairs, the next two instructions must wait until the pair of decode pipeline stages has cleared. To guarantee **in-order completion**, when there is a conflict for a functional unit or when a functional unit requires more than one cycle to generate a result, the issuing of instructions temporarily stalls.

In this example, the elapsed time from decoding the first instruction to writing the last results is eight cycles.

IN-ORDER ISSUE WITH OUT-OF-ORDER COMPLETION

Out-of-order completion is used in scalar RISC processors to improve the performance of instructions that require multiple cycles. [Figure 18.5b](#) illustrates its use on a superscalar processor. Instruction I2 is allowed to run to completion prior to I1. This allows I3 to be completed earlier, with the net result of a savings of one cycle.

With out-of-order completion, any number of instructions may be in the execution stage at any one time, up to the maximum degree of machine parallelism across all functional units. Instruction issuing is stalled by a resource conflict, a data dependency, or a procedural dependency.

In addition to the aforementioned limitations, a new dependency, which we referred to earlier as an **output dependency** (also called **write after write [WAW] dependency**), arises. The following code fragment illustrates this dependency (*op* represents any operation):

```
I1: R3 ← R3 op R5  
I2: R4 ← R3 + 1  
I3: R3 ← R5 + 1  
I4: R7 ← R3 op R4
```

Instruction I2 cannot execute before instruction I1, because it needs the result in register R3 produced in I1; this is an example of a true data dependency, as described in [Section 18.1](#). Similarly, I4 must wait for I3, because it uses a result produced by I3. What about the relationship between I1 and I3? There is no data dependency here, as we have defined it. However, if I3 executes to completion prior to I1, then the wrong value of the contents of R3 will be fetched for the execution of I4. Consequently, I3 must complete after I1 to produce the correct output values. To ensure this, the issuing of the third instruction must be stalled if its result might later be overwritten by an older instruction that takes longer to complete.

Out-of-order completion requires more complex instruction issue logic than in-order completion. In addition, it is more difficult to deal with instruction interrupts and exceptions. When an interrupt occurs, instruction execution at the current point is suspended, to be resumed later. The processor must assure that the resumption takes into account that, at the time of interruption, instructions ahead of the instruction that caused the interrupt may already have completed.

OUT-OF-ORDER ISSUE WITH OUT-OF-ORDER COMPLETION

With in-order issue, the processor will only decode instructions up to the point of a dependency or conflict. No additional instructions are decoded until the conflict is resolved. As a result, the processor cannot look ahead of the point of conflict to subsequent instructions that may be independent of those already in the pipeline and that may be usefully introduced into the pipeline.

To allow **out-of-order issue**, it is necessary to decouple the decode and execute stages of the pipeline. This is done with a buffer referred to as an **instruction window**. With this organization, after a processor has finished decoding an instruction, it is placed in the instruction window. As long as this buffer is not full, the processor can continue to fetch and decode new instructions. When a functional unit becomes available in the execute stage, an instruction from the instruction window may be issued to the execute stage. Any instruction may be issued, provided that (1) it needs the particular functional unit that is available, and (2) no conflicts or dependencies block this instruction. [Figure 18.6](#) suggests this organization.

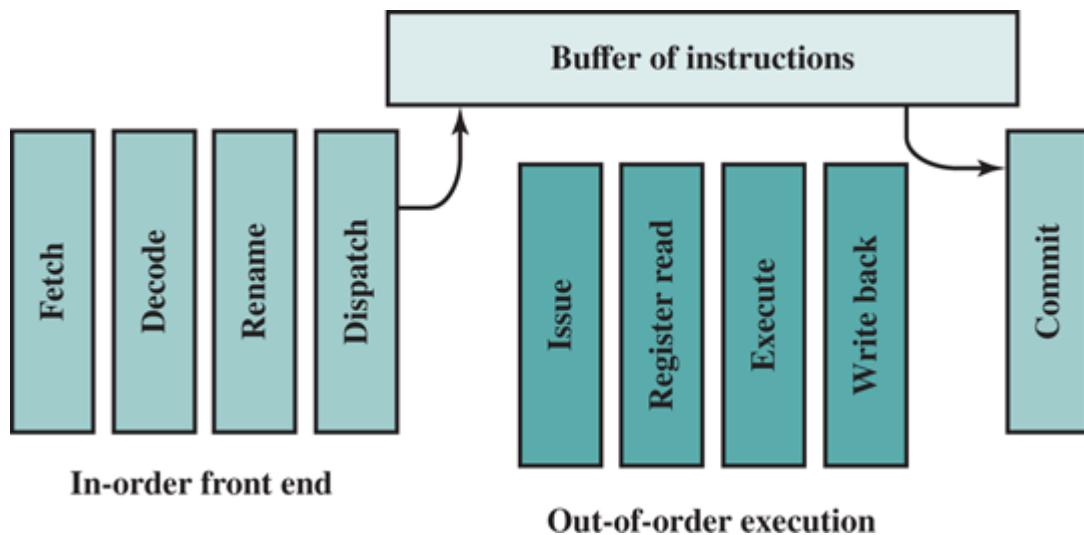

Figure 18.6 Organization for Out-of-Order Issue with Out-of-Order Completion

The result of this organization is that the processor has a lookahead capability, allowing it to identify independent instructions that can be brought into the execute stage. Instructions are issued from the instruction window with little regard for their original program order. As before, the only constraint is that the program execution behaves correctly.

Figures 18.5c illustrates this policy. During each of the first three cycles, two instructions are fetched into the decode stage. During each cycle, subject to the constraint of the buffer size, two instructions move from the decode stage to the instruction window. In this example, it is possible to issue instruction I6 ahead of I5 (recall that I5 depends on I4, but I6 does not). Thus, one cycle is saved in both the execute and write-back stages, and the end-to-end savings, compared with **Figure 18.5b**, is one cycle.

The instruction window is depicted in **Figure 18.5c** to illustrate its role. However, this window is not an additional pipeline stage. An instruction being in the window simply implies that the processor has sufficient information about that instruction to decide when it can be issued.

The out-of-order issue, out-of-order completion policy is subject to the same constraints described earlier. An instruction cannot be issued if it violates a dependency or conflict. The difference is that more instructions are available for issuing, reducing the probability that a pipeline stage will have to stall. In addition, a new dependency, which we referred to earlier as an **antidependency** (also called **write after read [WAR] dependency**), arises. The code fragment considered earlier illustrates this dependency:

```

I1: R3 ← R3 op R5
I2: R4 ← R3 + 1
I3: R3 ← R5 + 1
I4: R7 ← R3 op R4
  
```

Instruction I3 cannot complete execution before instruction I2 begins execution and has fetched its operands. This is so because I3 updates register R3, which is a source operand for I2. The term **antidependency** is used because the constraint is similar to that of a true data dependency, but reversed: Instead of the first instruction producing a value that the second instruction uses, the second instruction destroys a value that the first instruction uses.

Aleksandr Lukin/123RF

Reorder Buffer Simulator

Tomasulo's Algorithm Simulator

Alternative Simulation of Tomasulo's Algorithm

One common technique that is used to support out-of-order completion is the reorder buffer. The reorder buffer is temporary storage for results completed out of order that are then committed to the register file in program order. A related concept is Tomasulo's algorithm. [Appendix G](#) examines these concepts.

Register Renaming

When out-of-order instruction issuing and/or out-of-order instruction completion are allowed, we have seen that this gives rise to the possibility of WAW dependencies and WAR dependencies. These dependencies differ from RAW data dependencies and resource conflicts, which reflect the flow of data through a program and the sequence of execution. WAW dependencies and WAR dependencies, on the other hand, arise because the values in registers may no longer reflect the sequence of values dictated by the program flow.

When instructions are issued in sequence and complete in sequence, it is possible to specify the contents of each register at each point in the execution. When out-of-order techniques are used, the values in registers cannot be fully known at each point in time just from a consideration of the sequence of instructions dictated by the program. In effect, values are in conflict for the use of registers, and the processor must resolve those conflicts by occasionally stalling a pipeline stage.

Antidependencies and output dependencies are both examples of storage conflicts. Multiple instructions are competing for the use of the same register locations, generating pipeline constraints that retard performance. The problem is made more acute when register optimization techniques are used (as discussed in [Chapter 15](#)), because these compiler techniques attempt to maximize the use of registers, hence maximizing the number of storage conflicts.

One method for coping with these types of storage conflicts is based on a traditional resource-conflict solution: duplication of resources. In this context, the technique is referred to as **register renaming**. In essence, registers are allocated dynamically by the processor hardware, and they are associated with the values needed by instructions at various points in time. When a new register value is created (i.e., when an instruction executes that has a register as a destination operand), a new register is allocated for that value. Subsequent instructions that access that value as a source operand in that register must go through a renaming process: the register references in those instructions must be revised to refer to the register containing the needed value. Thus, the same original register reference in several different instructions may refer to different actual registers, if different values are intended.

Let us consider how register renaming could be used on the code fragment we have been examining:

```

I1: R3b ← R3a op R5a
I2: R4b ← R3b + 1
I3: R3c ← R5a + 1
I4: R7b ← R3c op R4b

```

The register reference without the subscript refers to the logical register reference found in the instruction. The register reference with the subscript refers to a hardware register allocated to hold a new value. When a new allocation is made for a particular logical register, subsequent instruction references to that logical register as a source operand are made to refer to the most recently allocated hardware register (recent in terms of the program sequence of instructions).

In this example, the creation of register $R3_c$ in instruction I3 avoids the WAR dependency on the second instruction and the WAW on the first instruction, and it does not interfere with the correct value being accessed by I4. The result is that I3 can be issued immediately; without renaming, I3 cannot be issued until the first instruction is complete and the second instruction is issued.

Aleksandr Lukin/123RF

Scoreboarding Simulator

An alternative to register renaming is scoreboardding. In essence, scoreboardding is a bookkeeping technique that allows instructions to execute whenever they are not dependent on previous instructions and no structural hazards are present. See [Appendix G](#) for a discussion.

Machine Parallelism

In the preceding discussion, we looked at three hardware techniques that can be used in a superscalar processor to enhance performance: duplication of resources, out-of-order issue, and renaming. One study that illuminates the relationship among these techniques was reported in [SMIT89]. The study made use of a simulation that modeled a machine with the characteristics of the MIPS R2000, augmented with various superscalar features. A number of different program sequences were simulated.

Figure 18.7 shows the results. In each of the graphs, the vertical axis corresponds to the mean speedup of the superscalar machine over the scalar machine. The horizontal axis shows the results for four alternative processor organizations. The base machine does not duplicate any of the functional units, but it can issue instructions out of order. The second configuration duplicates the load/store functional unit that accesses a data cache. The third configuration duplicates the ALU, and the fourth configuration duplicates both load/store and ALU. In each graph, results are shown for instruction window sizes of 8, 16, and 32 instructions, which dictates the amount of lookahead the processor can do. The difference between the two graphs is that, in the second, register renaming is allowed. This is equivalent to saying that the first graph reflects a machine that is limited by all dependencies, whereas the second graph corresponds to a machine that is limited only by true dependencies.

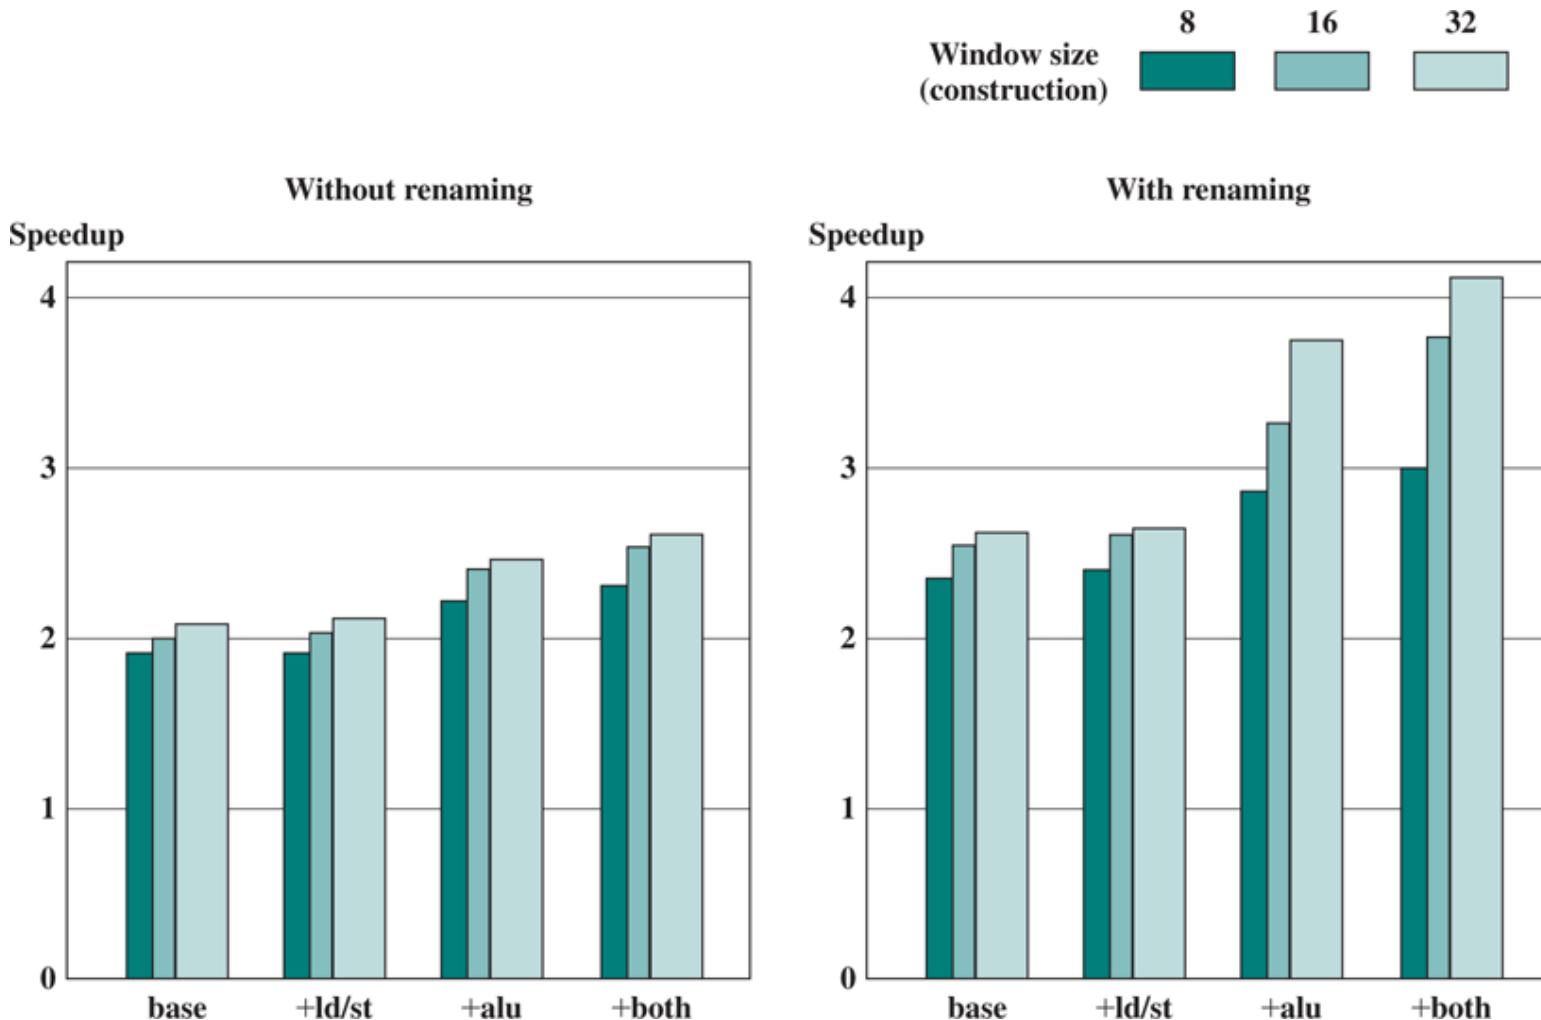

Figure 18.7 Speedups of Various Machine Organizations without Procedural Dependencies

The two graphs, combined, yield some important conclusions. The first is that it is probably not worthwhile to add functional units without register renaming. There is some slight improvement in performance, but at the cost of increased hardware complexity. With register renaming, which eliminates antidependencies and output dependencies, noticeable gains are achieved by adding more functional units. Note, however, that there is a significant difference in the amount of gain achievable between using an instruction window of 8 versus a larger instruction window. This indicates that if the instruction window is too small, data dependencies will prevent effective utilization of the extra functional units; the processor must be able to look quite far ahead to find independent instructions to utilize the hardware more fully.

Aleksandr Lukin/123RF

Pipeline with Static vs. Dynamic Scheduling—Simulator

Branch Prediction

Any high-performance pipelined machine must address the issue of dealing with branches. For example, the Intel 80486 addressed the problem by fetching both the next sequential instruction after

a branch and speculatively fetching the branch target instruction. However, because there are two pipeline stages between prefetch and execution, this strategy incurs a two-cycle delay when the branch gets taken.

With the advent of RISC machines, the delayed branch strategy was explored. This allows the processor to calculate the result of conditional branch instructions before any unusable instructions have been prefetched. With this method, the processor always executes the single instruction that immediately follows the branch. This keeps the pipeline full while the processor fetches a new instruction stream.

With the development of superscalar machines, the delayed branch strategy has less appeal. The reason is that multiple instructions need to execute in the delay slot, raising several problems relating to instruction dependencies. Thus, superscalar machines have returned to pre-RISC techniques of **branch prediction**. Some, like the PowerPC 601, use a simple static branch prediction technique. More sophisticated processors, such as the PowerPC 620 and the Pentium 4, use dynamic branch prediction based on branch history analysis.

Superscalar Execution

We are now in a position to provide an overview of superscalar execution of programs; this is illustrated in **Figure 18.8**. The program to be executed consists of a linear sequence of instructions. This is the static program as written by the programmer or generated by the compiler. The instruction fetch stage, which includes branch prediction, is used to form a dynamic stream of instructions. This stream is examined for dependencies, and the processor may remove artificial dependencies. The processor then dispatches the instructions into a window of execution. In this window, instructions no longer form a sequential stream, but are structured according to their true data dependencies. The processor executes each instruction in an order determined by the true data dependencies and hardware resource availability. Finally, instructions are conceptually put back into sequential order and their results are recorded.

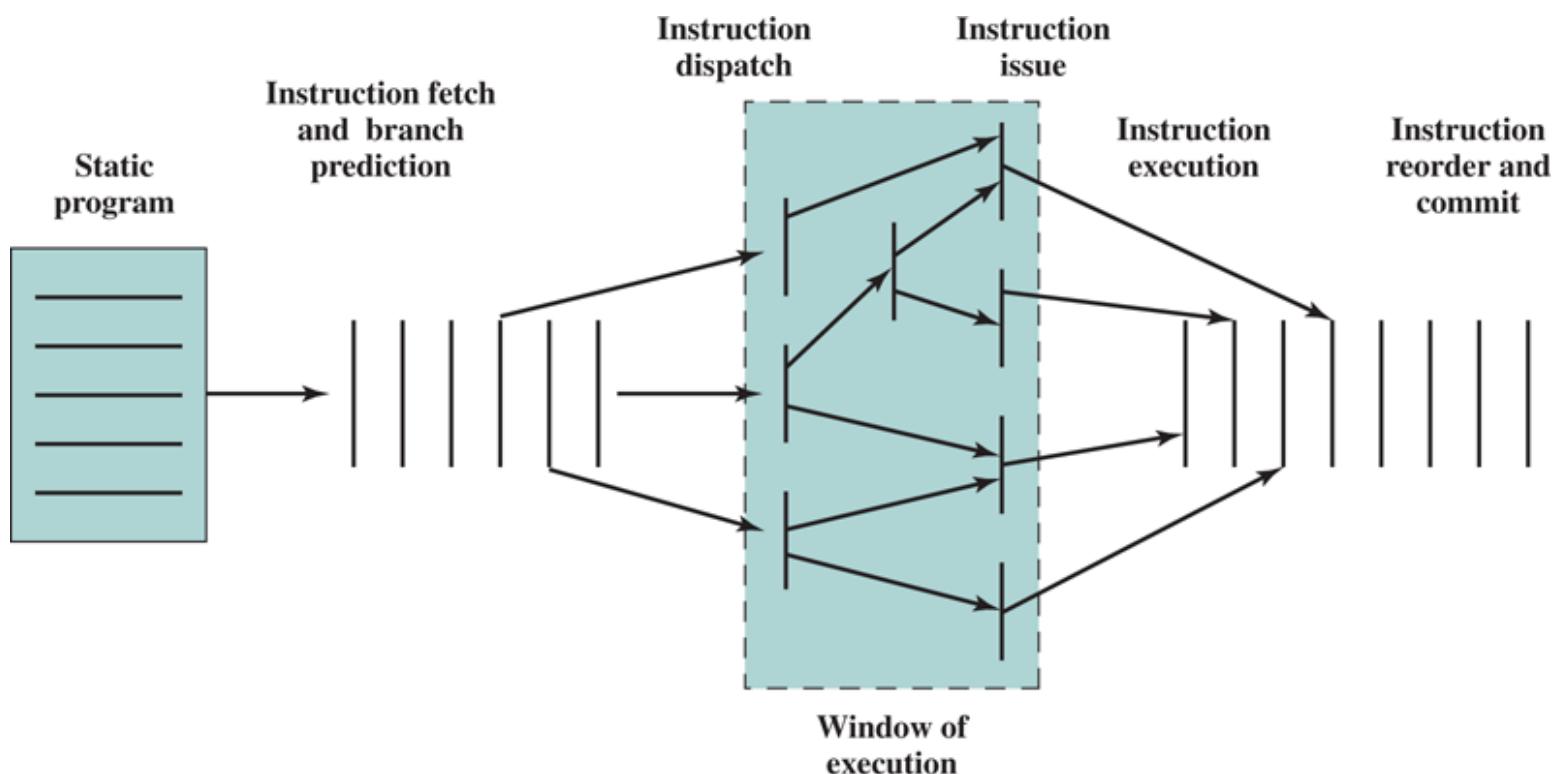

Figure 18.8 Conceptual Depiction of Superscalar Processing

The final step mentioned in the preceding paragraph is referred to as **committing**, or **retiring**, the instruction. This step is needed for the following reason. Because of the use of parallel, multiple pipelines, instructions may complete in an order different from that shown in the static program. Further, the use of branch prediction and speculative execution means that some instructions may complete execution and then must be abandoned because the branch they represent is not taken. Therefore, permanent storage and program-visible registers cannot be updated immediately when instructions complete execution. Results must be held in some sort of temporary storage that is usable by dependent instructions and then made permanent when it is determined that the sequential model would have executed the instruction.

Superscalar Implementation

Based on our discussion so far, we can make some general comments about the processor hardware required for the superscalar approach. [SMIT95] lists the following key elements:

- Instruction fetch strategies that simultaneously fetch multiple instructions, often by predicting the outcomes of, and fetching beyond, conditional branch instructions. These functions require the use of multiple pipeline fetch and decode stages, and branch prediction logic.
- Logic for determining true dependencies involving register values, and mechanisms for communicating these values to where they are needed during execution.
- Mechanisms for initiating, or issuing, multiple instructions in parallel.
- Resources for parallel execution of multiple instructions, including multiple pipelined functional units and memory hierarchies capable of simultaneously servicing multiple memory references.
- Mechanisms for committing the process state in correct order.

18.3 Intel Core Microarchitecture

Although the concept of superscalar design is generally associated with the RISC architecture, the same superscalar principles can be applied to a CISC machine. Perhaps the most notable example of this is the Intel x86 architecture. The evolution of superscalar concepts in the Intel line is interesting to note. The 386 is a traditional CISC nonpipelined machine. The 486 introduced the first pipelined x86 processor, reducing the average latency of integer operations from between two and four cycles to one cycle, but still limited to executing a single instruction each cycle, with no superscalar elements. The original Pentium had a modest superscalar component, consisting of the use of two separate integer execution units. The Pentium Pro introduced a full-blown superscalar design with out-of-order execution. Subsequent x86 models have refined and enhanced the superscalar design.

Figure 18.9 shows the current version of the x86 pipeline architecture. Intel refers to a pipeline architecture as a *microarchitecture*. The microarchitecture underlies and implements the machine's instruction set architecture. The microarchitecture is referred to as the Intel Core Microarchitecture. It is implemented on each processor core in the Intel Core 2 and Intel Xeon processor families. There is also an Enhanced Intel Core Microarchitecture. One key difference between the two microarchitectures is that the Enhanced Intel Core Microarchitecture provides a third level of cache.

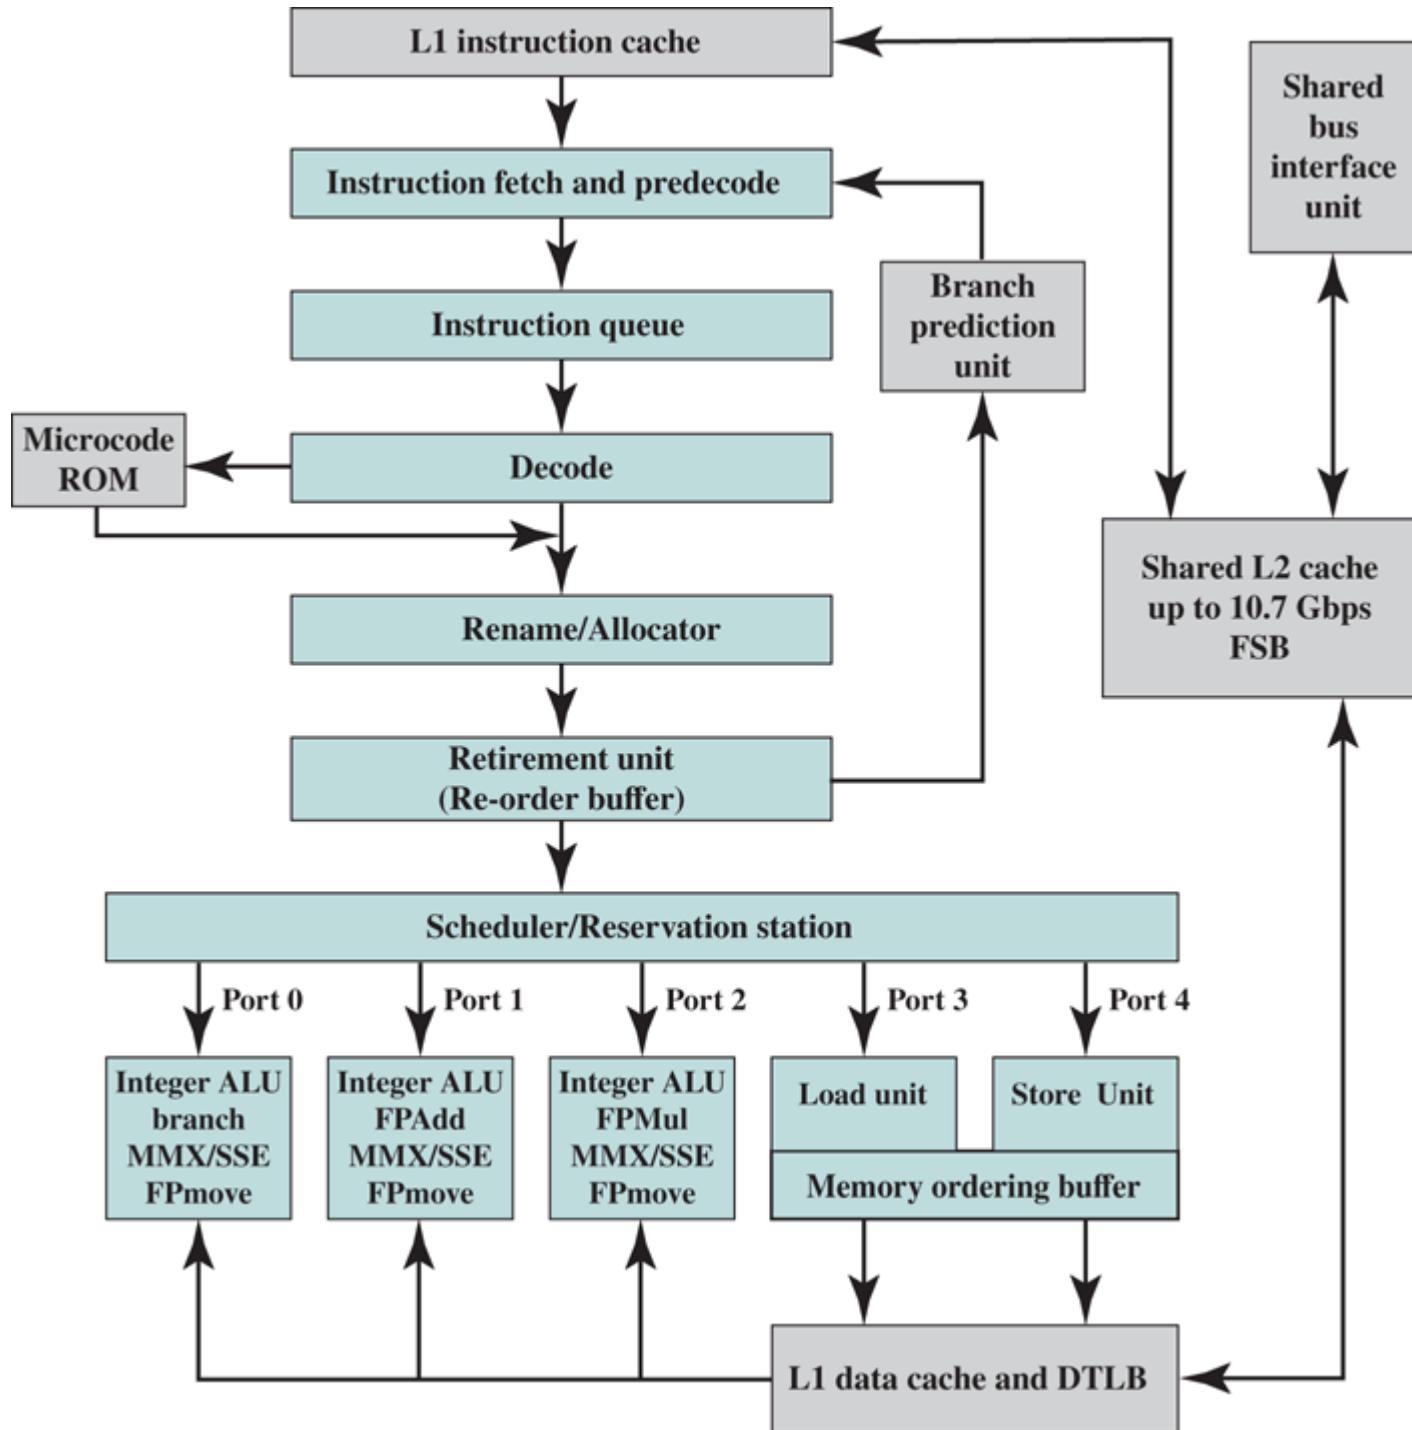

Figure 18.9 Intel Core Microarchitecture

Table 18.2 shows some of the parameters and performance characteristics of the cache architecture. All of the caches use a writeback update policy. When an instruction reads data from a memory location, the processor looks for the cache line that contains this data in the caches and main memory in the following order:

Table 18.2 Cache/Memory Parameters and Performance of Processors Based on Intel Core Microarchitecture

Notes:

1. Intel Core Microarchitecture
2. Enhanced Intel Core Microarchitecture

(a) Cache Parameters

Cache Level	Capacity	Associativity (ways)	Line Size (bytes)	Writeback Update Policy
L1 data	32 kB	8	64	Writeback
L1 instruction	32 kB	8	N/A	N/A
L2 (shared) ¹	2, 4 MB	8 or 16	64	Writeback
L2 (shared) ²	3, 6 MB	12 or 24	64	Writeback
L3 (shared) ²	8, 12, 16 MB	15	64	Writeback

(b) Load/Store Performance

Data Locality	Load		Store	
	Latency	Throughput	Latency	Throughput
L1 data cache	3 clock cycles	1 clock cycle	2 clock cycles	3 clock cycles
L1 data cache of the other core in modified state	14clock cycles + 5.5bus cycles	14clock cycles + 5.5bus cycles	14clock cycles + 5.5bus cycles	N/A
L2 cache	14	3	14	3
Memory	14clock cycles + 5.5bus cycles + memory latency	Depends on bus read protocol	14clock cycles + 5.5bus cycles + memory latency	Depends on bus read protocol

1. L1 data cache of the initiating core
2. L1 data cache of other cores and L2 cache
3. System memory

The cache line is taken from the L1 data cache of another core only if it is modified, ignoring the cache line availability or state in the L2 cache. **Table 18.2b** shows the characteristics of fetching the first four bytes of different localities from the memory cluster. The latency column provides an estimate of access latency. However, the actual latency can vary depending on the load of cache, memory components, and their parameters.

The pipeline of the Intel Core microarchitecture contains:

- An in-order issue front end that fetches instruction streams from memory, with four instruction decoders to supply decoded instructions to the out-of-order execution core. Each instruction is translated into one or more fixed-length RISC instructions, known as **micro-operations**, or **micro-ops**.
- An out-of-order superscalar execution core that can issue up to six micro-ops per cycle and reorder micro-ops to execute as soon as sources are ready and execution resources are available.
- An in-order retirement unit that ensures the results of execution of micro-ops are processed and architectural states and the processor's register set are updated according to the original program order.

In effect, the Intel Core Microarchitecture implements a CISC instruction set architecture on a RISC microarchitecture. The inner RISC micro-ops pass through a pipeline with at least 14 stages; in some cases, the micro-op requires multiple execution stages, resulting in an even longer pipeline. This contrasts with the five-stage pipeline (**Figure 16.21**) used on the earlier Intel x86 processors and on the Pentium.

Front End

The front end needs to supply decoded instructions (micro-ops) and sustain the stream to a six-issue wide out-of-order engine. It consists of three major components: branch prediction unit (BPU), instruction fetch and predecode unit, and instruction queue and decode unit.

BRANCH PREDICTION UNIT

This unit helps the instruction fetch unit fetch the most likely instruction to be executed by predicting the various branch types: conditional, indirect, direct, call, and return. The BPU uses dedicated hardware for each branch type. Branch prediction enables the processor to begin executing instructions long before the branch outcome is decided.

The microarchitecture uses a dynamic branch prediction strategy based on the history of recent executions of branch instructions. A branch target buffer (BTB) is maintained that caches information about recently encountered branch instructions. Whenever a branch instruction is encountered in the instruction stream, the BTB is checked. If an entry already exists in the BTB, then the instruction unit is guided by the history information for that entry in determining whether to predict that the branch is taken. If a branch is predicted, then the branch destination address associated with this entry is used for prefetching the branch target instruction.

Once the instruction is executed, the history portion of the appropriate entry is updated to reflect the result of the branch instruction. If this instruction is not represented in the BTB, then the address of this instruction is loaded into an entry in the BTB; if necessary, an older entry is deleted.

The description of the preceding two paragraphs fits, in general terms, the branch prediction strategy used on the original Pentium model, as well as the later Pentium models, including current Intel models. However, in the case of the Pentium, a relatively simple 2-bit history scheme is used. The later models have much longer pipelines (14 stages for the Intel Core Microarchitecture compared with 5 stages for the Pentium) and therefore the penalty for misprediction is greater. Accordingly, the later models use a more

elaborate branch prediction scheme with more history bits to reduce the misprediction rate.

Conditional branches that do not have a history in the BTB are predicted using a static prediction algorithm, according to the following rules:

- For branch addresses that are not instruction pointer (IP) relative, predict taken if the branch is a return and not taken otherwise.
- For IP-relative backward conditional branches, predict taken. This rule reflects the typical behavior of loops.
- For IP-relative forward conditional branches, predict not taken.

INSTRUCTION FETCH AND PREDECODE UNIT

The instruction fetch unit comprises the instruction translation lookaside buffer (ITLB), an instruction prefetcher, the instruction cache, and the predecode logic.

Instruction fetch is performed from an L1 instruction cache. When an L1 cache miss occurs, the in-order front end feeds new instructions into the L1 cache from the L2 cache 64 bytes at a time. As a default, instructions are fetched sequentially, so that each L2 cache line fetch includes the next instruction to be fetched. Branch prediction via the branch prediction unit may alter this sequential fetch operation. The ITLB translates the linear IP address given it into physical addresses needed to access the L2 cache. Static branch prediction in the front end is used to determine which instructions to fetch next.

The predecode unit accepts the sixteen bytes from the instruction cache or prefetch buffers and carries out the following tasks:

- Determine the length of the instructions.
- Decode all prefixes associated with instructions.
- Mark various properties of instructions for the decoders (for example, “is branch”).

The predecode unit can write up to six instructions per cycle into the instruction queue. If a fetch contains more than six instructions, the predecoder continues to decode up to six instructions per cycle until all instructions in the fetch are written to the instruction queue. Subsequent fetches can only enter predecoding after the current fetch completes.

INSTRUCTION QUEUE AND DECODE UNIT

Fetched instructions are placed in an instruction queue. From there, the decode unit scans the bytes to determine instruction boundaries; this is a necessary operation because of the variable length of x86 instructions. The decoder translates each machine instruction into from one to four micro-ops, each of which is a 118-bit RISC instruction. Note for comparison that most pure RISC machines have an instruction length of just 32 bits. The longer micro-op length is required to accommodate the more complex x86 instructions. Nevertheless, the micro-ops are easier to manage than the original instructions from which they derive.

A few instructions require more than four micro-ops. These instructions are transferred to microcode ROM, which contains the series of micro-ops (five or more) associated with a complex machine instruction. For example, a string instruction may translate into a very large (even hundreds), repetitive sequence of micro-ops. Thus, the microcode ROM is a microprogrammed control unit in the sense discussed in Part Six.

The resulting micro-op sequence is delivered to the rename/allocator module.

Out-of-Order Execution Logic

This part of the processor reorders micro-ops to allow them to execute as quickly as their input operands are ready.

ALLOCATE

The allocate stage allocates resources required for execution. It performs the following functions:

- If a needed resource, such as a register, is unavailable for one of the three micro-ops arriving at the allocator during a clock cycle, the allocator stalls the pipeline.
- The allocator allocates a reorder buffer (ROB) entry, which tracks the completion status of one of the 126 micro-ops that could be in process at any time.³

³ See [Appendix G](#) for a discussion of reorder buffers.

- The allocator allocates one of the 128 integer or floating-point register entries for the result data value of the micro-op, and possibly a load or store buffer used to track one of the 48 loads or 24 stores in the machine pipeline.
- The allocator allocates an entry in one of the two micro-op queues in front of the instruction schedulers.

The ROB is a circular buffer that can hold up to 126 micro-ops and also contains the 128 hardware registers. Each buffer entry consists of the following fields:

- **State:** Indicates whether this micro-op is scheduled for execution, has been dispatched for execution, or has completed execution and is ready for retirement.
- **Memory Address:** The address of the Pentium instruction that generated the micro-op.
- **Micro-op:** The actual operation.
- **Alias Register:** If the micro-op references one of the 16 architectural registers, this entry redirects that reference to one of the 128 hardware registers.

Micro-ops enter the ROB in order. Micro-ops are then dispatched from the ROB to the Dispatch/Execute unit out of order. The criterion for dispatch is that the appropriate execution unit and all necessary data items required for this micro-op are available. Finally, micro-ops are retired from the ROB in order. To accomplish in-order retirement, micro-ops are retired oldest first after each micro-op has been designated as ready for retirement.

REGISTER RENAMING

The rename stage remaps references to the 16 architectural registers (8 floating-point registers, plus EAX, EBX, ECX, EDX, ESI, EDI, EBP, and ESP) into a set of 128 physical registers. The stage removes false dependencies caused by a limited number of architectural registers while preserving the true data dependencies (reads after writes).

MICRO-OP QUEUING

After resource allocation and register renaming, micro-ops are placed in one of two micro-op queues, where they are held until there is room in the schedulers. One of the two queues is for memory operations (loads and stores) and the other for micro-ops that do not involve memory references. Each queue obeys a FIFO (first-in-first-out) discipline, but no order is maintained between queues. That is, a micro-op may be read out of one queue out of order with respect to micro-ops in the other queue. This provides greater flexibility to the schedulers.

MICRO-OP SCHEDULING AND DISPATCHING

The schedulers are responsible for retrieving micro-ops from the micro-op queues and dispatching these

for execution. Each scheduler looks for micro-ops whose status indicates that the micro-op has all of its operands. If the execution unit needed by that micro-op is available, then the scheduler fetches the micro-op and dispatches it to the appropriate execution unit. Up to six micro-ops can be dispatched in one cycle. If more than one micro-op is available for a given execution unit, then the scheduler dispatches them in sequence from the queue. This is a sort of FIFO discipline that favors in-order execution, but by this time the instruction stream has been so rearranged by dependencies and branches that it is substantially out of order.

Four ports attach the schedulers to the execution units. Port 0 is used for both integer and floating-point instructions, with the exception of simple integer operations and the handling of branch mispredictions, which are allocated to Port 1. In addition, MMX execution units are allocated between these two ports. The remaining ports are for memory loads and stores.

Integer and Floating-Point Execution Units

The integer and floating-point register files are the source for pending operations by the execution units. The execution units retrieve values from the register files as well as from the L1 data cache. A separate pipeline stage is used to compute flags (e.g., zero, negative); these are typically the input to a branch instruction.

A subsequent pipeline stage performs branch checking. This function compares the actual branch result with the prediction. If a branch prediction turns out to have been wrong, then there are micro-operations in various stages of processing that must be removed from the pipeline. The proper branch destination is then provided to the Branch Predictor during a drive stage, which restarts the whole pipeline from the new target address.

18.4 ARM Cortex-A8

Recent implementations of the ARM architecture have seen the introduction of superscalar techniques in the instruction pipeline. In this section, we focus on the ARM Cortex-A8, which provides a good example of a RISC-based superscalar design.

The Cortex-A8 is in the ARM family of processors that ARM refers to as application processors. An ARM application processor is an embedded processor running complex operating systems for wireless, consumer and imaging applications. The Cortex-A8 targets a wide variety of mobile and consumer applications including mobile phones, set-top boxes, gaming consoles and automotive navigation/entertainment systems.

Figure 18.10 shows a logical view of the Cortex-A8 architecture, emphasizing the flow of instructions among functional units. The main instruction flow is through three functional units that implement a dual, in-order-issue, 13-stage pipeline. The Cortex designers decided to stay with in-order issue to keep additional power required to a minimum. Out-of-order issue and **retire** can require extensive amounts of logic consuming extra power.

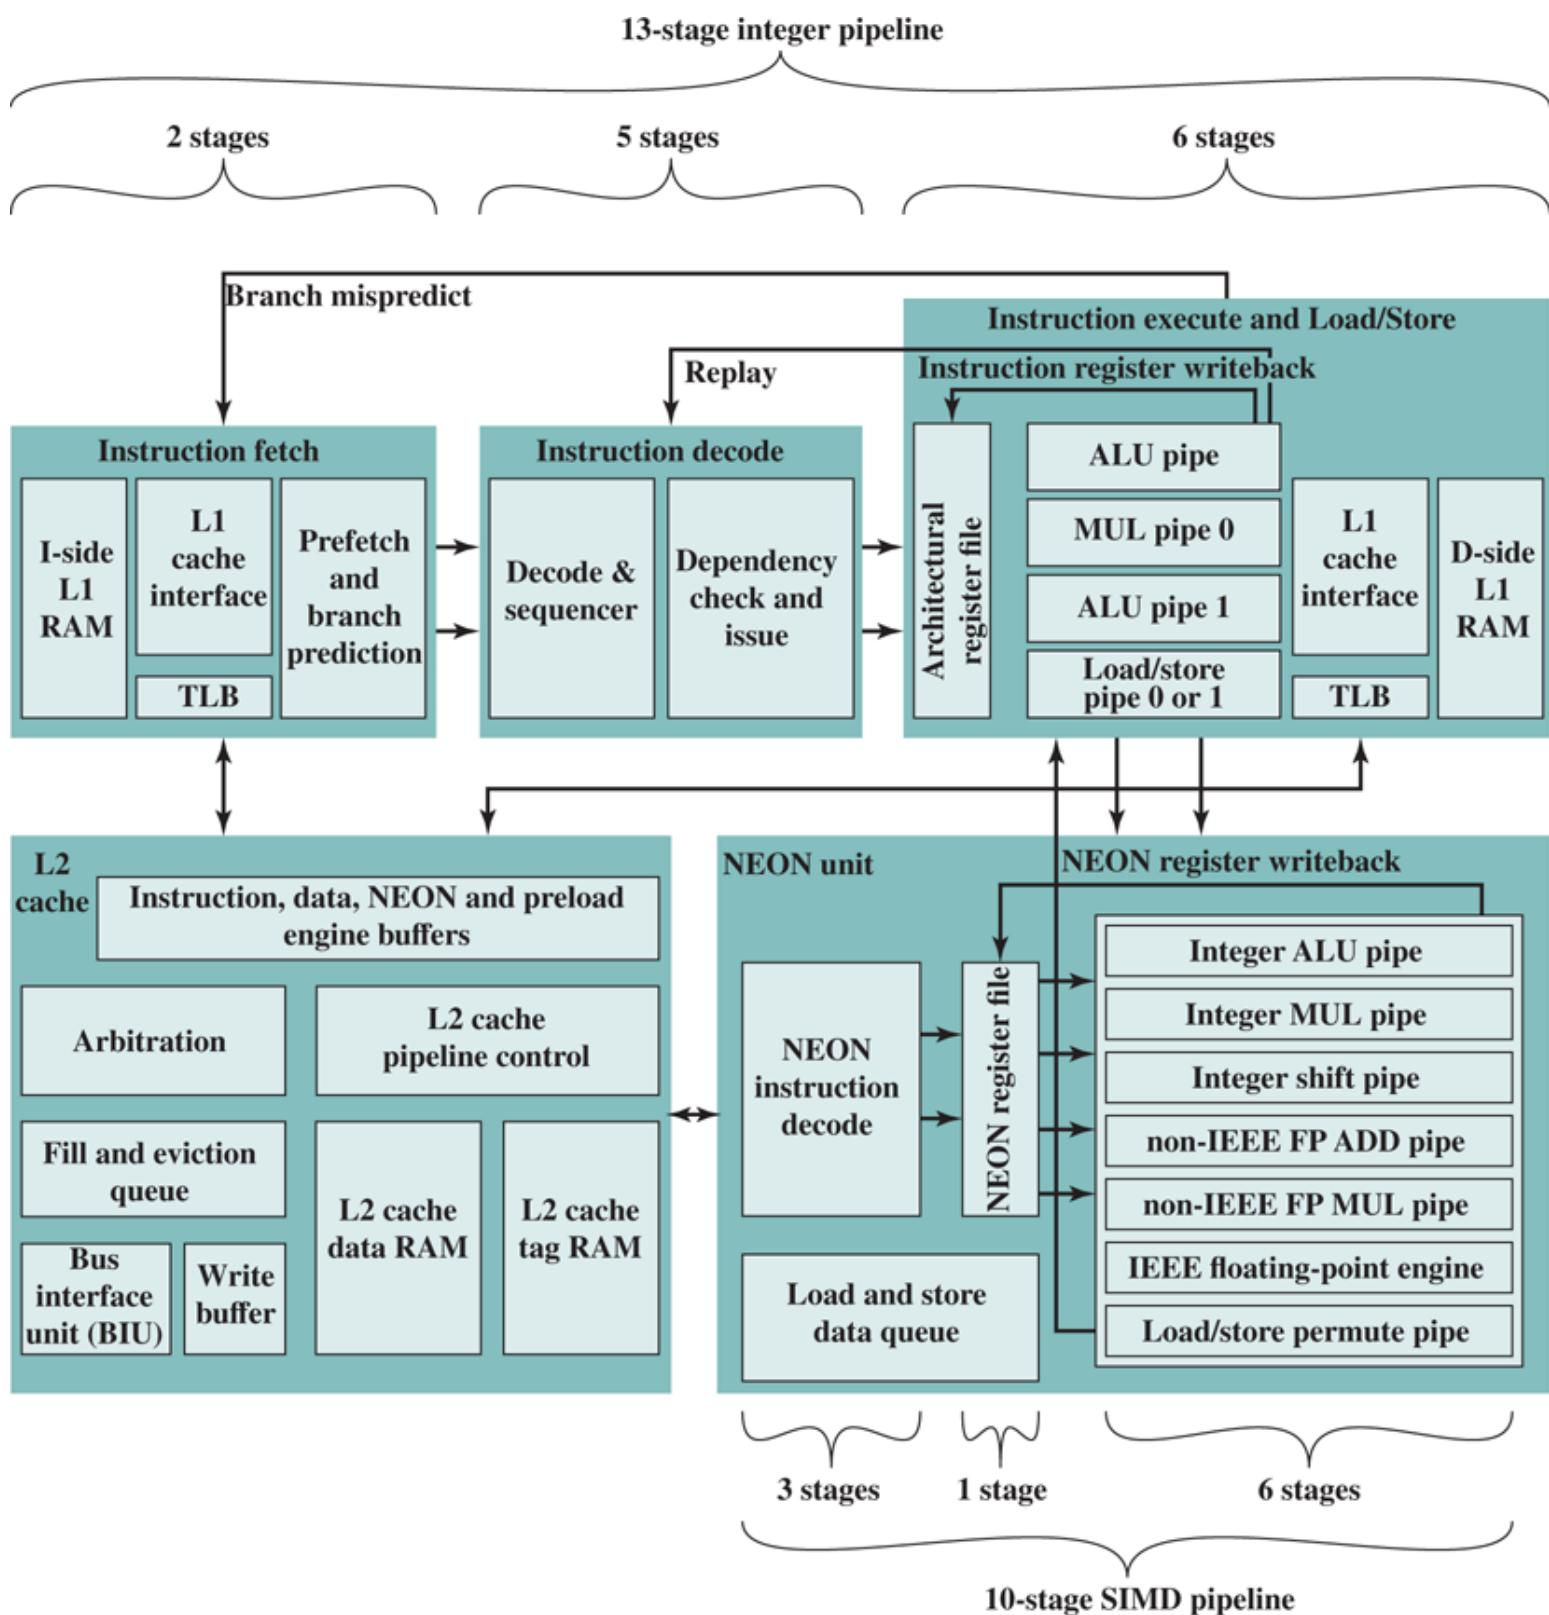

Figure 18.10 Architectural Block Diagram of ARM Cortex-A8

Figure 18.11 shows the details of the main Cortex-A8 pipeline. There is a separate unit for SIMD (single-instruction-multiple-data) that implements a 10-stage pipeline.

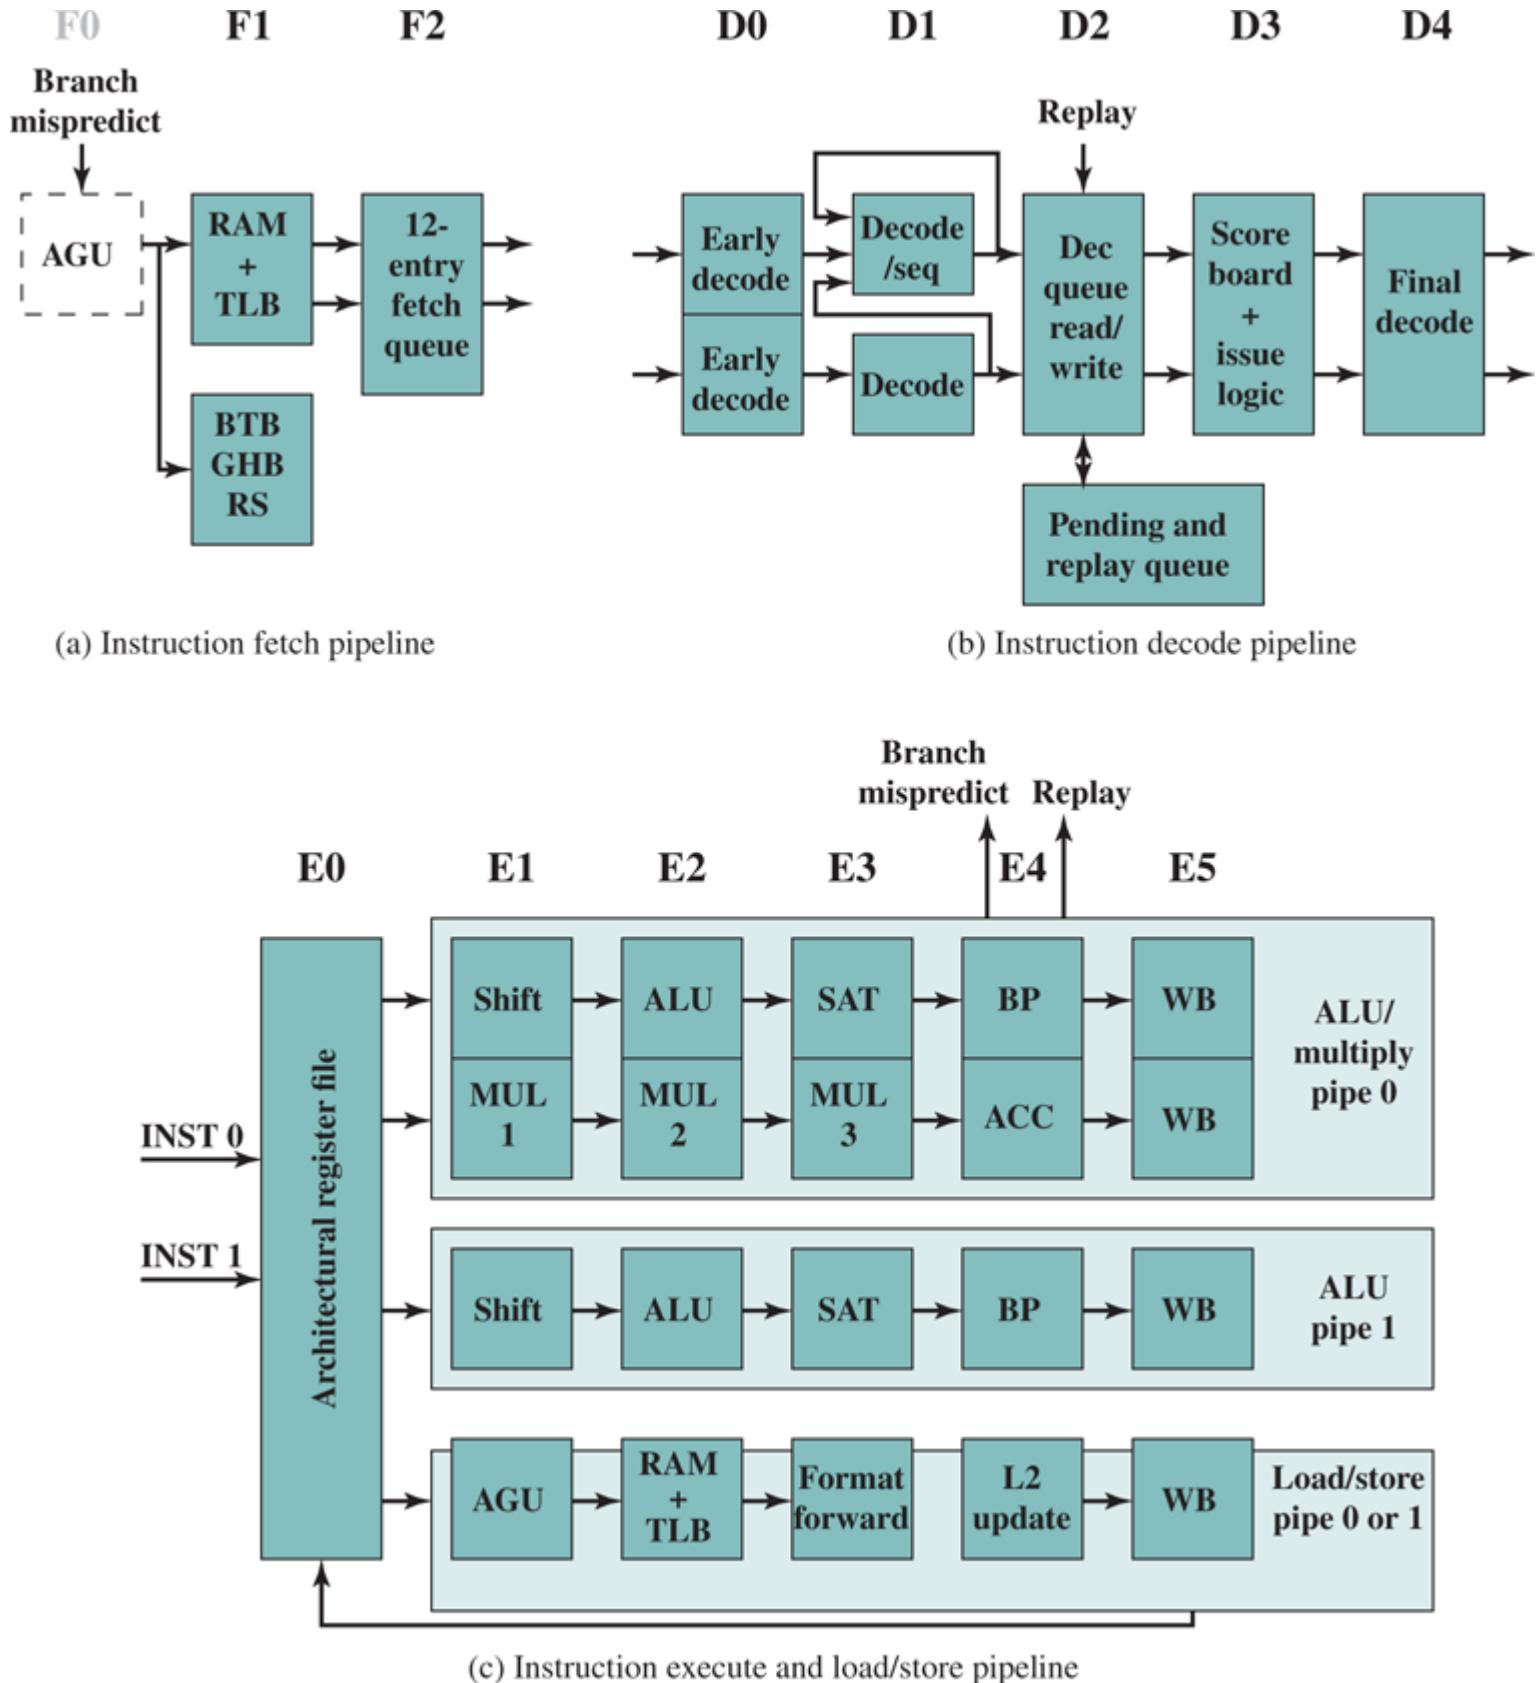

Figure 18.11 ARM Cortex-A8 Integer Pipeline

Instruction Fetch Unit

The instruction fetch unit predicts the instruction stream, fetches instructions from the L1 instruction cache, and places the fetched instructions into a buffer for consumption by the decode pipeline. The instruction fetch unit also includes the L1 instruction cache. Because there can be several unresolved branches in the pipeline, instruction fetches are speculative, meaning there is no guarantee that they

are executed. A branch or exceptional instruction in the code stream can cause a pipeline flush, discarding the currently fetched instructions. The instruction fetch unit can fetch up to four instructions per cycle, and goes through the following stages:

F0: The address generation unit (AGU) generates a new virtual address. Normally, this address is the next address sequentially from the preceding fetch address. The address can also be a branch target address provided by a branch prediction for a previous instruction. F0 is not counted as part of the 13-stage pipeline, because ARM processors have traditionally defined instruction cache access as the first stage.

F1: The calculated address is used to fetch instructions from the L1 instruction cache. In parallel, the fetch address is used to access the branch prediction arrays to determine if the next fetch address should be based on a branch prediction.

F3: Instruction data are placed into the instruction queue. If an instruction results in branch prediction, the new target address is sent to the address generation unit.

To minimize the branch penalties typically associated with a deeper pipeline, the Cortex-A8 processor implements a two-level global history branch predictor, consisting of the branch target buffer (BTB) and the global history buffer (GHB). These data structures are accessed in parallel with instruction fetches. The BTB indicates whether or not the current fetch address will return a branch instruction and its branch target address. It contains 512 entries. On a hit in the BTB a branch is predicted and the GHB is accessed. The GHB consists of 4096 2-bit counters that encode the strength and direction information of branches. The GHB is indexed by 10-bit history of the direction of the last ten branches encountered and 4 bits of the PC. In addition to the dynamic branch predictor, a return stack is used to predict subroutine return addresses. The return stack has eight 32-bit entries that store the link register value in r14 and the ARM or Thumb state of the calling function. When a return-type instruction is predicted taken, the return stack provides the last pushed address and state.

The instruction fetch unit can fetch and queue up to 12 instructions. It issues instructions to the decode unit two at a time. The queue enables the instruction fetch unit to prefetch ahead of the rest of the integer pipeline and build up a backlog of instructions ready for decoding.

Instruction Decode Unit

The instruction decode unit decodes and sequences all ARM and Thumb instructions. It has a dual pipeline structure, called *pipe0* and *pipe1*, so that two instructions can progress through the unit at a time. When two instructions are issued from the instruction decode pipeline, *pipe0* will always contain the older instruction in program order. This means that if the instruction in *pipe0* cannot issue, then the instruction in *pipe1* will not issue. All issued instructions progress in order down the execution pipeline with results written back into the register file at the end of the execution pipeline. This in-order instruction issue and retire prevents WAR hazards and keeps tracking of WAW hazards and recovery from flush conditions straightforward. Thus, the main concern of the instruction decode pipeline is the prevention of RAW hazards.

Each instruction goes through five stages of processing.

D0: Thumb instructions are decompressed into 32-bit ARM instructions. A preliminary decode function is performed.

D1: The instruction decode function is completed.

D2: This stage writes instructions into and reads instructions from the pending/replay queue structure.

D3: This stage contains the instruction scheduling logic. A scoreboard predicts register availability

using static scheduling techniques.⁴ Hazard checking is also done at this stage.

⁴ See [Appendix G](#) for a discussion of scoreboardng.

D4: Performs the final decode for all the control signals required by the integer execute and load/store units.

In the first two stages, the instruction type, the source and destination operands, and resource requirements for the instruction are determined. A few less commonly used instructions are referred to as multicycle instructions. The D1 stage breaks these instructions down into multiple instruction opcodes that are sequenced individually through the execution pipeline.

The pending queue serves two purposes. First, it prevents a stall signal from D3 from rippling any further up the pipeline. Second, by buffering instructions, there should always be two instructions available for the dual pipeline. In the case where only one instruction is issued, the pending queue enables two instructions to proceed down the pipeline together, even if they were originally sent from the fetch unit in different cycles.

The replay operation is designed to deal with the effects of the memory system on instruction timing. Instructions are statically scheduled in the D3 stage based on a prediction of when the source operand will be available. Any stall from the memory system can result in the minimum of an 8-cycle delay. This 8-cycle delay minimum is balanced with the minimum number of possible cycles to receive data from the L2 cache in the case of an L1 load miss. [Table 18.3](#) gives the most common cases that can result in an instruction replay because of a memory system stall.

Table 18.3 Cortex-A8 Memory System Effects on Instruction Timings

Replay Event	Delay	Description
Load data miss	8 cycles	<ol style="list-style-type: none">1. A load instruction misses in the L1 data cache.2. A request is then made to the L2 data cache.3. If a miss also occurs in the L2 data cache, then a second replay occurs. The number of stall cycles depends on the external system memory timing. The minimum time required to receive the critical word for an L2 cache miss is approximately 25 cycles, but can be much longer because of L3 memory latencies.
Data TLB miss	24 cycles	<ol style="list-style-type: none">1. A table walk because of a miss in the L1 TLB causes a 24-cycle delay, assuming the translation table entries are found in the L2 cache.2. If the translation table entries are not present in the L2 cache, the number of stall cycles depends on the external system memory timing.
Store buffer full	8 cycles	<ol style="list-style-type: none">1. A store instruction miss does not result in any stalls unless the store buffer is full.

	plus latency to drain fill buffer	2. In the case of a full store buffer, the delay is at least eight cycles. The delay can be more if it takes longer to drain some entries from the store buffer.
Unaligned load or store request	8 cycles	1. If a load instruction address is unaligned and the full access is not contained within a 128-bit boundary, there is a 8-cycle penalty. 2. If a store instruction address is unaligned and the full access is not contained within a 64-bit boundary, there is a 8-cycle penalty.

To deal with these stalls, a recovery mechanism is used to flush all subsequent instructions in the execution pipeline and reissue (replay) them. To support replay, instructions are copied into the replay queue before they are issued and removed as they write back their results and retire. If a replay signal is issued, instructions are retrieved from the replay queue and reenter the pipeline.

The decode unit issues two instructions in parallel to the execution unit, unless it encounters an issue restriction. **Table 18.4** shows the most common restriction cases.

Table 18.4 Cortex-A8 Dual-Issue Restrictions

Restriction Type	Description	Example	Cycle	Restriction
Load/store resource hazard	There is only one LS pipeline. Only one LS instruction can be issued per cycle. It can be in pipeline 0 or pipeline 1.	LDR r5, [r6] STR r7, [r8] MOV r9, r10	1 2 2	Wait for LS unit Dual issue possible
Multiply resource hazard	There is only one multiply pipeline, and it is only available in pipeline 0.	ADD r1, r2, r3 MUL r4, r5, r6 MUL r7, r8, r9	1 2 3	Wait for pipeline 0 Wait for multiply unit
Branch resource hazard	There can be only one branch per cycle. It can be in pipeline 0 or pipeline 1. A branch is any instruction that changes the PC.	BX r1 BEQ	1 2	Wait for branch Dual issue

		0x1000 ADD r1, r2, r3	2	possible
Data output hazard	Instructions with the same destination cannot be issued in the same cycle. This can happen with conditional code.	MOVEQ r1, r2 MOVNE r1, r3 LDR r5, [r6]	1 2 2	Wait because of output dependency Dual issue possible
Data source hazard	Instructions cannot be issued if their data is not available. See the scheduling tables for source requirements and stages results.	ADD r1, r2, r3 ADD r4, r1, r6 LDR r7, [r4]	1 2 4	Wait for r1 Wait two cycles for r4
Multi-cycle instructions	Multi-cycle instructions must issue in pipeline 0 and can only dual issue in their last iteration.	MOV r1, r2 LDM r3, {r4-r7} LDM (cycle 2) LDM (cycle 3) ADD r8, r9, r10	1 2 3 4 4	Wait for pipeline 0, transfer r4 Transfer r5, r6 Transfer r7 Dual issue possible on last transfer

Integer Execute Unit

The instruction execute unit consists of two symmetric arithmetic logic unit (ALU) pipelines, an address generator for load and store instructions, and the multiply pipeline. The execute pipelines also perform register write back. The instruction execute unit:

- Executes all integer ALU and multiply operations, including flag generation.
- Generates the virtual addresses for loads and stores and the base write-back value, when required.
- Supplies formatted data for stores and forwards data and flags.
- Processes branches and other changes of instruction stream, and evaluates instruction condition codes.

For ALU instructions, either pipeline can be used, consisting of the following stages:

E0: Access register file. Up to six registers can be read from the register file for two instructions.

E1: The barrel shifter (see [Figure 16.25](#)) performs its function, if needed.

E2: The ALU unit (see [Figure 16.25](#)) performs its function.

E3: If needed, this stage completes saturation arithmetic used by some ARM data processing instructions.

E4: Any change in control flow, including branch misprediction, exceptions, and memory system replays are prioritized and processed.

E5: Results of ARM instructions are written back into the register file.

Instructions that invoke the multiply unit (see [Figure 16.25](#)) are routed to pipe0; the multiply operation is performed in stages E1 through E3, and the multiply accumulate operation in stage E4.

The load/store pipeline runs parallel to the integer pipeline. The stages are as follows:

E1: The memory address is generated from the base and index register.

E2: The address is applied to the cache arrays.

E3: In the case of a load, data are returned and formatted for forwarding to the ALU or MUL unit. In the case of a store, the data are formatted and ready to be written into the cache.

E4: Performs updates to the L2 cache, if required.

E5: Results of ARM instructions are written back into the register file.

[Table 18.5](#) shows a sample code segment and indicates how the processor might schedule it.

Table 18.5 Cortex-A8 Example Dual Issue Instruction Sequence for Integer Pipeline

Cycle	Program Counter	Instruction	Timing Description
1	0x00000ed0	BX r14	Dual issue pipeline 0
1	0x00000ee4	CMP r0,#0	Dual issue in pipeline 1
2	0x00000ee8	MOV r3,#3	Dual issue pipeline 0
2	0x00000eec	MOV r0,#0	Dual issue in pipeline 1
3	0x00000ef0	STREQ r3, [r1,#0]	Dual issue in pipeline 0, r3 not needed until E3

3	0x00000ef4	CMP r2,#4	Dual issue in pipeline 1
4	0x00000ef8	LDRLS pc, [pc,r2,LSL #2]	Single issue pipeline 0, +1 cycle for load to pc, no extra cycle for shift since LSL #2
5	0x00000f2c	MOV r0,#1	Dual issue with 2nd iteration of load in pipeline 1
6	0x00000f30	B {pc} +8	#0xf38 dual issue pipeline 0
6	0x00000f38	STR r0, [r1,#0]	Dual issue pipeline 1
7	0x00000f3c:	LDR pc, [r13],#4	Single issue pipeline 0, +1 cycle for load to pc
8	0x0000017c	ADD r2,r4,#0xc	Dual issue with 2nd iteration of load in pipeline 1
9	0x00000180	LDR r0, [r6,#4]	Dual issue pipeline 0
9	0x00000184	MOV r1,#0xa	Dual issue pipeline 1
12	0x00000188	LDR r0, [r0,#0]	Single issue pipeline 0: r0 produced in E3, required in E1, so +2 cycle stall
13	0x0000018c	STR r0, [r4,#0]	Single issue pipeline 0 due to LS resource hazard, no extra delay for r0 since produced in E3 and consumed in E3
14	0x00000190	LDR r0, [r4,#0xc]	Single issue pipeline 0 due to LS resource hazard
15	0x00000194	LDMFD r13!,{r4- r6,r14}	Load multiple: loads r4 in 1st cycle, r5 and r6 in 2nd cycle, r14 in 3rd cycle, 3 cycles total
17	0x00000198	B {pc} + 0xda8	#0xf40 dual issue in pipeline 1 with 3rd cycle of LDM
18	0x00000f40	ADD r0,r0,#2 ARM	Single issue in pipeline 0

19	0x00000f44	ADD r0,r1,r0 ARM	Single issue in pipeline 0, no dual issue due to hazard on r0 produced in E2 and required in E2
----	------------	------------------------	---

SIMD and Floating-Point Pipeline

All SIMD and floating-point instructions pass through the integer pipeline and are processed in a separate 10-stage pipeline ([Figure 18.12](#)). This unit, referred to as the NEON unit, handles packed SIMD instructions, and provides two types of floating-point support. If implemented, a vector floating-point (VFP) coprocessor performs floating-point operations in compliance with IEEE 754. If the coprocessor is not present, then separate multiply and add pipelines implement the floating-point operations.

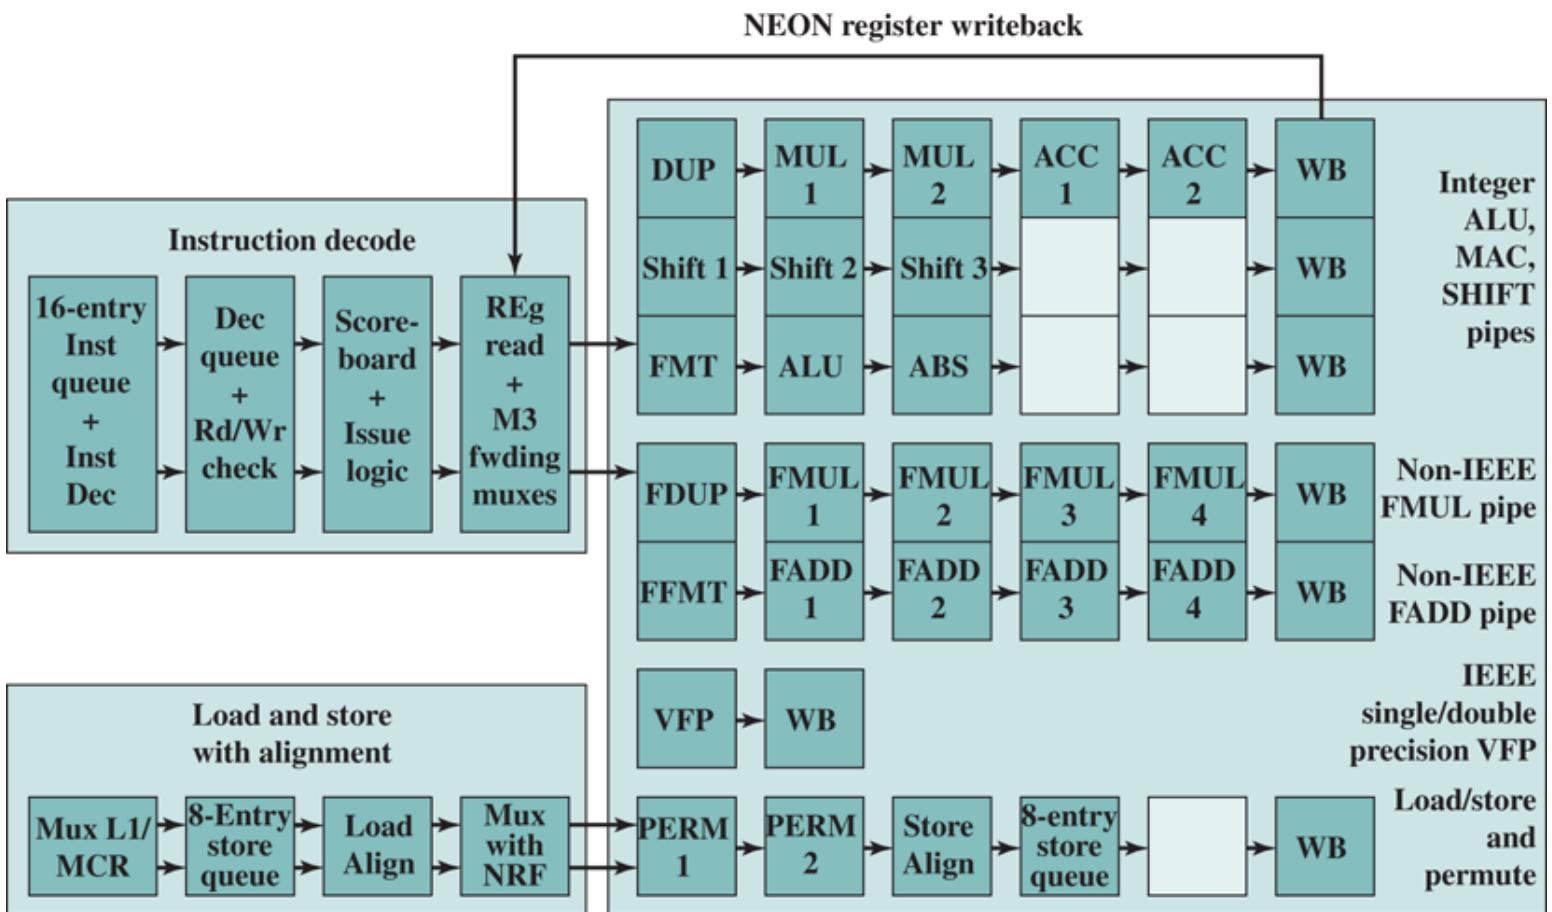

Figure 18.12 ARM Cortex-A8 NEON and Floating-Point Pipeline

18.5 ARM Cortex-M3

The preceding section looked at the rather complex pipeline organization of the Cortex-A8, an application processor. As a useful contrast, this section examines the considerably simpler pipeline organization of the Cortex-M3. The Cortex-M series is designed for the microcontroller domain. As such, the Cortex-M processors need to be as simple and efficient as possible.

Figure 18.13 provides a block diagram overview of the Cortex-M3 processor. This figure provides more detail than that shown in **Figure 1.16**. Key elements include:

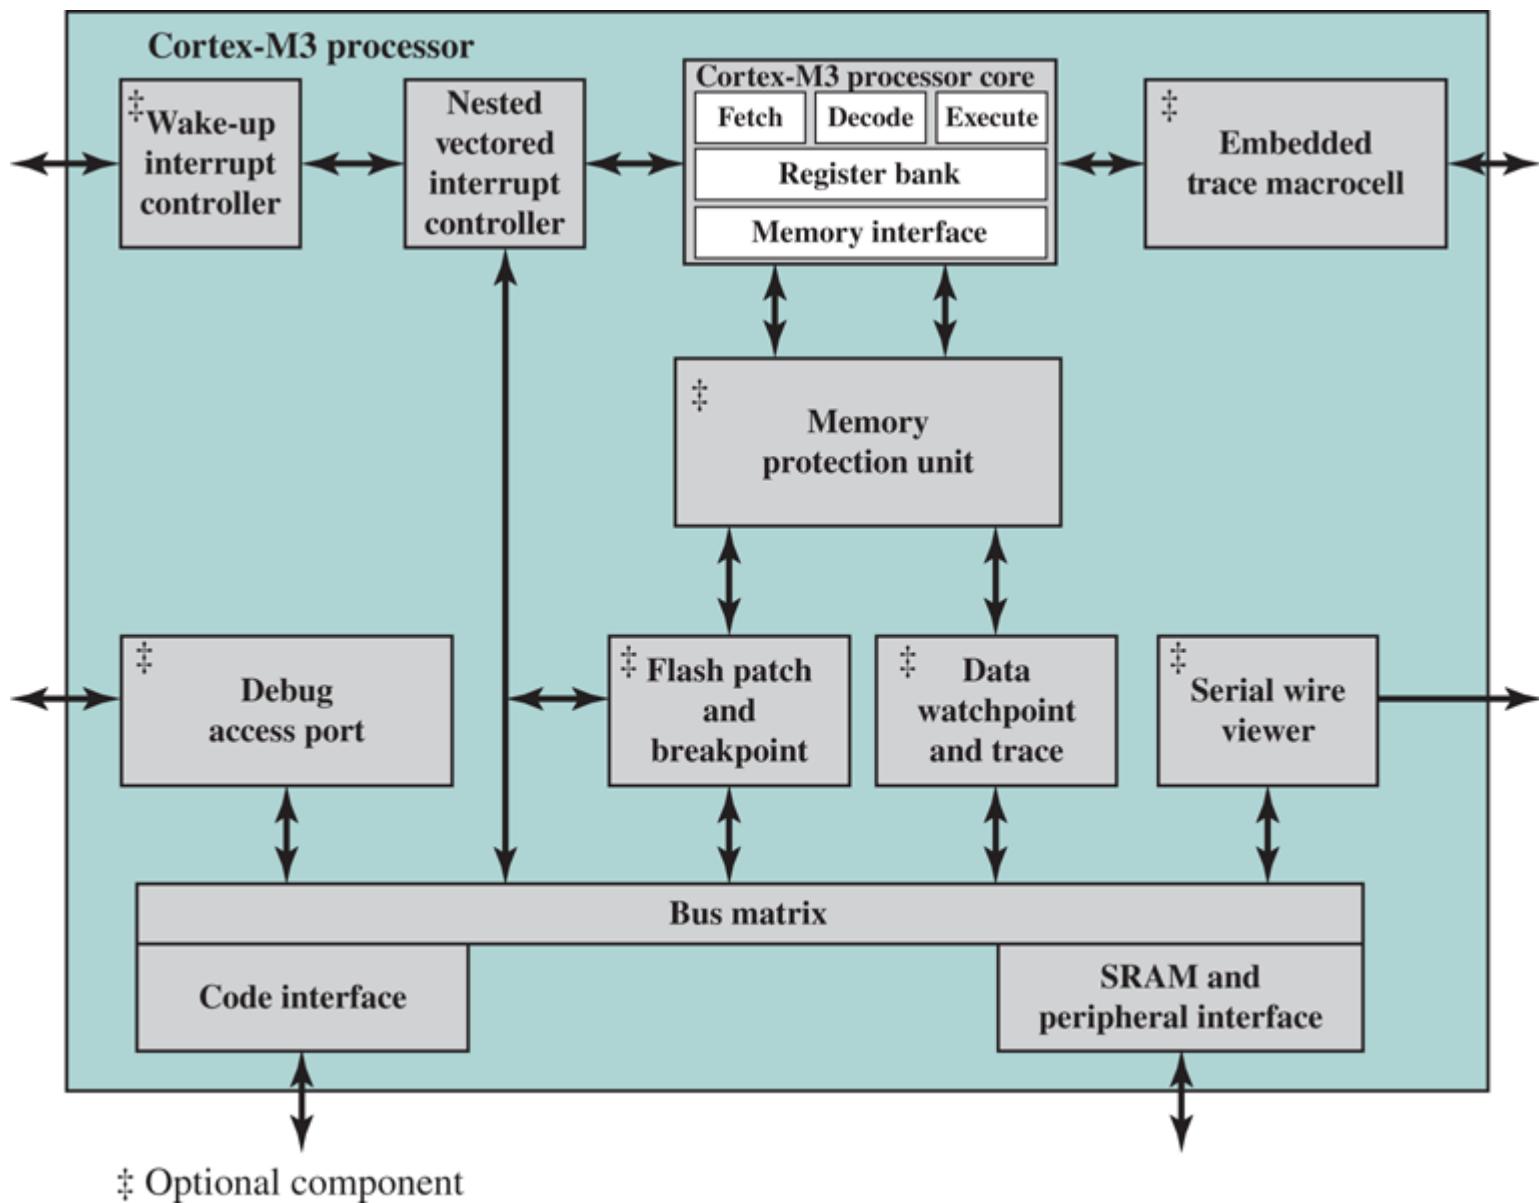

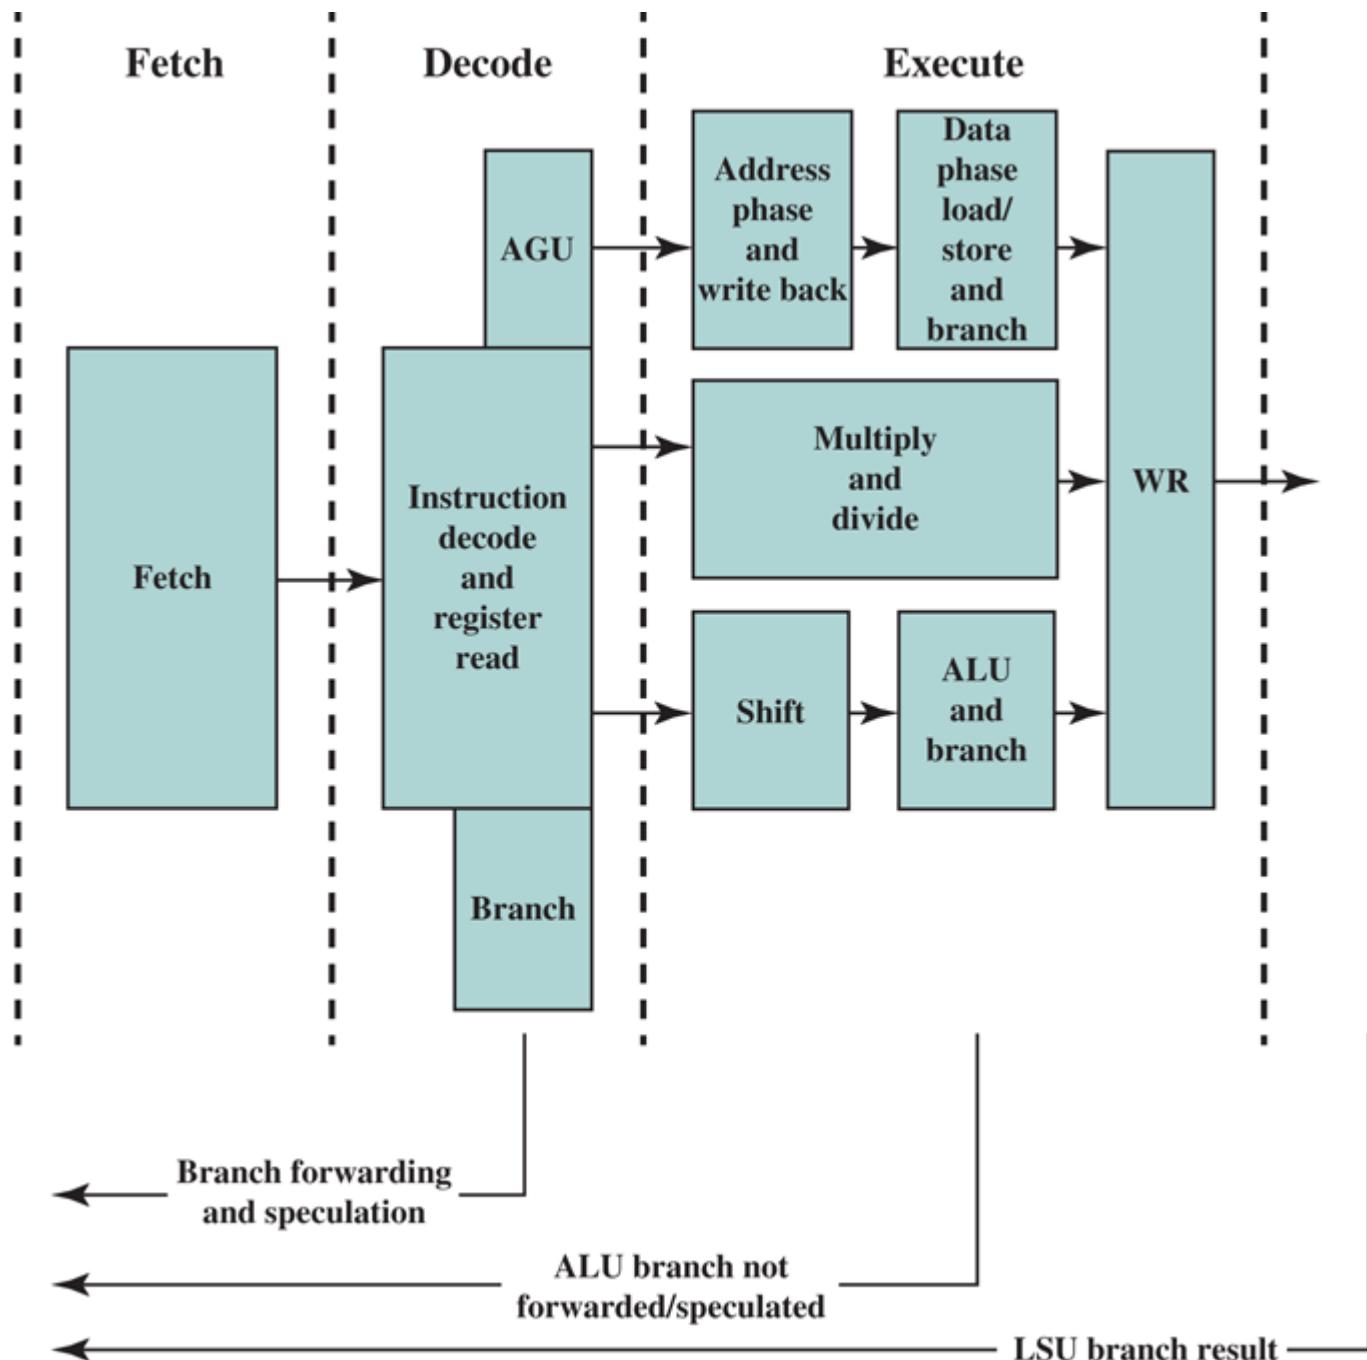

Figure 18.13 ARM Cortex-M3 Block Diagram

- **Processor core:** Includes a three-stage pipeline, a register bank, and a memory interface.
- **Memory protection unit:** Protects critical data used by the operating system from user applications, separating processing tasks by disallowing access to each other's data, disabling access to memory regions, allowing memory regions to be defined as read-only, and detecting unexpected memory accesses that could potentially break the system.
- **Nested vectored interrupt controller (NVIC):** Provides configurable interrupt handling abilities to the processor. It facilitates low-latency exception and interrupt handling, and controls power management.

- **Wake-up interrupt controller (NVIC):** Provides configurable interrupt handling abilities to the processor. It facilitates low-latency exception and interrupt handling, and controls power management.
- **Flash patch and breakpoint unit:** Implements breakpoints and code patches.
- **Data watchpoint and trace (DWT):** Implements watchpoints, data tracing, and system profiling.
- **Serial wire viewer:** Can export a stream of software-generated messages, data trace, and profiling information through a single pin.
- **Debug access port:** Provides an interface for external debug access to the processor.
- **Embedded trace macrocell:** Is an application-driven trace source that supports printf() style debugging to trace operating system and application events, and generates diagnostic system information.
- **Bus matrix:** Connects the core and debug interfaces to external buses on the microcontroller.

Pipeline Structure

The Cortex-M3 pipeline has three stages ([Figure 18.14](#)). We examine these in turn.

AGU = address generation unit

Figure 18.14 ARM Cortex-M3 Pipeline

During the fetch stage, one 32-bit word is fetched at a time and loaded into a 3-word buffer. The 32-bit word may consist of:

- two Thumb instructions,
- one word-aligned Thumb-2 instruction, or
- the upper/lower halfword of a halfword-aligned Thumb-2 instruction with
 - one Thumb instruction, or
 - the lower/upper halfword of another halfword-aligned Thumb-2 instruction.

All fetch addresses from the core are word aligned. If a Thumb-2 instruction is halfword aligned, two fetches are necessary to fetch the Thumb-2 instruction. However, the three-entry prefetch buffer ensures that a stall cycle is only necessary for the first halfword Thumb-2 instruction fetched.

This decode stage performs three key functions:

- **Instruction decode and register read:** Decodes Thumb and Thumb-2 instructions.
- **Address generation:** The address generation unit (AGU) generates main memory addresses for the load/store unit.
- **Branch:** Performs branch based on immediate offset in branch instruction or a return based on the contents of the link register (register R14).

Finally, there is a single execute stage for instruction execution, which includes ALU, load/store, and branch instructions.

Dealing with Branches

To keep the processor as simple as possible, the Cortex-M3 processor does not use branch prediction, but instead use the simple techniques of branch forwarding and branch speculation, defined as follows:

- **Branch forwarding:** The term *forwarding* refers to presenting an instruction address to be fetched from memory. The processor forwards certain branch types, by which the memory transaction of the branch is presented at least one cycle earlier than when the opcode reaches execute. Branch forwarding increases the performance of the core, because branches are a significant part of embedded controller applications. Branches affected are PC relative with immediate offset, or use link register (LR) as the target register.
- **Branch speculation:** For conditional branches, the instruction address is presented speculatively, so that the instruction is fetched from memory before it is known if the instruction will be executed.

The Cortex-M3 processor prefetches instruction ahead of execution using the fetch buffer. It also speculatively prefetches from branch target addresses. Specifically, when a conditional branch instruction is encountered, the decode stage also includes a speculative instruction fetch that could lead to faster execution. The processor fetches the branch destination instruction during the decode stage itself. Later, during the execute stage, the branch is resolved and it is known which instruction is to be executed next.

If the branch is not to be taken, the next sequential instruction is already available. If the branch is to be taken, the branch instruction is made available at the same time as the decision is made, restricting idle time to just one cycle.

Figure 18.14 clarifies the manner in which branches are handled, which can be described as follows:

1. The decode stage forwards addresses from unconditional branches and speculatively forwards addresses from conditional branches when it is possible to calculate the address.
2. If the ALU determines that a branch is not taken, this information is fed back to empty the instruction cache.
3. A load instruction to the program counter results in a branch address to be forwarded for fetching.

As can be seen, the manner in which branches are handled is considerably simpler for the Cortex-M than the Cortex-A, requiring less processor logic and processing.

Review Questions

- 18.1 What is the essential characteristic of the superscalar approach to processor design?
- 18.2 What is the difference between the superscalar and superpipelined approaches?
- 18.3 What is instruction-level parallelism?

18.4 Briefly define the following terms:

- True data dependency
- Procedural dependency
- Resource conflicts
- Output dependency
- Antidependency

18.5 What is the distinction between instruction-level parallelism and machine parallelism?

18.6 List and briefly define three types of superscalar instruction issue policies.

18.7 What is the purpose of an instruction window?

18.8 What is register renaming and what is its purpose?

18.9 What are the key elements of a superscalar processor organization?

Problems

18.1 When out-of-order completion is used in a superscalar processor, resumption of execution after interrupt processing is complicated, because the exceptional condition may have been detected as an instruction that produced its result out of order. The program cannot be restarted at the instruction following the exceptional instruction, because subsequent instructions have already completed, and doing so would cause these instructions to be executed twice. Suggest a mechanism or mechanisms for dealing with this situation.

18.2 Consider the following sequence of instructions, where the syntax consists of an opcode followed by the destination register followed by one or two source registers:

0	ADD	R3, R1, R2
1	LOAD	R6, [R3]
2	AND	R7, R5, 3
3	ADD	R1, R6, R7
4	SRL	R7, R0, 8
5	OR	R2, R4, R7
6	SUB	R5, R3, R4
7	ADD	R0, R1, 10
8	LOAD	R6, [R5]
9	SUB	R2, R1, R6
10	AND	R3, R7, 15

Assume the use of a four-stage pipeline: fetch, decode/issue, execute, write back. Assume that all pipeline stages take one clock cycle except for the execute stage. For simple integer arithmetic and logical instructions, the execute stage takes one cycle, but for a LOAD from memory, five cycles are consumed in the execute stage.

If we have a simple scalar pipeline but allow out-of-order execution, we can construct the following table for the execution of the first seven instructions:

Instruction	Fetch	Decode	Execute	Write Back
0	0	1	2	3
1	1	2	4	9
2	2	3	5	6

3	3	4	10	11
4	4	5	6	7
5	5	6	8	10
6	6	7	9	12

The entries under the four pipeline stages indicate the clock cycle at which each instruction begins each phase. In this program, the second ADD instruction (instruction 3) depends on the LOAD instruction (instruction 1) for one of its operands, r6. Because the LOAD instruction takes five clock cycles, and the issue logic encounters the dependent ADD instruction after two clocks, the issue logic must delay the ADD instruction for three clock cycles. With an out-of-order capability, the processor can stall instruction 3 at clock cycle 4, and then move on to issue the following three independent instructions, which enter execution at clocks 6, 8, and 9. The LOAD finishes execution at clock 9, and so the dependent ADD can be launched into execution on clock 10.

- a. Complete the preceding table.
- b. Redo the table assuming no out-of-order capability. What is the savings using the capability?
- c. Redo the table assuming a superscalar implementation that can handle two instructions at a time at each stage.

18.3 Consider the following assembly language program:

<i>I1: Move R3, R7</i>	<i>/R3 ← (R7) /</i>
<i>I2: Load R8, (R3)</i>	<i>/R8 ← Memory (R3) /</i>
<i>I3: Add R3, R3, 4</i>	<i>/R3 ← (R3) + 4 /</i>
<i>I4: Load R9, (R3)</i>	<i>/R9 ← Memory (R3) /</i>
<i>I5: BLE R8, R9, I3</i>	<i>/Branch if (R9) > (R8) /</i>

This program includes WAW, RAW, and WAR dependencies. Show these.

18.4

- a. Identify the RAW, WAR, and WAW dependencies in the following instruction sequence:

<i>I1: R1 = 100</i>
<i>I2: R1 = R2 + R4</i>
<i>I3: R2 = r4 - 25</i>
<i>I4: R4 = R1 + R3</i>
<i>I5: R1 = R1 + 30</i>

- b. Rename the registers from part (a) to prevent dependency problems. Identify references to initial register values using the subscript "a" to the register reference.

18.5 Consider the “in-order-issue/in-order-completion” execution sequence shown in [Figure 18.15](#).

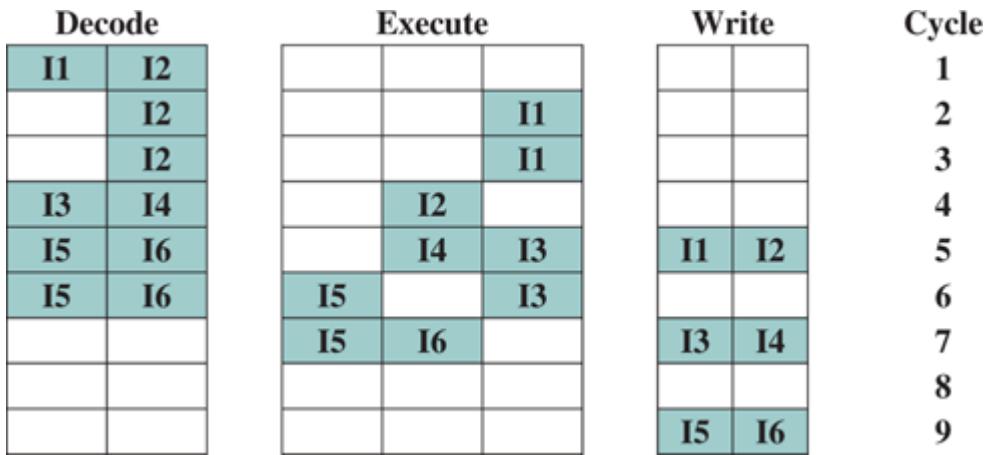

Figure 18.15 An In-Order Issue, In-Order-Completion Execution Sequence

- Identify the most likely reason why I2 could not enter the execute stage until the fourth cycle. Will “in-order issue/out-of-order completion” or “out-of-order issue/out-of-order completion” fix this? If so, which?
- Identify the reason why I6 could not enter the write stage until the ninth cycle. Will “in-order issue/out-of-order completion” or “out-of-order issue/out-of-order completion” fix this? If so, which?

18.6 **Figure 18.16** shows an example of a superscalar processor organization. The processor can issue two instructions per cycle if there is no resource conflict and no data dependence problem. There are essentially two pipelines, with four processing stages (fetch, decode, execute, and store). Each pipeline has its own fetch decode and store unit. Four functional units (multiplier, adder, logic unit, and load unit) are available for use in the execute stage and are shared by the two pipelines on a dynamic basis. The two store units can be dynamically used by the two pipelines, depending on availability at a particular cycle. There is a lookahead window with its own fetch and decoding logic. This window is used for instruction lookahead for out-of-order instruction issue.

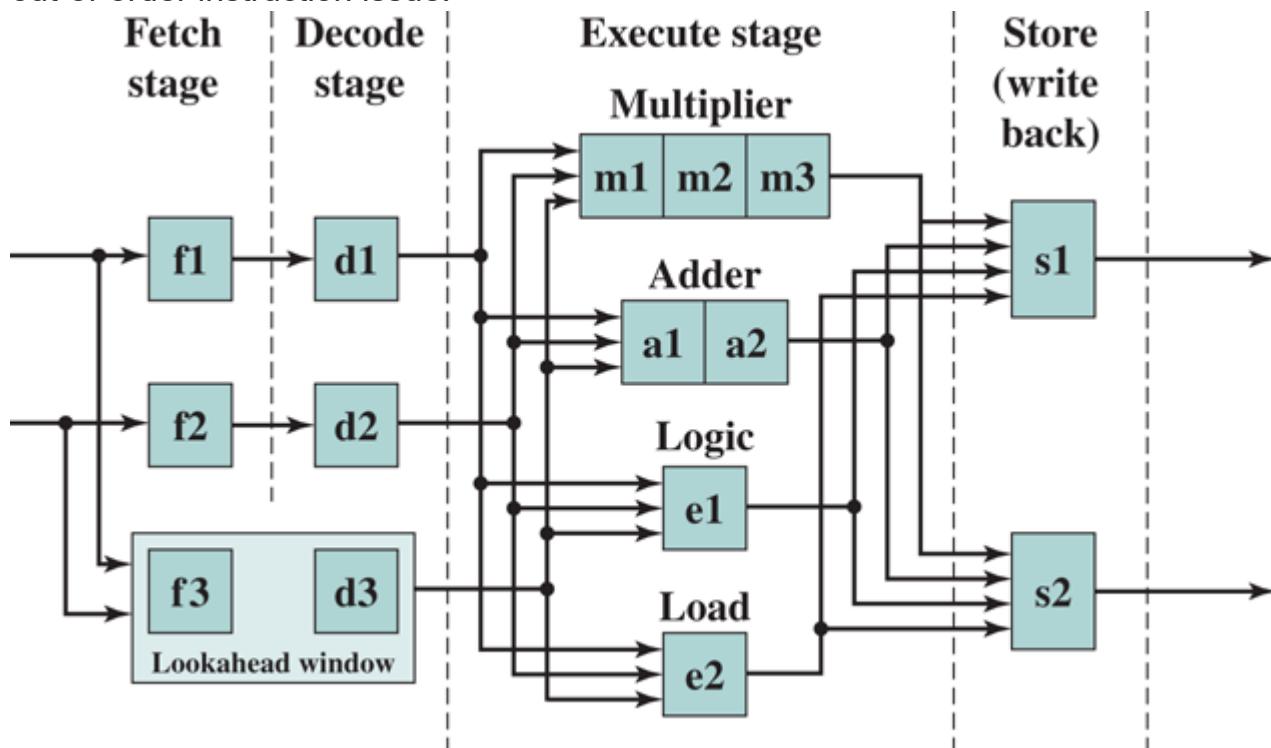

Figure 18.16 A Dual-Pipeline Superscalar Processor

Consider the following program to be executed on this processor:

```

I1: Load R1, A      /R1 ← Memory (A) /
I2: Add R2, R1     /R2 ← (R2) + R(1) /
I3: Add R3, R4     /R3 ← (R3) + R(4) /
I4: Mul R4, R5     /R4 ← (R4) + R(5) /
I5: Comp R6        /R6 ← (R6) /
I6: Mul R6, R7     /R6 ← (R6) × R(7) /

```

- What dependencies exist in the program?
- Show the pipeline activity for this program on the processor of [Figure 18.16](#) using in-order issue with in-order completion policies and using a presentation similar to [Figure 18.3](#).
- Repeat for in-order issue with out-of-order completion.
- Repeat for out-of-order issue with out-of-order completion.

18.7 [Figure 18.17](#) is from a paper on superscalar design. Explain the three parts of the figure, and define w, x, y, and z.

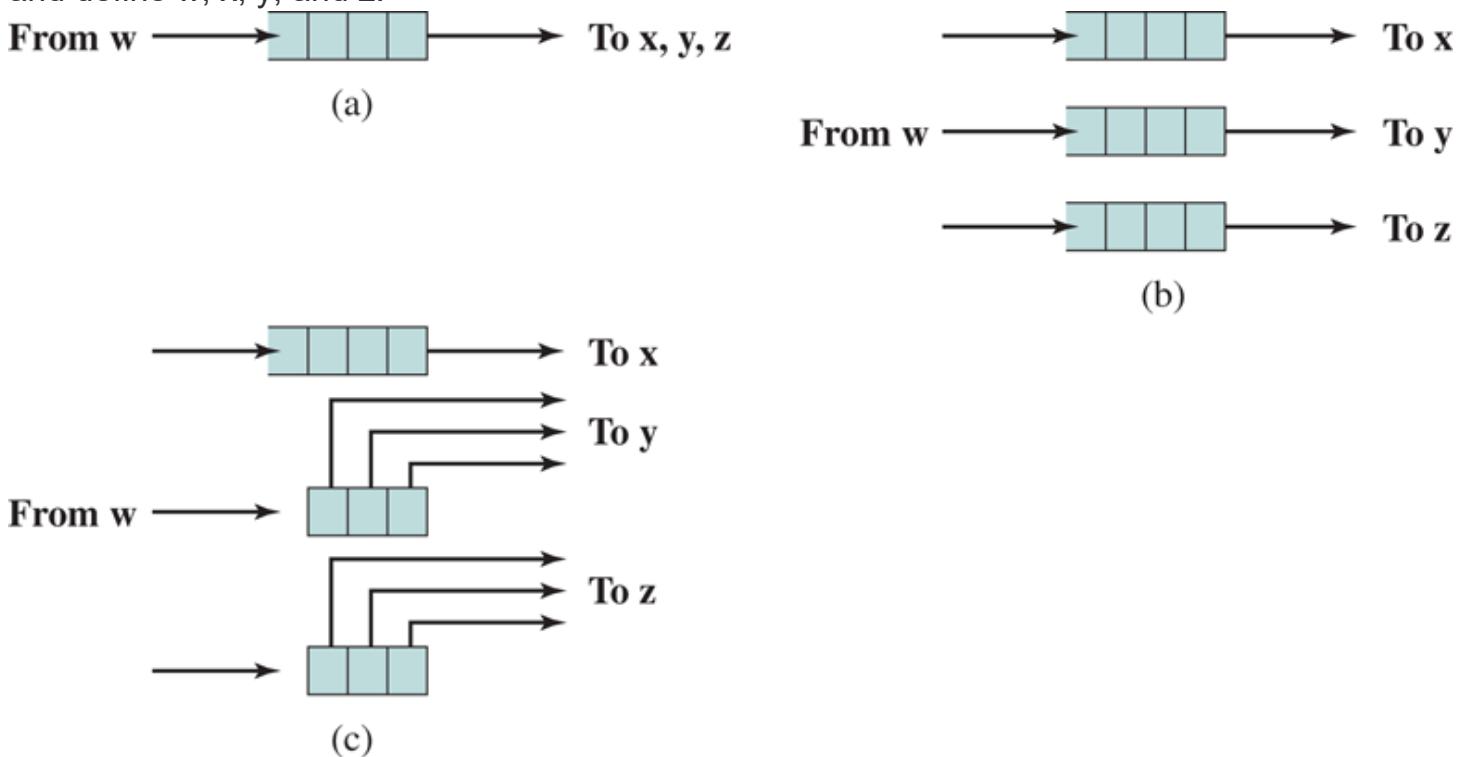

Figure 18.17 Figure for Problem 18.7

18.8 Yeh's dynamic branch prediction algorithm, used on the Pentium 4, is a two-level branch prediction algorithm. The first level is the history of the last n branches. The second level is the branch behavior of the last s occurrences of that unique pattern of the last n branches. For each conditional branch instruction in a program, there is an entry in a Branch History Table (BHT). Each entry consists of n bits corresponding to the last n executions of the branch instruction, with a 1 if the branch was taken and a 0 if the branch was not. Each BHT entry indexes into a Pattern Table (PT) that has $2n$ entries, one for each possible pattern of n bits. Each PT entry

consists of s bits that are used in branch prediction, as was described in **Chapter 16** (e.g., **Figure 16.19**). When a conditional branch is encountered during instruction fetch and decode, the address of the instruction is used to retrieve the appropriate BHT entry, which shows the recent history of the instruction. Then, the BHT entry is used to retrieve the appropriate PT entry for branch prediction. After the branch is executed, the BHT entry is updated, and then the appropriate PT entry is updated.

- In testing the performance of this scheme, Yeh tried five different prediction schemes, illustrated in **Figure 18.18**. Identify which three of these schemes correspond to those shown in **Figures 16.19** and **16.28**. Describe the remaining two schemes.

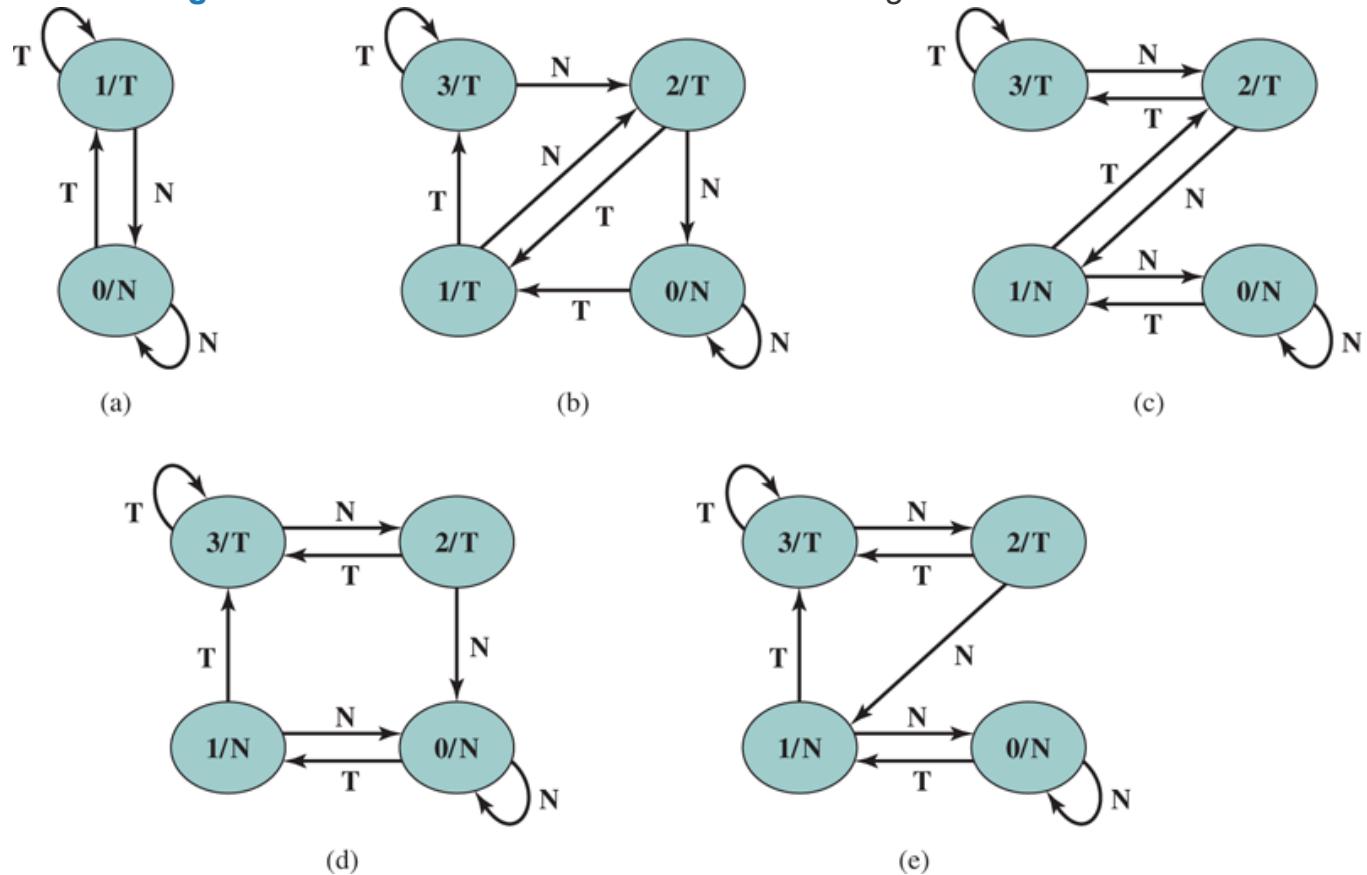

Figure 18.18 Figure for Problem 18.8

- With this algorithm, the prediction is not based on just the recent history of this particular branch instruction. Rather, it is based on the recent history of all patterns of branches that match the n -bit pattern in the BHT entry for this instruction. Suggest a rationale for such a strategy.

Learning Objectives

After studying this chapter, you should be able to:

- Explain the concept of micro-operations and define the principal instruction cycle phases in terms of micro-operations.
- Discuss how micro-operations are organized to control a processor.
- Understand hardwired control unit organization.
- Present an overview of the basic concepts of microprogrammed control.
- Understand the difference between hardwired control and microprogrammed control.

In Chapter 13, we pointed out that a machine instruction set goes a long way toward defining the processor. If we know the machine instruction set, including an

understanding of the effect of each opcode and an understanding of the addressing modes, and if we know the set of user-visible registers, then we know the functions that the processor must perform. This is not the complete picture. We must know the external interfaces, usually through a bus, and how interrupts are handled. With this line of reasoning, the following list of those things needed to specify the function of a processor emerges:

1. Operations (opcodes)
2. Addressing modes
3. Registers
4. I/O module interface
5. Memory module interface
6. Interrupts

This list, though general, is rather complete. Items 1 through 3 are defined by the instruction set. Items 4 and 5 are typically defined by specifying the system bus. Item 6 is defined partially by the system bus and partially by the type of support the processor offers to the operating system.

This list of six items might be termed the functional requirements for a processor. They determine what a processor must do. This is what occupied us in previous chapters. Now, we turn to the question of how these functions are performed or, more specifically, how the various elements of the processor are controlled to provide these functions. Thus, we turn to a discussion of the control unit, which controls the operation of the processor.

19.1 Micro-Operations

We have seen that the operation of a computer, in executing a program, consists of a sequence of instruction cycles with one machine instruction per cycle. Of course, we must remember that this sequence of instruction cycles is not necessarily the same as the *written sequence* of instructions that make up the program, because of the existence of branching instructions. What we are referring to here is the execution *time sequence* of instructions.

We have further seen that each instruction cycle is made up of a number of smaller units. One subdivision that we found convenient is fetch, indirect, execute, and interrupt, with only fetch and execute cycles always occurring.

To design a control unit, however, we need to break down the description further. In our discussion of pipelining in [Chapter 16](#), we began to see that a further decomposition is possible. In fact, we will see that each of the smaller cycles involves a series of steps, each of which involves the processor registers. We will refer to these steps as **micro-operations**. The prefix *micro* refers to the fact that each step is very simple and accomplishes very little. [Figure 19.1](#) depicts the relationship among the various concepts we have been discussing. To summarize, the execution of a program consists of the sequential execution of instructions. Each instruction is executed during an instruction cycle made up of shorter subcycles (e.g., fetch, indirect, execute, interrupt). The execution of each subcycle involves one or more shorter operations, that is, micro-operations.

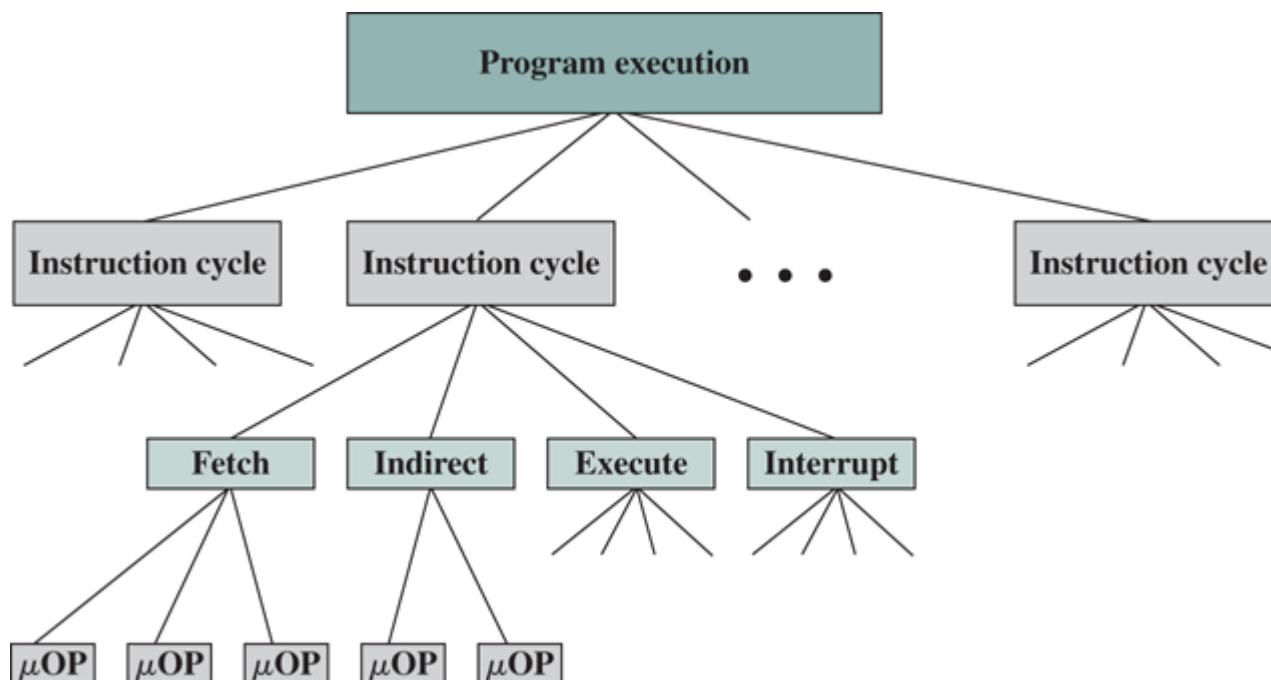

Figure 19.1 Constituent Elements of a Program Execution

Micro-operations are the functional, or atomic, operations of a processor. In this section, we will examine micro-operations to gain an understanding of how the events of any instruction cycle can be described as a sequence of such micro-operations. A simple example will be used. In the remainder of this chapter, we then show how the concept of micro-operations serves as a guide to the design of the control unit.

The Fetch Cycle

We begin by looking at the fetch cycle, which occurs at the beginning of each instruction cycle and

causes an instruction to be fetched from memory. For purposes of discussion, we assume the organization depicted in [Figure 16.5](#) (*Data Flow, Fetch Cycle*). We begin by looking at the fetch cycle, which occurs at the beginning of each instruction cycle and causes an instruction to be fetched from memory (*Data Flow, Fetch Cycle*). Four registers are involved:

- **Memory address register (MAR):** Is connected to the address lines of the system bus. It specifies the address in memory for a read or write operation.
- **Memory buffer register (MBR):** Is connected to the data lines of the system bus. It contains the value to be stored in memory or the last value read from memory.
- **Program counter (PC):** Holds the address of the next instruction to be fetched.
- **Instruction register (IR):** Holds the last instruction fetched.

Let us look at the sequence of events for the fetch cycle from the point of view of its effect on the processor registers. An example appears in [Figure 19.2](#). At the beginning of the fetch cycle, the address of the next instruction to be executed is in the program counter (PC); in this case, the address is 1100100. The first step is to move that address to the memory address register (MAR) because this is the only register connected to the address lines of the system bus. The second step is to bring in the instruction. The desired address (in the MAR) is placed on the address bus, the control unit issues a READ command on the control bus, and the result appears on the data bus and is copied into the memory buffer register (MBR). We also need to increment the PC by the instruction length to get ready for the next instruction. Because these two actions (read word from memory, increment PC) do not interfere with each other, we can do them simultaneously to save time. The third step is to move the contents of the MBR to the instruction register (IR). This frees up the MBR for use during a possible indirect cycle.

tMAR	
MBR	
PC	0000000001100100
IR	
AC	

(a) Beginning (before t_1)

MAR	0000000001100100
MBR	
PC	0000000001100100
IR	
AC	

(b) After first step

MAR	0000000001100100
MBR	0001000000100000
PC	0000000001100101
IR	
AC	

(c) After second step

MAR	0000000001100100
MBR	0001000000100000
PC	0000000001100101
IR	0001000000100000
AC	

(d) After third step

Figure 19.2 Sequence of Events, Fetch Cycle

Thus, the simple fetch cycle actually consists of three steps and four micro-operations. Each micro-operation involves the movement of data into or out of a register. So long as these movements do not interfere with one another, several of them can take place during one step, saving time. Symbolically, we can write this sequence of events as follows:

$$t1: \text{MAR} \leftarrow (\text{PC})$$

$$t2: \text{MBR} \leftarrow \text{Memory}$$

PC	\leftarrow	$(PC) + I$
$t3: IR$	\leftarrow	(MBR)

where I is the instruction length. We need to make several comments about this sequence. We assume that a clock is available for timing purposes and that it emits regularly spaced clock pulses. Each clock pulse defines a time unit. Thus, all time units are of equal duration. Each micro-operation can be performed within the time of a single time unit. The notation (t_1, t_2, t_3) represents successive time units. In words, we have

- **First time unit:** Move contents of PC to MAR.
- **Second time unit:** Move contents of memory location specified by MAR to MBR. Increment by I the contents of the PC.
- **Third time unit:** Move contents of MBR to IR.

Note that the second and third micro-operations both take place during the second time unit. The third micro-operation could have been grouped with the fourth without affecting the fetch operation:

$t1: MAR \leftarrow (PC)$
$t2: MBR \leftarrow Memory$
$t3: PC \leftarrow (PC) + I$
$IR \leftarrow (MBR)$

The groupings of micro-operations must follow two simple rules:

1. The proper sequence of events must be followed. Thus $(MAR \leftarrow (PC))$ must precede $(MBR \leftarrow Memory)$ because the memory read operation makes use of the address in the MAR.
2. Conflicts must be avoided. One should not attempt to read to and write from the same register in one time unit, because the results would be unpredictable. For example, the micro-operations $(MBR \leftarrow Memory)$ and $(IR \leftarrow MBR)$ should not occur during the same time unit.

A final point worth noting is that one of the micro-operations involves an addition. To avoid duplication of circuitry, this addition could be performed by the ALU. The use of the ALU may involve additional micro-operations, depending on the functionality of the ALU and the organization of the processor. We defer a discussion of this point until later in this chapter.

It is useful to compare events described in this and the following subsections to [Figure 3.5 \(Example of Program Execution\)](#). Whereas micro-operations are ignored in that figure, this discussion shows the micro-operations needed to perform the subcycles of the instruction cycle.

The Indirect Cycle

Once an instruction is fetched, the next step is to fetch source operands. Continuing our simple example, let us assume a one-address instruction format, with direct and indirect addressing allowed. If the instruction specifies an indirect address, then an indirect cycle must precede the execute cycle. The data flow differs somewhat from that indicated in [Figure 16.6 \(Data Flow, Indirect Cycle\)](#) and includes the following micro-operations:

$t1: MAR \leftarrow (IR(Address))$

```

t2: MBR ← Memory
t3: IR(Address) ← (MBR(Address))

```

The address field of the instruction is transferred to the MAR. This is then used to fetch the address of the operand. Finally, the address field of the IR is updated from the MBR, so that it now contains a direct rather than an indirect address.

The IR is now in the same state as if indirect addressing had not been used, and it is ready for the execute cycle. We skip that cycle for a moment, to consider the interrupt cycle.

The Interrupt Cycle

At the completion of the execute cycle, a test is made to determine whether any enabled interrupts have occurred. If so, the interrupt cycle occurs. The nature of this cycle varies greatly from one machine to another. We present a very simple sequence of events, as illustrated in **Figure 16.7 (Data Flow, Interrupt Cycle)**. We have

```

t1: MBR ← (PC)
t2: MAR ← Save_Address
      PC ← Routine_Address
t3: Memory ← (MBR)

```

In the first step, the contents of the PC are transferred to the MBR, so that they can be saved for return from the interrupt. Then the MAR is loaded with the address at which the contents of the PC are to be saved, and the PC is loaded with the address of the start of the interrupt-processing routine. These two actions may each be a single micro-operation. However, because most processors provide multiple types and/or levels of interrupts, it may take one or more additional micro-operations to obtain the *Save_Address* and the *Routine_Address* before they can be transferred to the MAR and PC, respectively. In any case, once this is done, the final step is to store the MBR, which contains the old value of the PC, into memory. The processor is now ready to begin the next instruction cycle.

The Execute Cycle

The fetch, indirect, and interrupt cycles are simple and predictable. Each involves a small, fixed sequence of micro-operations and, in each case, the same micro-operations are repeated each time around.

This is not true of the execute cycle. Because of the variety of opcodes, there are a number of different sequences of micro-operations that can occur. The control unit examines the opcode and generates a sequence of micro-operations based on the value of the opcode. This is referred to as instruction decoding.

Let us consider several hypothetical examples.

First, consider an add instruction:

```
ADD R1, X
```

which adds the contents of the location X to register R1. The following sequence of micro-operations might occur:

```
t1: MAR ← (IR(address))
t2: MBR ← Memory
t3: R1 ← (R1) + (MBR)
```

We begin with the IR containing the ADD instruction. In the first step, the address portion of the IR is loaded into the MAR. Then the referenced memory location is read. Finally, the contents of R1 and MBR are added by the ALU. Again, this is a simplified example. Additional micro-operations may be required to extract the register reference from the IR and perhaps to stage the ALU inputs or outputs in some intermediate registers.

Let us look at two more complex examples. A common instruction is increment and skip if zero:

```
ISZ X
```

The content of location X is incremented by 1. If the result is 0, the next instruction is skipped. A possible sequence of micro-operations is

```
t1: MAR ← (IR(address))
t2: MBR ← Memory
t3: MBR ← (MBR) + 1
t4: Memory ← (MBR)
IF ((MBR) = 0) then (PC ← (PC) + I)
```

The new feature introduced here is the conditional action. The PC is incremented if $(MBR) = 0$. This test and action can be implemented as one micro-operation. Note also that this micro-operation can be performed during the same time unit during which the updated value in MBR is stored back to memory.

Finally, consider a subroutine call instruction. As an example, consider a branch-and-save-address instruction:

```
BSA X
```

The address of the instruction that follows the BSA instruction is saved in location X, and execution continues at location $X + I$. The saved address will later be used for return. This is a straightforward technique for supporting subroutine calls. The following micro-operations suffice:

```
t1: MAR ← (IR(address))
      MBR ← (PC)
t2: PC ← (IR(address))
      Memory ← (MBR)
```

$t3: PC \leftarrow (PC) + I$

The address in the PC at the start of the instruction is the address of the next instruction in sequence. This is saved at the address designated in the IR. The latter address is also incremented to provide the address of the instruction for the next instruction cycle.

The Instruction Cycle

We have seen that each phase of the instruction cycle can be decomposed into a sequence of elementary micro-operations. In our example, there is one sequence each for the fetch, indirect, and interrupt cycles, and, for the execute cycle, there is one sequence of micro-operations for each opcode.

To complete the picture, we need to tie sequences of micro-operations together, and this is done in **Figure 19.3**. We assume a new 2-bit register called the *instruction cycle code* (ICC). The ICC designates the state of the processor in terms of which portion of the cycle it is in:

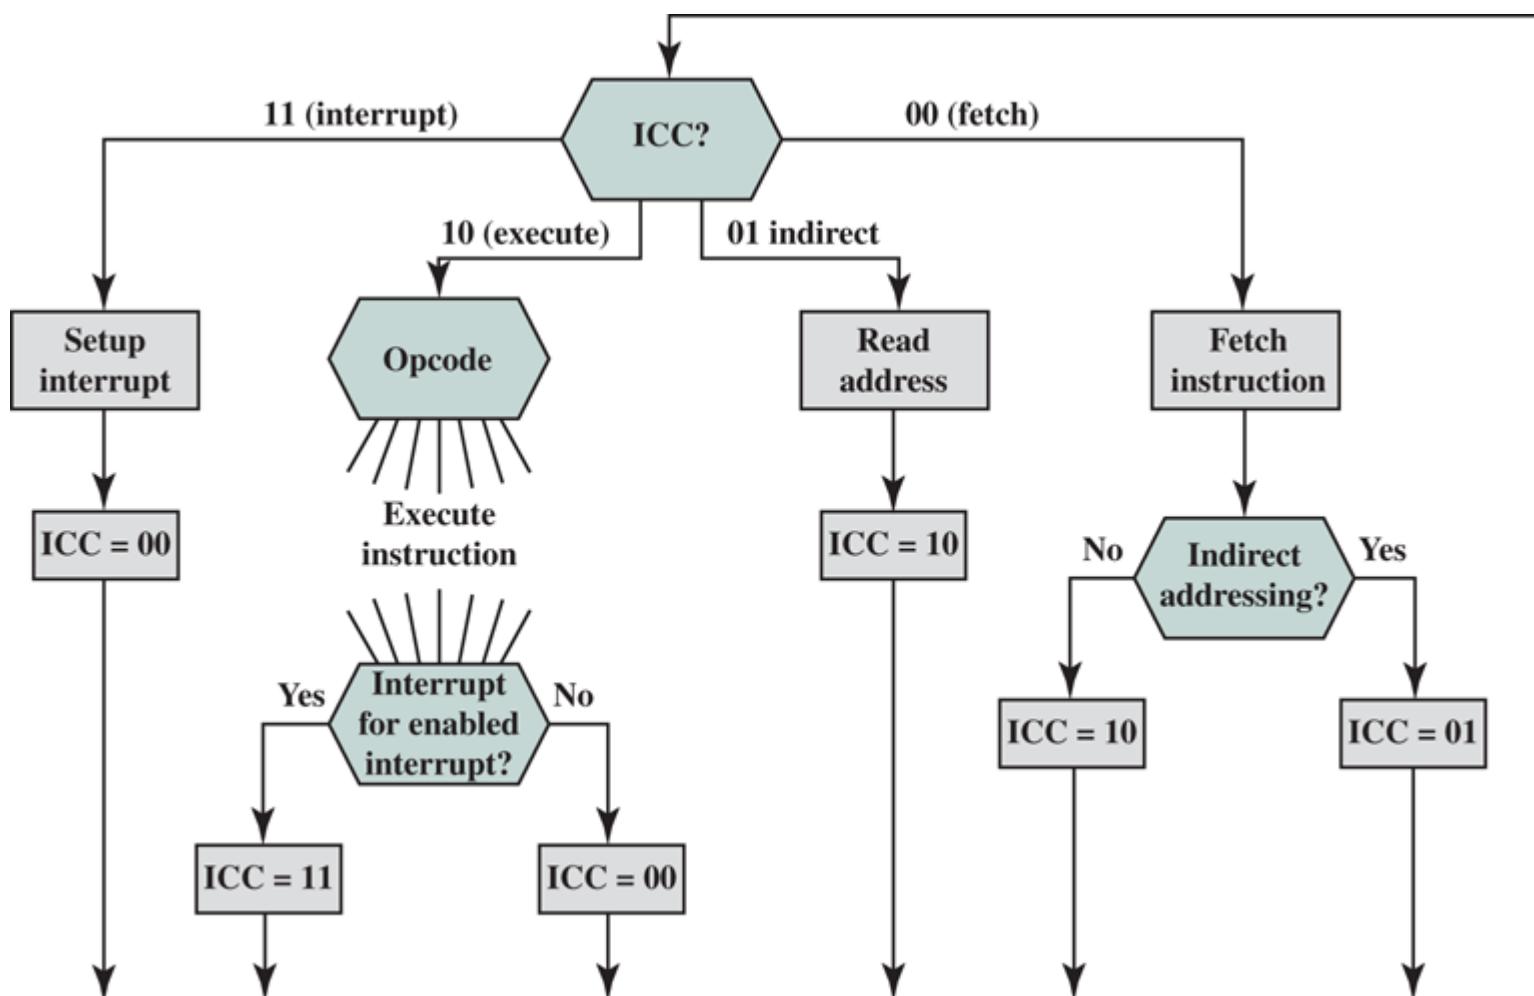

Figure 19.3 Flowchart for Instruction Cycle

00: Fetch

01: Indirect

10: Execute

11: Interrupt

At the end of each of the four cycles, the ICC is set appropriately. The indirect cycle is always followed by the execute cycle. The interrupt cycle is always followed by the fetch cycle (see [Figure 16.3, The Instruction Cycle](#)). For both the fetch and execute cycles, the next cycle depends on the state of the system.

Thus, the flowchart of [Figure 19.3](#) defines the complete sequence of micro-operations, depending only on the instruction sequence and the interrupt pattern. Of course, this is a simplified example. The flowchart for an actual processor would be more complex. In any case, we have reached the point in our discussion in which the operation of the processor is defined as the performance of a sequence of micro-operations. We can now consider how the control unit causes this sequence to occur.

19.2 Control of the Processor

Functional Requirements

As a result of our analysis in the preceding section, we have decomposed the behavior or functioning of the processor into elementary operations, called micro-operations. By reducing the operation of the processor to its most fundamental level, we are able to define exactly what it is that the control unit must cause to happen. Thus, we can define the *functional requirements* for the control unit: those functions that the control unit must perform. A definition of these functional requirements is the basis for the design and implementation of the control unit.

With the information at hand, the following three-step process leads to a characterization of the control unit:

1. Define the basic elements of the processor.
2. Describe the micro-operations that the processor performs.
3. Determine the functions that the control unit must perform to cause the micro-operations to be performed.

We have already performed steps 1 and 2. Let us summarize the results. First, the basic functional elements of the processor are the following:

- ALU
- Registers
- Internal data paths
- External data paths
- Control unit

Some thought should convince you that this is a complete list. The ALU is the functional essence of the computer. Registers are used to store data internal to the processor. Some registers contain status information needed to manage instruction sequencing (e.g., a program status word). Others contain data that go to or come from the ALU, memory, and I/O modules. Internal data paths are used to move data between registers and between register and ALU. External data paths link registers to memory and I/O modules, often by means of a system bus. The control unit causes operations to happen within the processor.

The execution of a program consists of operations involving these processor elements. As we have seen, these operations consist of a sequence of micro-operations. Upon review of [Section 19.1](#), the reader should see that all micro-operations fall into one of the following categories:

- Transfer data from one register to another.
- Transfer data from a register to an external interface (e.g., system bus).
- Transfer data from an external interface to a register.
- Perform an arithmetic or logic operation, using registers for input and output.

All of the micro-operations needed to perform one instruction cycle, including all of the micro-operations to execute every instruction in the instruction set, fall into one of these categories.

We can now be somewhat more explicit about the way in which the control unit functions. The control unit performs two basic tasks:

- **Sequencing:** The control unit causes the processor to step through a series of micro-operations in the proper sequence, based on the program being executed.

- **Execution:** The control unit causes each micro-operation to be performed. The preceding is a functional description of what the control unit does. The key to how the control unit operates is the use of control signals.

Control Signals

We have defined the elements that make up the processor (ALU, registers, data paths) and the micro-operations that are performed. For the control unit to perform its function, it must have inputs that allow it to determine the state of the system and outputs that allow it to control the behavior of the system. These are the external specifications of the control unit. Internally, the control unit must have the logic required to perform its sequencing and execution functions. We defer a discussion of the internal operation of the control unit to [Section 19.3](#) and [19.4](#). The remainder of this section is concerned with the interaction between the control unit and the other elements of the processor.

[Figure 19.4](#) is a general model of the control unit, showing all of its inputs and outputs. The inputs are:

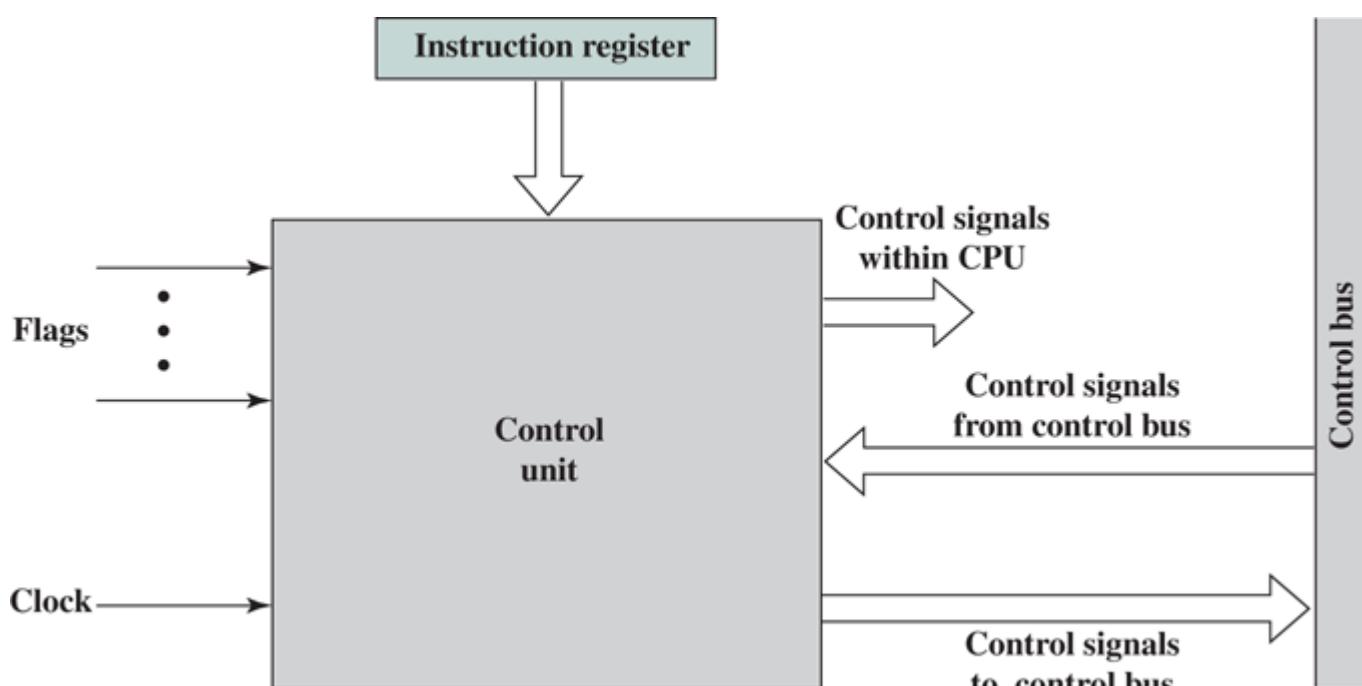

Figure 19.4 Block Diagram of the Control Unit

- **Clock:** This is how the control unit “keeps time.” The control unit causes one micro-operation (or a set of simultaneous micro-operations) to be performed for each clock pulse. This is sometimes referred to as the processor cycle time, or the clock cycle time.
- **Instruction register:** The opcode and addressing mode of the current instruction are used to determine which micro-operations to perform during the execute cycle.
- **Flags:** These are needed by the control unit to determine the status of the processor and the outcome of previous ALU operations. For example, for the increment-and-skip-if-zero (ISZ) instruction, the control unit will increment the PC if the zero flag is set.
- **Control signals from control bus:** The control bus portion of the system bus provides signals to the control unit.

The outputs are as follows:

- **Control signals within the processor:** These are two types: those that cause data to be moved from one register to another, and those that activate specific ALU functions.
- **Control signals to control bus:** These are also of two types: control signals to memory, and control signals to the I/O modules.

Three types of control signals are used: those that activate an ALU function; those that activate a data path; and those that are signals on the external system bus or other external interface. All of these signals are ultimately applied directly as binary inputs to individual logic gates.

Let us consider again the fetch cycle to see how the control unit maintains control. The control unit keeps track of where it is in the instruction cycle. At a given point, it knows that the fetch cycle is to be performed next. The first step is to transfer the contents of the PC to the MAR. The control unit does this by activating the control signal that opens the gates between the bits of the PC and the bits of the MAR. The next step is to read a word from memory into the MBR and increment the PC. The control unit does this by sending the following control signals simultaneously:

- A control signal that opens gates, allowing the contents of the MAR onto the address bus;
- A memory read control signal on the control bus;
- A control signal that opens the gates, allowing the contents of the data bus to be stored in the MBR;
- Control signals to logic that add 1 to the contents of the PC and store the result back to the PC.

Following this, the control unit sends a control signal that opens gates between the MBR and the IR.

This completes the fetch cycle except for one thing: The control unit must decide whether to perform an indirect cycle or an execute cycle next. To decide this, it examines the IR to see if an indirect memory reference is made.

The indirect and interrupt cycles work similarly. For the execute cycle, the control unit begins by examining the opcode and, on the basis of that, decides which sequence of micro-operations to perform for the execute cycle.

A Control Signals Example

To illustrate the functioning of the control unit, let us examine a simple example. [Figure 19.5](#) illustrates the example. This is a simple processor with a single accumulator (AC). The data paths between elements are indicated. The control paths for signals emanating from the control unit are not shown, but the terminations of control signals are labeled C_i and indicated by a circle. The control unit receives inputs from the clock, the IR, and flags. With each clock cycle, the control unit reads all of its inputs and emits a set of control signals. Control signals go to three separate destinations:

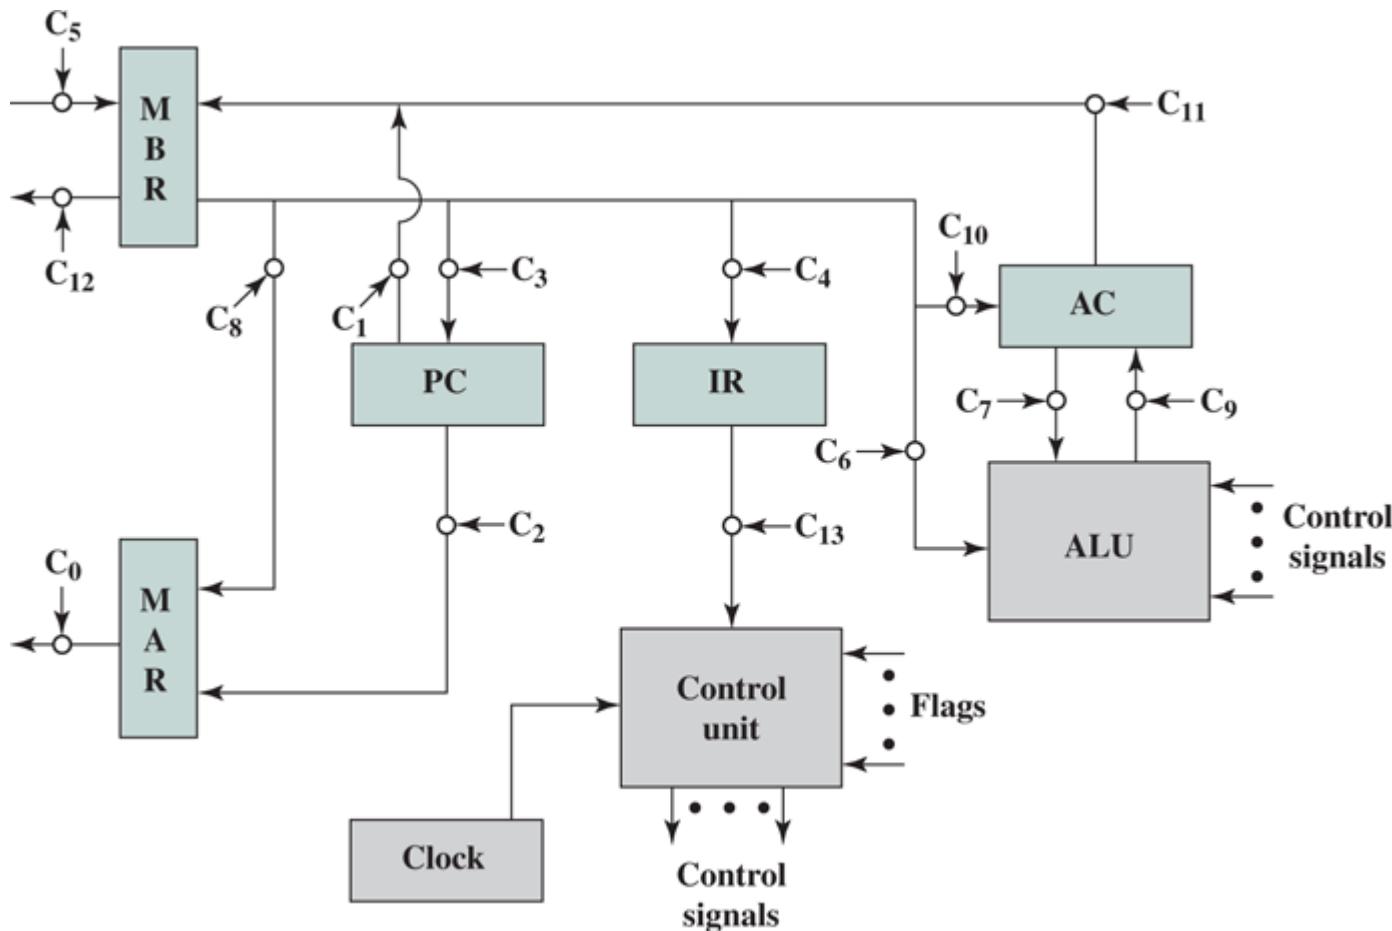

Figure 19.5 Data Paths and Control Signals

- **Data paths:** The control unit controls the internal flow of data. For example, on instruction fetch, the contents of the memory buffer register are transferred to the IR. For each path to be controlled, there is a switch (indicated by a circle in the figure). A control signal from the control unit temporarily opens the gate to let data pass.
- **ALU:** The control unit controls the operation of the ALU by a set of control signals. These signals activate various logic circuits and gates within the ALU.
- **System bus:** The control unit sends control signals out onto the control lines of the system bus (e.g., memory READ).

The control unit must maintain knowledge of where it is in the instruction cycle. Using this knowledge, and by reading all of its inputs, the control unit emits a sequence of control signals that causes micro-operations to occur. It uses the clock pulses to time the sequence of events, allowing time between events for signal levels to stabilize. **Table 19.1** indicates the control signals that are needed for some of the micro-operation sequences described earlier. For simplicity, the data and control paths for incrementing the PC and for loading the fixed addresses into the PC and MAR are not shown.

Table 19.1 Micro-operations and Control Signals
 C_R = Read control signal to system bus.

C_W = Write control signal to system bus.

	Micro-operations	Active Control Signals
Fetch:	$t_1 : MAR \leftarrow (PC)$	C_2
	$t_2: MBR \leftarrow \text{Memory}$ $PC \leftarrow (PC) + 1$	C_5, C_R

	$t_3 : IR \leftarrow (MBR)$	C_4
Indirect:	$t_1 : MAR \leftarrow (IR(\text{Address}))$	C_8
	$t_2 : MBR \leftarrow \text{Memory}$	C_5, C_R
	$t_3 : IR(\text{Address}) \leftarrow (MBR(\text{Address}))$	C_4
Interrupt:	$t_1 : MBR \leftarrow (PC)$	C_1
	$t_2 : MAR \leftarrow \text{Save-address}$ $PC \leftarrow \text{Routine-address}$	
	$t_3 : \text{Memory} \leftarrow (MBR)$	C_{12}, C_W

It is worth pondering the minimal nature of the control unit. The control unit is the engine that runs the entire computer. It does this based only on knowing the instructions to be executed and the nature of the results of arithmetic and logical operations (e.g., positive, overflow, etc.). It never gets to see the data being processed or the actual results produced. And it controls everything with a few control signals to points within the processor and a few control signals to the system bus.

Internal Processor Organization

Figure 19.5 indicates the use of a variety of data paths. The complexity of this type of organization should be clear. More typically, some sort of internal bus arrangement, as was suggested in **Figure 16.1 (Internal Structure of the CPU)**, , some sort of internal bus arrangement, as was suggested in Internal Structure of the CPU will be used.

Using an internal processor bus, **Figure 19.5** can be rearranged as shown in **Figure 19.6**. A single internal bus connects the ALU and all processor registers. Gates and control signals are provided for movement of data onto and off the bus from each register. Additional control signals control data transfer to and from the system (external) bus and the operation of the ALU.

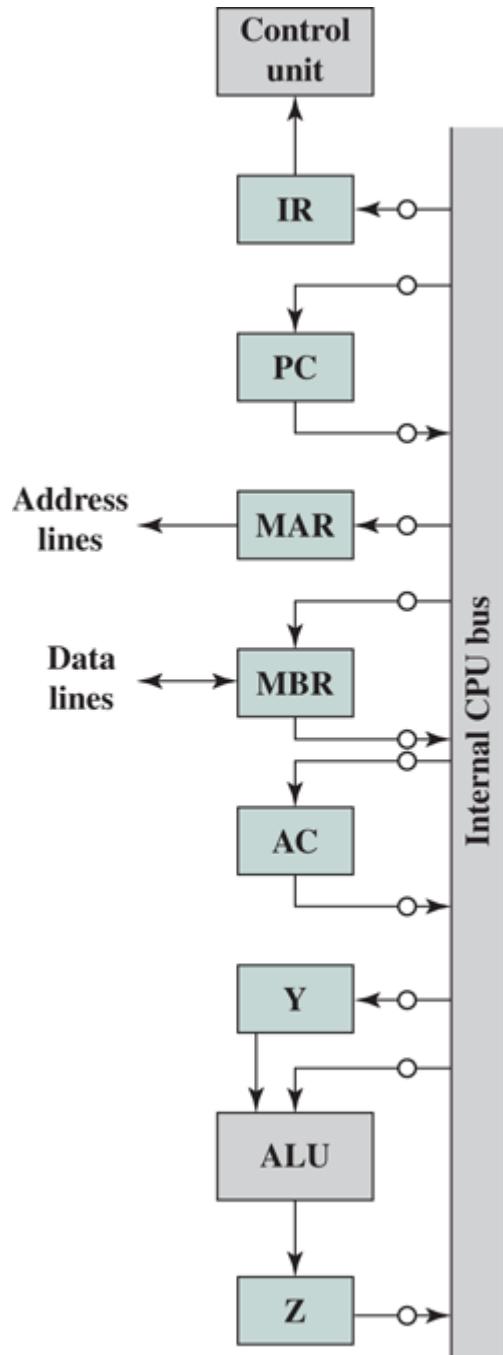

Figure 19.6 CPU with Internal Bus

Two new registers, labeled Y and Z, have been added to the organization. These are needed for the proper operation of the ALU. When an operation involving two operands is performed, one can be obtained from the internal bus, but the other must be obtained from another source. The AC could be used for this purpose, but this limits the flexibility of the system and would not work with a processor with multiple general-purpose registers. Register Y provides temporary storage for the other input. The ALU is a combinatorial circuit (see [Chapter 12](#)) with no internal storage. Thus, when control signals activate an ALU function, the input to the ALU is transformed to the output. Therefore, the output of the ALU cannot be directly connected to the bus, because this output would feed back to the input. Register Z provides temporary output storage. With this arrangement, an operation to add a value from memory to the AC would have the following steps:

```

t1: MAR ← (IR (address))
t2: MBR ← Memory
t3: Y ← (MBR)

```

```

t4: Z ← (AC) + (Y)
t5: AC ← (Z)

```

Other organizations are possible, but, in general, some sort of internal bus or set of internal buses is used. The use of common data paths simplifies the interconnection layout and the control of the processor. Another practical reason for the use of an internal bus is to save space.

The Intel 8085

To illustrate some of the concepts introduced thus far in this chapter, let us consider the Intel 8085. Its organization is shown in **Figure 19.7**. Several key components that may not be self-explanatory are:

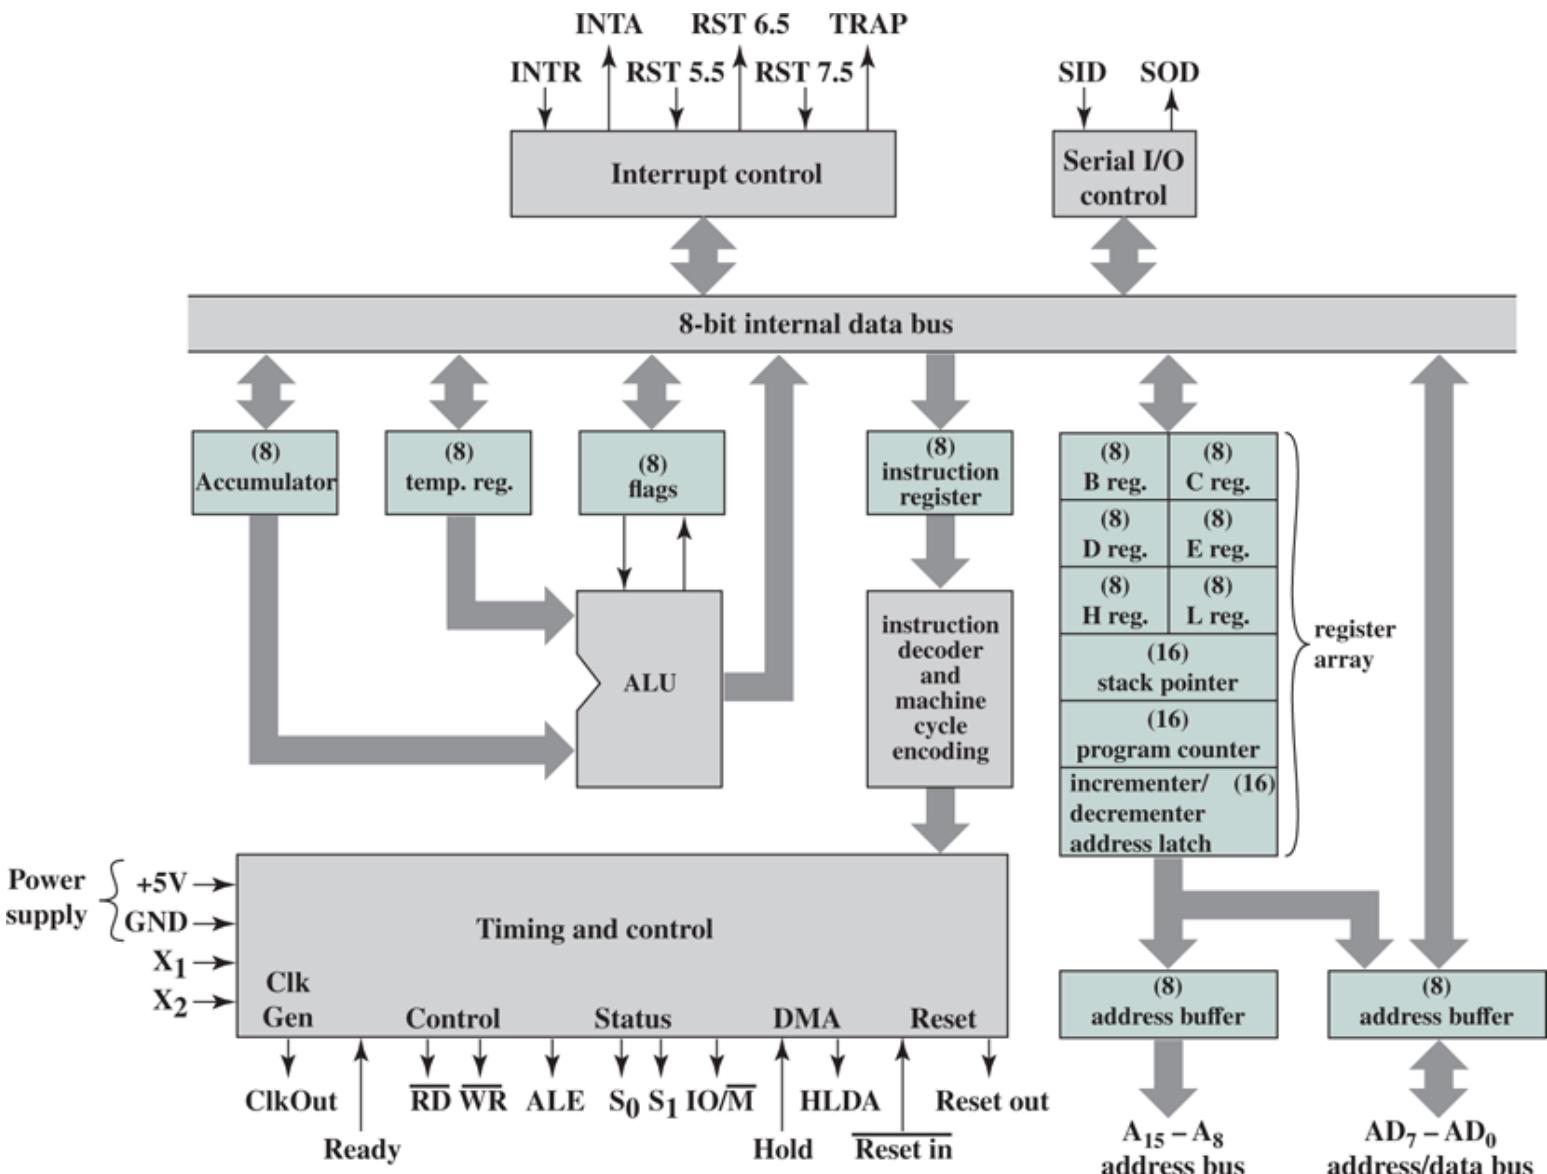

Figure 19.7 Intel 8085 CPU Block Diagram

- **Incrementer/decrementer address latch:** Logic that can add 1 to or subtract 1 from the contents of the stack pointer or program counter. This saves time by avoiding the use of the ALU for this purpose.
 - **Interrupt control:** This module handles multiple levels of interrupt signals.
 - **Serial I/O control:** This module interfaces to devices that communicate 1 bit at a time.
- Table 19.2** describes the external signals into and out of the 8085. These are linked to the external

system bus. These signals are the interface between the 8085 processor and the rest of the system ([Figure 19.8](#)).

Table 19.2 Intel 8085 External Signals

<i>Address and Data Signals</i>	
High Address (A15–A8)	The high-order 8 bits of a 16-bit address.
Address/Data (AD7–AD0)	The lower-order 8 bits of a 16-bit address or 8 bits of data. This multiplexing saves on pins.
Serial Input Data (SID)	A single-bit input to accommodate devices that transmit serially (one bit at a time).
Serial Output Data (SOD)	A single-bit output to accommodate devices that receive serially.
<i>Timing and Control Signals</i>	
CLK (OUT)	The system clock. The CLK signal goes to peripheral chips and synchronizes their timing.
X1, X2	These signals come from an external crystal or other device to drive the internal clock generator.
Address Latch Enabled (ALE)	Occurs during the first clock state of a machine cycle and causes peripheral chips to store the address lines. This allows the address module (e.g., memory, I/O) to recognize that it is being addressed.
Status (S0, S1)	Control signals used to indicate whether a read or write operation is taking place.
IO/M	Used to enable either I/O or memory modules for read and write operations.

Read Control (RD)

Indicates that the selected memory or I/O module is to be read and that the data bus is available for data transfer.

Write Control (WR)

Indicates that data on the data bus is to be written into the selected memory or I/O location.

Memory and I/O Initiated Symbols

Hold

Requests the CPU to relinquish control and use of the external system bus. The CPU will complete execution of the instruction presently in the IR and then enter a hold state, during which no signals are inserted by the CPU to the control, address, or data buses. During the hold state, the bus may be used for DMA operations.

Hold Acknowledge (HOLDA)

This control unit output signal acknowledges the HOLD signal and indicates that the bus is now available.

READY

Used to synchronize the CPU with slower memory or I/O devices. When an addressed device asserts READY, the CPU may proceed with an input (DBIN) or output (WR) operation. Otherwise, the CPU enters a wait state until the device is ready.

Interrupt-Related Signals

TRAP

Restart Interrupts (RST 7.5, 6.5, 5.5)

Interrupt Request (INTR)

These five lines are used by an external device to interrupt the CPU. The CPU will not honor the request if it is in the hold state or if the interrupt is disabled. An interrupt is honored only at the completion of an instruction. The interrupts are in descending order of priority.

Interrupt Acknowledge

Acknowledges an interrupt.

CPU Initialization

RESET IN

Causes the contents of the PC to be set to zero. The CPU resumes execution at location zero.

RESET OUT

Acknowledges that the CPU has been reset. The signal can be used to reset the rest of the system.

Voltage and Ground

VCC

+5-volt power supply

VSS

Electrical ground

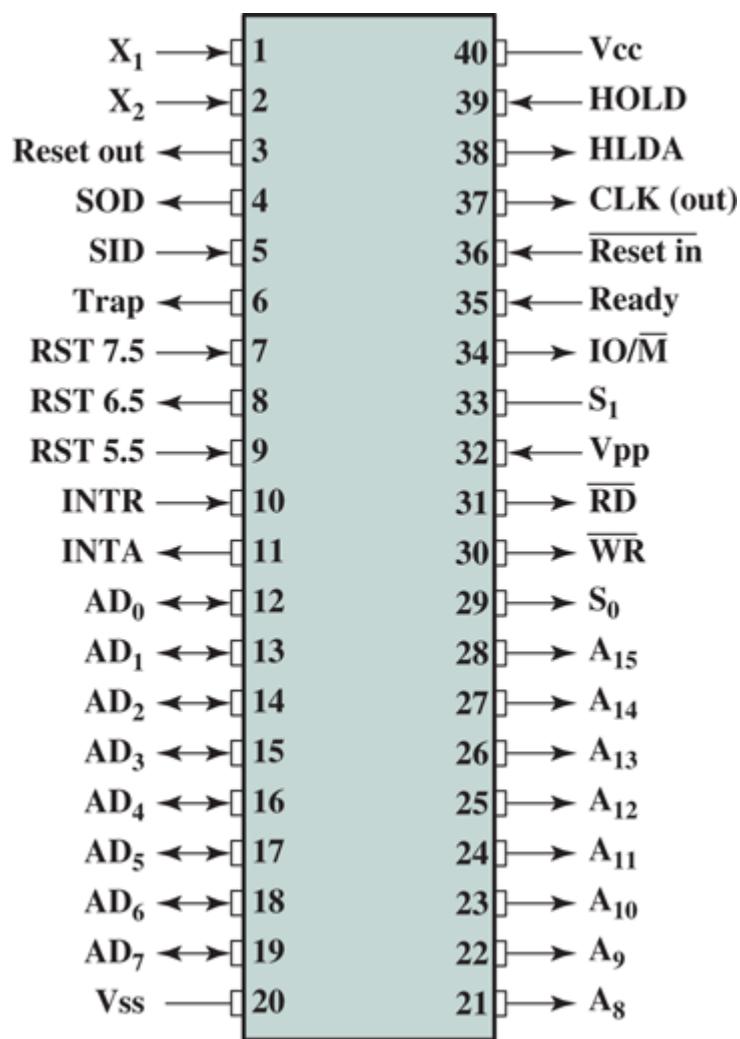

Figure 19.8 Intel 8085 Pin Configuration

The control unit is identified as having two components labeled (1) instruction decoder and machine cycle encoding and (2) timing and control. A discussion of the first component is deferred until the next section. The essence of the control unit is the timing and control module. This module includes a clock and accepts as inputs the current instruction and some external control signals. Its output consists of control signals to the other components of the processor plus control signals to the external system bus.

The timing of processor operations is synchronized by the clock and controlled by the control unit with control signals. Each instruction cycle is divided into from one to five *machine cycles*; each machine cycle is in turn divided into from three to five *states*. Each state lasts one clock cycle. During a state, the processor performs one or a set of simultaneous micro-operations as determined by the control signals.

The number of machine cycles is fixed for a given instruction but varies from one instruction to another. Machine cycles are defined to be equivalent to bus accesses. Thus, the number of machine cycles for an instruction depends on the number of times the processor must communicate with external devices. For example, if an instruction consists of two 8-bit portions, then two machine cycles are required to fetch the instruction. If that instruction involves a 1-byte memory or I/O operation, then a third machine cycle is required for execution.

Figure 19.9 gives an example of 8085 timing, showing the value of external control signals. Of course, at the same time, the control unit generates internal control signals that control internal data transfers. The diagram shows the instruction cycle for an OUT instruction. Three machine cycles (M_1, M_2, M_3) are needed. During the first, the OUT instruction is fetched. The second machine cycle fetches the second half of the instruction, which contains the number of the I/O device selected for output. During the third cycle, the contents of the AC are written out to the selected device over the data bus.

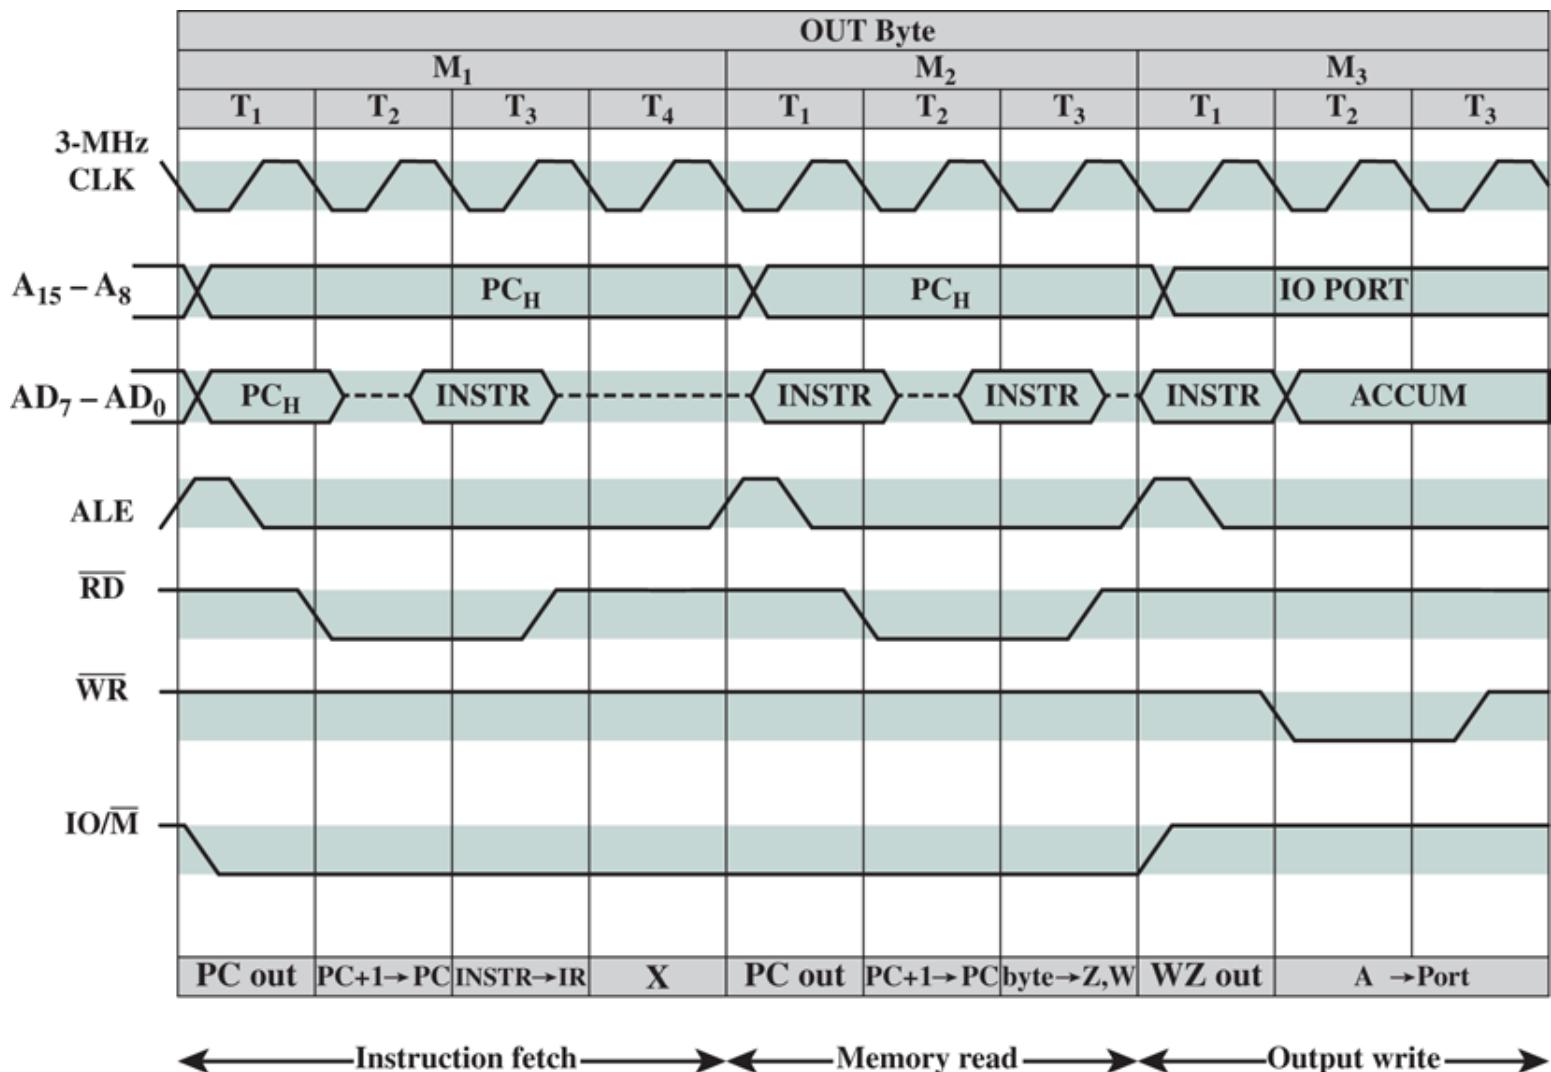

Figure 19.9 Timing Diagram for Intel 8085 OUT Instruction

The Address Latch Enabled (ALE) pulse signals the start of each machine cycle from the control unit. The ALE pulse alerts external circuits. During timing state T₁ of machine cycle M₁, the control unit sets the IO/M signal to indicate that this is a memory operation. Also, the control unit causes the contents of the PC to be placed on the address bus (A₁₅ through A₈) and the address/data bus (AD₇ through AD₀). With the falling edge of the Ale pulse, the other modules on the bus store the address.

During timing state T₂, the addressed memory module places the contents of the addressed memory location on the address/data bus. The control unit sets the Read Control (RD) signal to indicate a read, but it waits until T₃ to copy the data from the bus. This gives the memory module time to put the data on the bus and for the signal levels to stabilize. The final state, T₄, is a *bus idle* state during which the processor decodes the instruction. The remaining machine cycles proceed in a similar fashion.

19.3 Hardwired Implementation

We have discussed the control unit in terms of its inputs, output, and functions. We now turn to the topic of control unit implementation. A wide variety of techniques have been used. Most of these fall into one of two categories:

- Hardwired implementation
- Microprogrammed implementation

In a **hardwired implementation**, the control unit is essentially a state machine circuit. Its input logic signals are transformed into a set of output logic signals, which are the control signals. This approach is examined in this section. Microprogrammed implementation is the subject of [Section 19.4](#).

Control Unit Inputs

[Figure 19.4](#) depicts the control unit as we have so far discussed it. The key inputs are the IR, the clock, flags, and control bus signals. In the case of the flags and control bus signals, each individual bit typically has some meaning (e.g., overflow). The other two inputs, however, are not directly useful to the control unit.

First consider the IR. The control unit makes use of the opcode and will perform different actions (issue a different combination of control signals) for different instructions. To simplify the control unit logic, there should be a unique logic input for each opcode. This function can be performed by a *decoder*, which takes an encoded input and produces a single output. In general, a decoder will have n binary inputs and 2^n binary outputs. Each of the 2^n different input patterns will activate a single unique output. [Table 19.3](#) is an example for $n = 4$. The decoder for a control unit will typically have to be more complex than that, to account for variable-length opcodes. An example of the digital logic used to implement a decoder is presented in [Chapter 12](#).

Table 19.3 A Decoder with 4 Inputs and 16 Outputs

I1	0	0	0	0	0	0	0	0	1	1	1	1	1	1	1	1	1
I2	0	0	0	0	1	1	1	1	0	0	0	0	1	1	1	1	1
I3	0	0	1	1	0	0	1	1	0	0	1	1	0	0	1	1	1
I4	0	1	0	1	0	1	0	1	0	1	0	1	0	1	0	1	1
O1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1
O2	0	0	0	0	0	0	0	0	0	0	0	0	0	0	1	0	0
O3	0	0	0	0	0	0	0	0	0	0	0	0	0	1	0	0	0
O4	0	0	0	0	0	0	0	0	0	0	0	0	1	0	0	0	0
O5	0	0	0	0	0	0	0	0	0	0	0	1	0	0	0	0	0

O6	0	0	0	0	0	0	0	0	0	0	1	0	0	0	0	0
O7	0	0	0	0	0	0	0	0	0	1	0	0	0	0	0	0
O8	0	0	0	0	0	0	0	1	0	0	0	0	0	0	0	0
O9	0	0	0	0	0	0	0	1	0	0	0	0	0	0	0	0
O10	0	0	0	0	0	0	1	0	0	0	0	0	0	0	0	0
O11	0	0	0	0	0	1	0	0	0	0	0	0	0	0	0	0
O12	0	0	0	0	1	0	0	0	0	0	0	0	0	0	0	0
O13	0	0	0	1	0	0	0	0	0	0	0	0	0	0	0	0
O14	0	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0
O15	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0
O16	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

The clock portion of the control unit issues a repetitive sequence of pulses. This is useful for measuring the duration of micro-operations. Essentially, the period of the clock pulses must be long enough to allow the propagation of signals along data paths and through processor circuitry. However, as we have seen, the control unit emits different control signals at different time units within a single instruction cycle. Thus, we would like a counter as input to the control unit, with a different control signal being used for T_1 , T_2 , and so forth. At the end of an instruction cycle, the control unit must feed back to the counter to reinitialize it at T_1 .

With these two refinements, the control unit can be depicted as in [Figure 19.10](#).

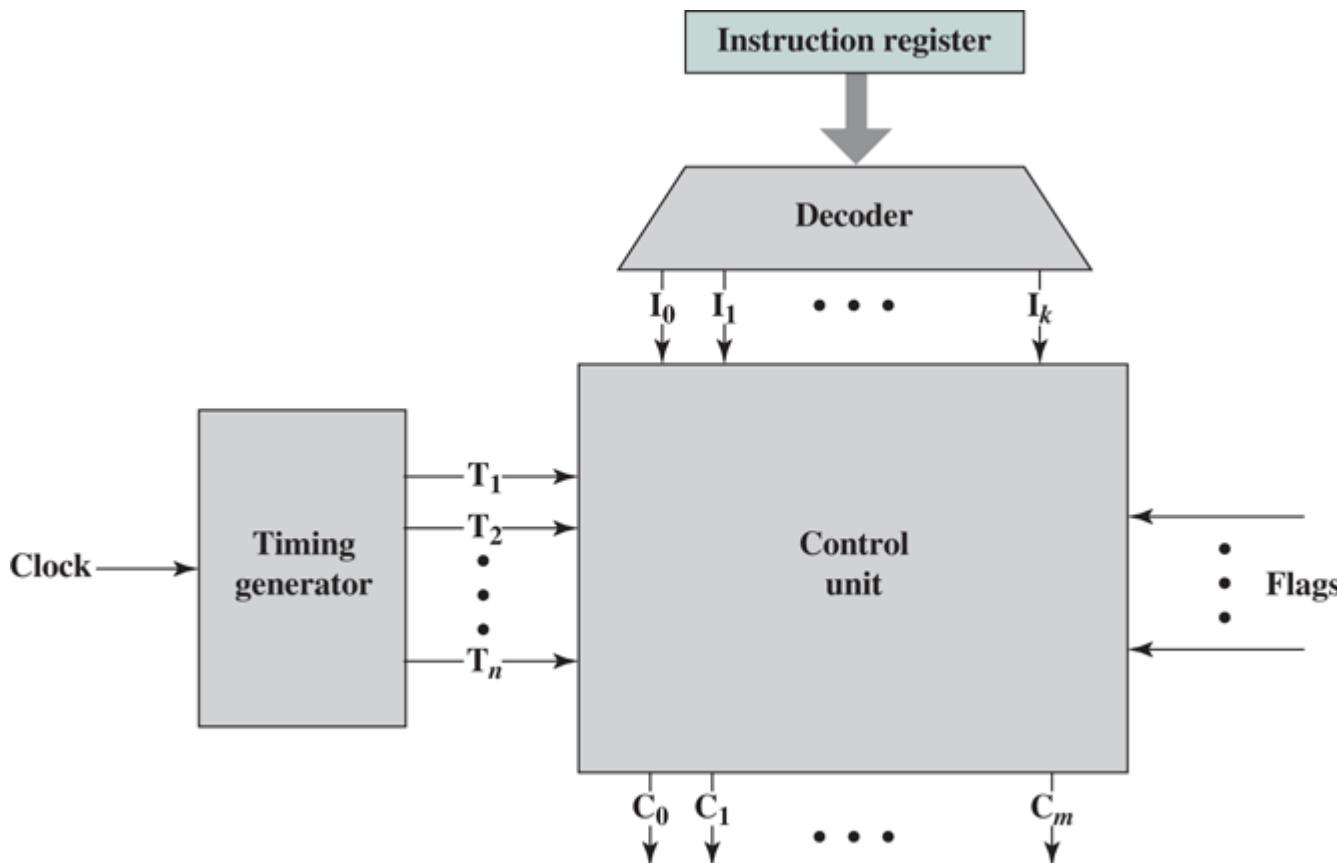

Figure 19.10 Control Unit with Decoded Inputs

Control Unit Logic

To define the hardwired implementation of a control unit, all that remains is to discuss the internal logic of the control unit that produces output control signals as a function of its input signals.

Essentially, what must be done is, for each control signal, to derive a Boolean expression of that signal as a function of the inputs. This is best explained by example. Let us consider again our simple example illustrated in [Figure 19.5](#). We saw in [Table 19.1](#) the micro-operation sequences and control signals needed to control three of the four phases of the instruction cycle.

Let us consider a single control signal, C_5 . This signal causes data to be read from the external data bus into the MBR. We can see that it is used twice in [Table 19.1](#). Let us define two new control signals, P and Q, that have the following interpretation:

- PQ = 00 Fetch Cycle
- PQ = 01 Indirect Cycle
- PQ = 10 Execute Cycle
- PQ = 11 Interrupt Cycle

Then the following Boolean expression defines $C_5 : v$

$$C_5 = P \bullet Q \bullet T_2 + P \bullet Q \bullet T_2$$

That is, the control signal C_5 will be asserted during the second time unit of both the fetch and indirect cycles.

This expression is not complete. C_5 is also needed during the execute cycle. For our simple example, let us assume that there are only three instructions that read from memory: LDA, ADD, and AND. Now we can define C_5 as

$$C_5 = P \bullet Q \bullet T_2 + P \bullet Q \bullet T_2 + P \bullet Q \bullet (LDA + ADD + AND) \bullet T_2$$

This same process could be repeated for every control signal generated by the processor. The result would be a set of Boolean equations that define the behavior of the control unit and hence of the processor.

To tie everything together, the control unit must control the state of the instruction cycle. As was mentioned, at the end of each subcycle (fetch, indirect, execute, interrupt), the control unit issues a signal that causes the timing generator to reinitialize and issue T_1 . The control unit must also set the appropriate values of P and Q to define the next subcycle to be performed.

The reader should be able to appreciate that in a modern complex processor, the number of Boolean equations needed to define the control unit is very large. The task of implementing a combinatorial circuit that satisfies all of these equations becomes extremely difficult. The result is that a far simpler approach, known as *microprogramming*, is usually used. This is the subject of the next section.

19.4 Microprogrammed Control

The term *microprogram* was first coined by M. V. Wilkes in the early 1950s [WILK51]. Wilkes proposed an approach to control unit design that was organized and systematic, and avoided the complexities of a hardwired implementation. The idea intrigued many researchers but appeared unworkable because it would require a fast, relatively inexpensive control memory.

The state of the microprogramming art was reviewed by *Datamation* in its February 1964 issue. No microprogrammed system was in wide use at that time, and one of the papers [HILL64] summarized the then-popular view that the future of microprogramming “is somewhat cloudy. None of the major manufacturers has evidenced interest in the technique, although presumably all have examined it.”

This situation changed dramatically within a very few months. IBM’s System/360 was announced in April, and all but the largest models were microprogrammed. Although the 360 series predated the availability of semiconductor ROM, the advantages of microprogramming were compelling enough for IBM to make this move. Microprogramming became a popular technique for implementing the control unit of CISC processors. In recent years, microprogramming has become less used but remains a tool available to computer designers. For example, as we have seen on the Pentium 4, machine instructions are converted into a RISC-like format, most of which are executed without the use of microprogramming. However, some of the instructions are executed using microprogramming.

Microinstructions

The control unit seems a reasonably simple device. Nevertheless, to implement a control unit as an interconnection of basic logic elements is no easy task. The design must include logic for sequencing through micro-operations, for executing micro-operations, for interpreting opcodes, and for making decisions based on ALU flags. It is difficult to design and test such a piece of hardware. Furthermore, the design is relatively inflexible. For example, it is difficult to change the design if one wishes to add a new machine instruction.

An alternative, which has been used in many CISC processors, is to implement a **microprogrammed control unit**.

Consider **Table 19.4**. In addition to the use of control signals, each micro-operation is described in symbolic notation. This notation looks suspiciously like a programming language. In fact it is a language, known as a **microprogramming language**. Each line describes a set of micro-operations occurring at one time and is known as a **microinstruction**. A sequence of instructions is known as a **microprogram**, or *firmware*. This latter term reflects the fact that a microprogram is midway between hardware and software. It is easier to design in firmware than hardware, but it is more difficult to write a firmware program than a software program.

Table 19.4 Machine Instruction Set for Wilkes Example

Acc = accumulator

*Acc*₁ = most significant half of accumulator

Notation: *Acc*₂ = least significant half of accumulator

n = storage location *n*

C(X) = contents of *X* (*X* = register or storage location)

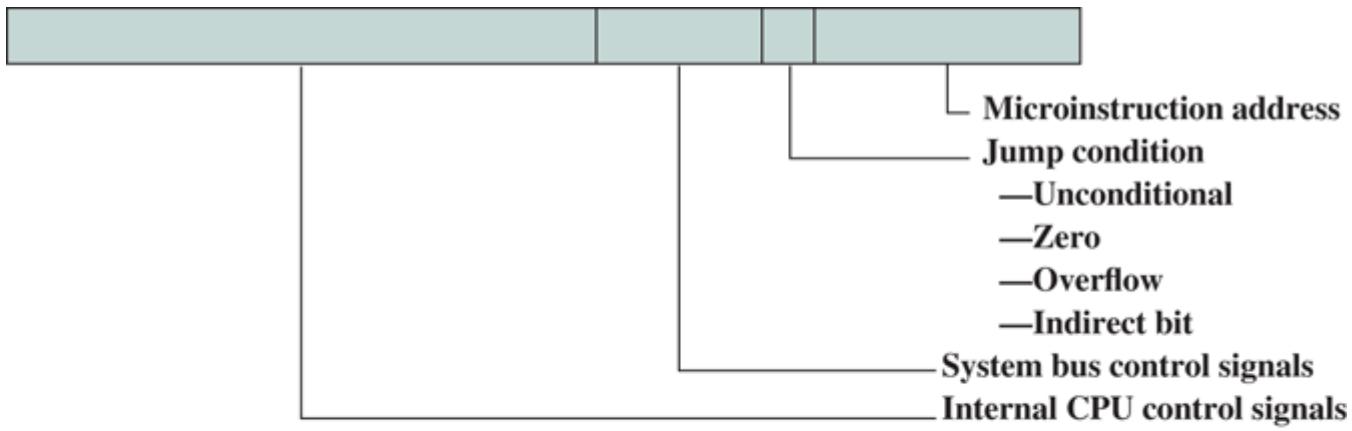

Order	Effect of Order
<i>A n</i>	<i>C(Acc) + C(n)</i> to <i>Acc</i> ₁

S_n	$C(Acc) - C(n)$ to Acc_1
H_n	$C(n)$ to Acc_2
V_n	$C(Acc_2) \times C(n)$ to Acc , where $C(n) \geq 0$
T_n	$C(Acc_1)$ to n , 0 to Acc
U_n	$C(Acc_1)$ to n
R_n	$C(Acc) \times 2^{(n+1)}$ to Acc
L_n	$C(Acc) \times 2^{n+1}$ to Acc
G_n	IF $C(Acc) < 0$, transfer control to n ; if $C(Acc) \geq 0$, ignore (i.e., proceed serially)
I_n	Read next character on input mechanism into n
O_n	Send $C(n)$ to output mechanism

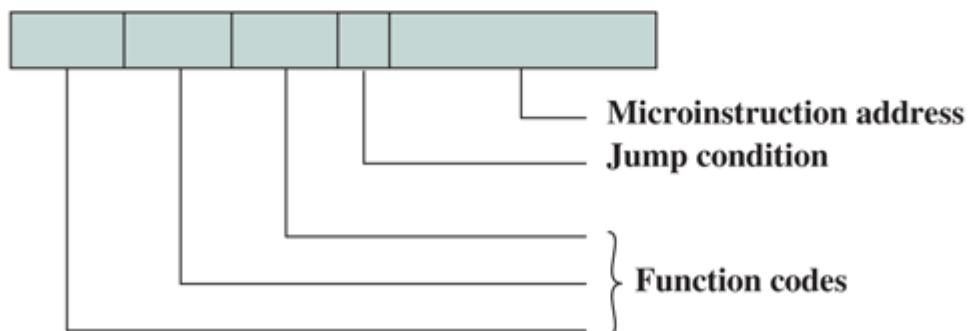

How can we use the concept of microprogramming to implement a control unit? Consider that for each micro-operation, all that the control unit is allowed to do is generate a set of control signals. Thus, for any micro-operation, each control line emanating from the control unit is either on or off. This condition can, of course, be represented by a binary digit for each control line. So we could construct a *control word* in which each bit represents one control line. Then each micro-operation would be represented by a different pattern of 1s and 0s in the control word.

Suppose we string together a sequence of control words to represent the sequence of micro-operations performed by the control unit. Next, we must recognize that the sequence of micro-operations is not fixed. Sometimes we have an indirect cycle; sometimes we do not. So let us put our control words in a memory, with each word having a unique address. Now add an address field to each control word, indicating the location of the next control word to be executed if a certain condition is true (e.g., the indirect bit in a memory-reference instruction is 1). Also, add a few bits to specify the condition.

The result is known as a **horizontal microinstruction**, an example of which is shown in [Figure 19.12a](#). The format of the microinstruction or control word is as follows. There is one bit for each internal processor control line and one bit for each system bus control line. There is a condition field indicating the condition under which there should be a branch, and there is a field with the address of the microinstruction to be executed next when a branch is taken. Such a microinstruction is interpreted as follows:

(a) Horizontal microinstruction

(b) Vertical microinstruction

Figure 19.12 Typical Microinstruction Formats

1. To execute this microinstruction, turn on all the control lines indicated by a 1 bit; leave off all control lines indicated by a 0 bit. The resulting control signals will cause one or more microoperations to be performed.
2. If the condition indicated by the condition bits is false, execute the next microinstruction in sequence.
3. If the condition indicated by the condition bits is true, the next microinstruction to be executed is indicated in the address field.

Figure 19.13 shows how these control words or microinstructions could be arranged in a **control memory**. The microinstructions in each routine are to be executed sequentially. Each routine ends with a branch or jump instruction indicating where to go next. There is a special execute cycle routine whose only purpose is to signify that one of the machine instruction routines (AND, ADD, and so on) is to be executed next, depending on the current opcode.

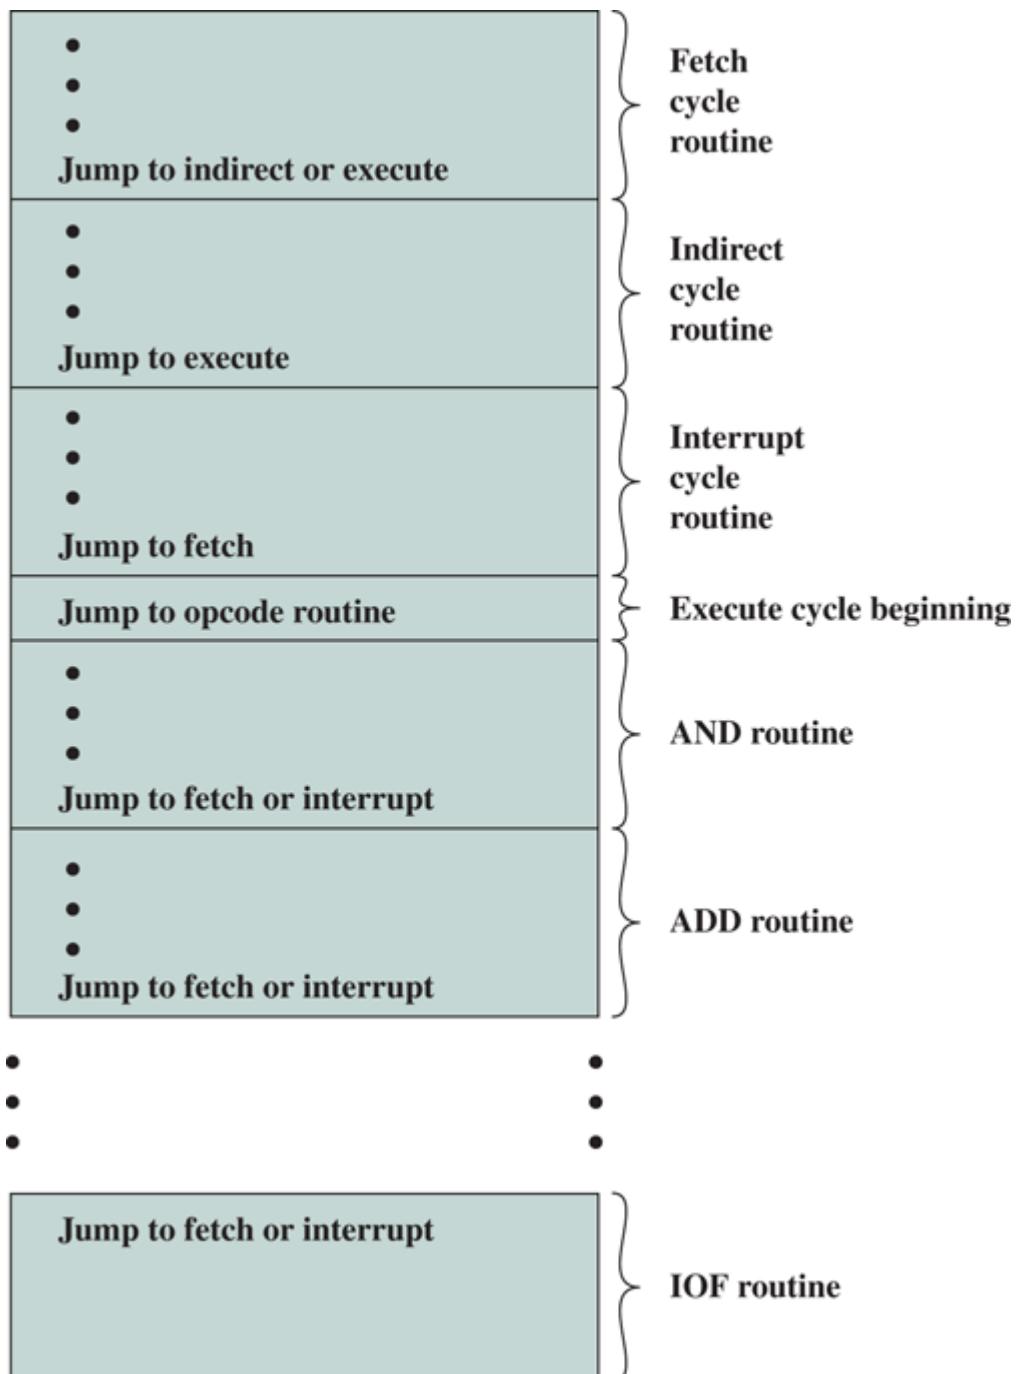

Figure 19.13 Organization of Control Memory

The control memory of [Figure 19.13](#) is a concise description of the complete operation of the control unit. It defines the sequence of micro-operations to be performed during each cycle (fetch, indirect, execute, interrupt), and it specifies the sequencing of these cycles. If nothing else, this notation would be a useful device for documenting the functioning of a control unit for a particular computer. But it is more than that. It is also a way of implementing the control unit.

Microprogrammed Control Unit

The control memory of [Figure 19.13](#) contains a program that describes the behavior of the control unit. It follows that we could implement the control unit by simply executing that program.

[Figure 19.14](#) shows the key elements of such an implementation. The set of microinstructions is stored in the *control memory*. The *control address register* contains the address of the next microinstruction to be read. When a microinstruction is read from the control memory, it is transferred

to a *control buffer register*. The left-hand portion of that register (see [Figure 19.12a](#)) connects to the control lines emanating from the control unit. Thus, *reading* a microinstruction from the control memory is the same as *executing* that microinstruction. The third element shown in the figure is a sequencing unit that loads the control address register and issues a read command.

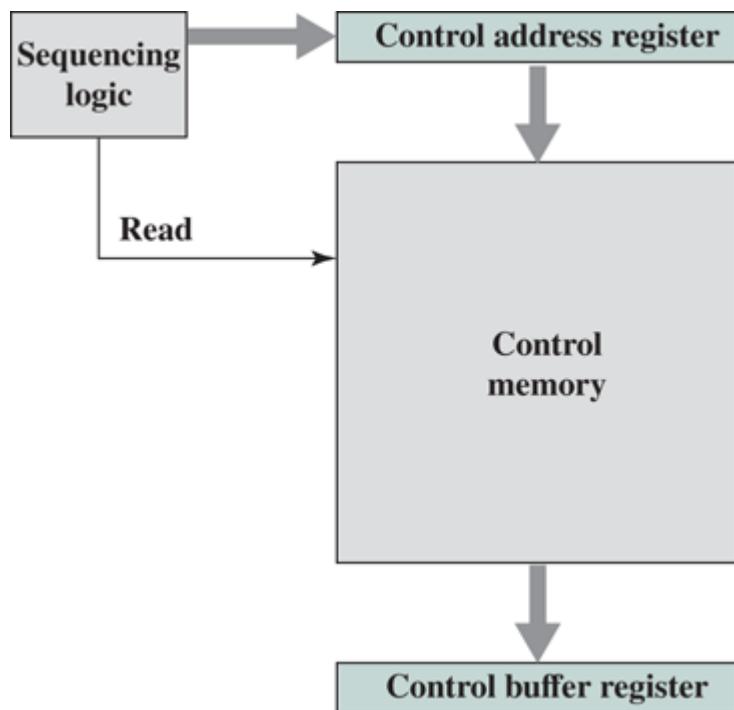

Figure 19.14 Control Unit Microarchitecture

Let us examine this structure in greater detail, as depicted in [Figure 19.15](#). Comparing this with [Figure 19.14](#), we see that the control unit still has the same inputs (IR, ALU flags, clock) and outputs (control signals). The control unit functions as follows:

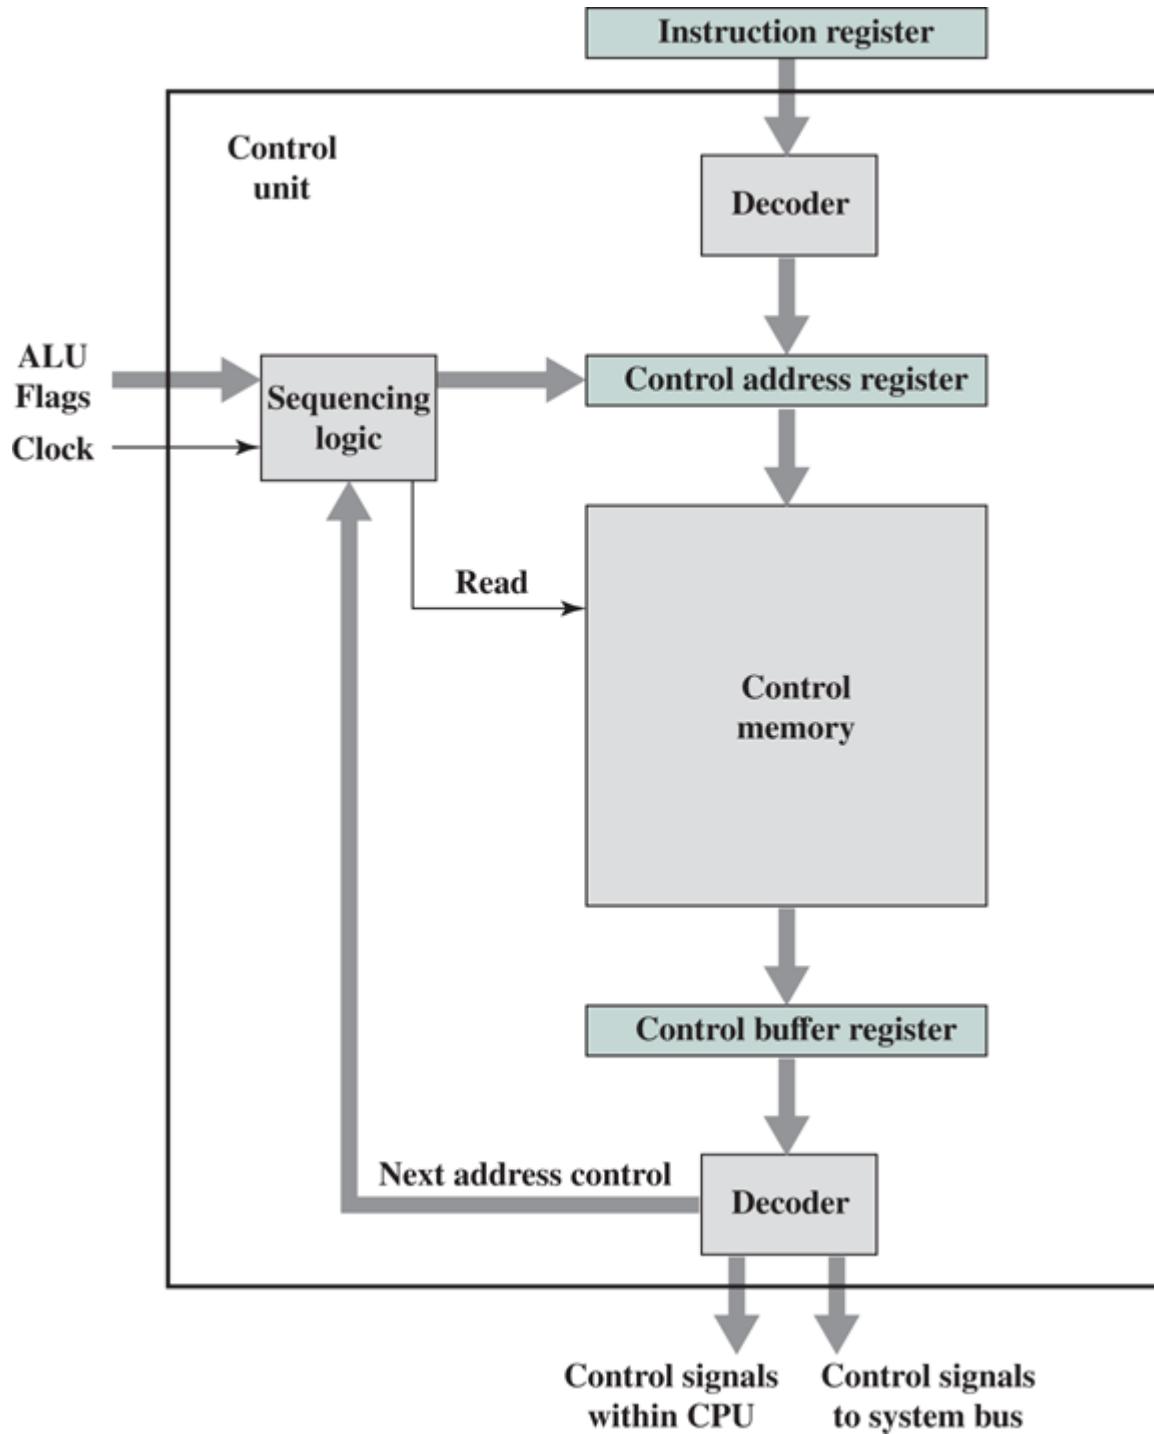

Figure 19.15 Functioning of Microprogrammed Control Unit

1. To execute an instruction, the sequencing logic unit issues a READ command to the control memory.
2. The word whose address is specified in the control address register is read into the control buffer register.
3. The content of the control buffer register generates control signals and next-address information for the sequencing logic unit.
4. The sequencing logic unit loads a new address into the control address register based on the next-address information from the control buffer register and the ALU flags.

All this happens during one clock pulse.

The last step just listed needs elaboration. At the conclusion of each microinstruction, the sequencing logic unit loads a new address into the control address register. Depending on the value of the ALU

flags and the control buffer register, one of three decisions is made:

- **Get the next instruction:** Add 1 to the control address register.
- **Jump to a new routine based on a jump microinstruction:** Load the address field of the control buffer register into the control address register.
- **Jump to a machine instruction routine:** Load the control address register based on the opcode in the IR.

Figure 19.15 shows two modules labeled *decoder*. The upper decoder translates the opcode of the IR into a control memory address. The lower decoder is not used for horizontal microinstructions but is used for **vertical microinstructions** (**Figure 19.12b**). As was mentioned, in a horizontal microinstruction every bit in the control field attaches to a control line. In a vertical microinstruction, a code is used for each action to be performed [e.g., $\text{MAR} \leftarrow (\text{PC})$], and the decoder translates this code into individual control signals. The advantage of vertical microinstructions is that they are more compact (fewer bits) than horizontal microinstructions, at the expense of a small additional amount of logic and time delay.

Wilkes Control

As was mentioned, Wilkes first proposed the use of a microprogrammed control unit in 1951 [WILK51]. This proposal was subsequently elaborated into a more detailed design [WILK53]. It is instructive to examine this seminal proposal.

The configuration proposed by Wilkes is depicted in **Figure 19.16**. The heart of the system is a matrix partially filled with diodes. During a machine cycle, one row of the matrix is activated with a pulse. This generates signals at those points where a diode is present (indicated by a dot in the diagram). The first part of the row generates the control signals that control the operation of the processor. The second part generates the address of the row to be pulsed in the next machine cycle. Thus, each row of the matrix is one microinstruction, and the layout of the matrix is the control memory.

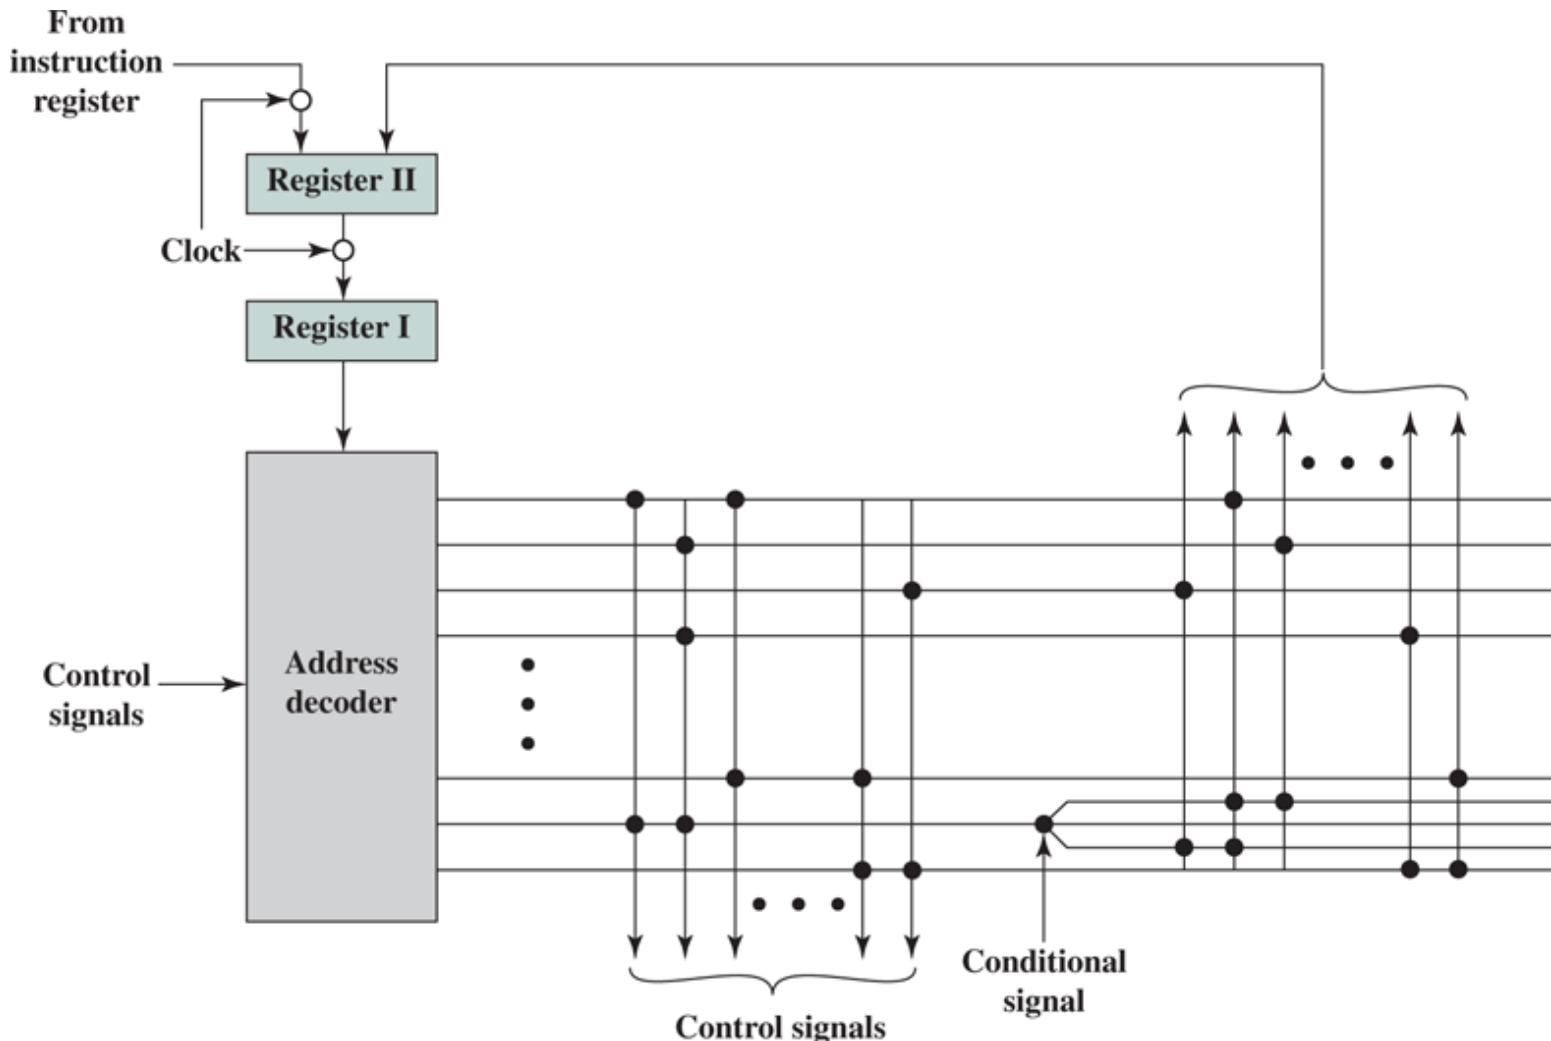

Figure 19.16 Wilkes's Microprogrammed Control Unit

At the beginning of the cycle, the address of the row to be pulsed is contained in Register I. This address is the input to the decoder, which, when activated by a clock pulse, activates one row of the matrix. Depending on the control signals, either the opcode in the instruction register or the second part of the pulsed row is passed into Register II during the cycle. Register II is then gated to Register I by a clock pulse. Alternating clock pulses are used to activate a row of the matrix and to transfer from Register II to Register I. The two-register arrangement is needed because the decoder is simply a combinatorial circuit; with only one register, the output would become the input during a cycle, causing an unstable condition.

This scheme is very similar to the horizontal microprogramming approach described earlier ([Figure 19.12a](#)). The main difference is this: In the previous description, the control address register could be incremented by one to get the next address. In the Wilkes scheme, the next address is contained in the microinstruction. To permit branching, a row must contain two address parts, controlled by a conditional signal (e.g., flag), as shown in the figure.

Having proposed this scheme, Wilkes provides an example of its use to implement the control unit of a simple machine. This example, the first known design of a microprogrammed processor, is worth repeating here because it illustrates many of the contemporary principles of microprogramming.

The processor of the hypothetical machine (the example machine by Wilkes) includes the following registers:

A

Multiplicand

B	Accumulator (least significant half)
C	Accumulator (most significant half)
D	Shift register

In addition, there are three registers and two 1-bit flags accessible only to the control unit. The registers are as follows:

E	Serves as both a memory address register (MAR) and temporary storage
F	Program counter
G	Another temporary register; used for counting

Table 19.4 lists the machine instruction set for this example. **Table 19.5** is the complete set of microinstructions, expressed in symbolic form, that implements the control unit. Thus, a total of 38 microinstructions is all that is required to define the system completely.

Table 19.5 Microinstructions for Wilkes Example

Notations: A, B, C, \dots stand for the various registers in the arithmetical and control register units. C to D indicates that the switching circuits connect the output of register C to the input register D ; $(D + A)$ to C indicates that the output register of A is connected to the one input of the adding unit (the output of D is permanently connected to the other input), and the output of the adder to register C . A numerical symbol n in quotes (e.g., “ n ”) stands for the source whose output is the number n in units of the least significant digit.

* Right shift. The switching circuits in the arithmetic unit are arranged so that the least significant digit of the register C is placed in the most significant place of register B during right shift micro-operations, and the most significant digit of register C (sign digit) is repeated (thus making the correction for negative numbers).

† Left shift. The switching circuits are similarly arranged to pass the most significant digit of register B to the least significant place of register C during left shift micro-operations.

	Arithmetical Unit	Control Register Unit	Conditional Flip-Flop		Next Microinstruction	
			Set	Use	0	1
0		F to G and E			1	
1		$(G$ to “1”) to F			2	
2		Store to G			3

	35	$C \rightarrow D (R)$			1	36	37
	36	$D \rightarrow C$				0	
	37	$(D - A) \rightarrow C$				0	

The first full column gives the address (row number) of each microinstruction. Those addresses corresponding to opcodes are labeled. Thus, when the opcode for the add instruction (A) is encountered, the microinstruction at location 5 is executed. Columns 2 and 3 express the actions to be taken by the ALU and control unit, respectively. Each symbolic expression must be translated into a set of control signals (microinstruction bits). Columns 4 and 5 have to do with the setting and use of the two flags (flip-flops). Column 4 specifies the signal that sets the flag. For example, (1) C_s means that flag number 1 is set by the sign bit of the number in register C. If column 5 contains a flag identifier, then columns 6 and 7 contain the two alternative microinstruction addresses to be used. Otherwise, column 6 specifies the address of the next microinstruction to be fetched.

Instructions 0 through 4 constitute the fetch cycle. Microinstruction 4 presents the opcode to a decoder, which generates the address of a microinstruction corresponding to the machine instruction to be fetched. The reader should be able to deduce the complete functioning of the control unit from a careful study of [Table 19.5](#).

Advantages and Disadvantages

The principal advantage of the use of microprogramming to implement a control unit is that it simplifies the design of the control unit. Thus, it is both cheaper and less error prone to implement. A *hardwired* control unit must contain complex logic for sequencing through the many micro-operations of the instruction cycle. On the other hand, the decoders and sequencing logic unit of a microprogrammed control unit are very simple pieces of logic.

The principal disadvantage of a microprogrammed unit is that it will be somewhat slower than a hardwired unit of comparable technology. Despite this, microprogramming is the dominant technique for implementing control units in pure CISC architectures, due to its ease of implementation. RISC processors, with their simpler instruction format, typically use hardwired control units.

19.5 Key Terms, Review Questions, and Problems

Key Terms

control bus
control path
control signal
control unit
hardwired implementation
micro-operations

Review Questions

- 19.1 Explain the distinction between the written sequence and the time sequence of an instruction.
- 19.2 What is the relationship between instructions and micro-operations?
- 19.3 What is the overall function of a processor's control unit?
- 19.4 Outline a three-step process that leads to a characterization of the control unit.
- 19.5 What basic tasks does a control unit perform?
- 19.6 Provide a typical list of the inputs and outputs of a control unit.
- 19.7 List three types of control signals.
- 19.8 Briefly explain what is meant by a hardwired implementation of a control unit.
- 19.9 What is the difference between a hardwired implementation and a microprogrammed implementation of a control unit?
- 19.10 How is a horizontal microinstruction interpreted?
- 19.11 What is the purpose of a control memory?

Problems

- 19.1 Your ALU can add its two input registers, and it can logically complement the bits of either input register, but it cannot subtract. Numbers are to be stored in two's complement representation. List the micro-operations your control unit must perform to cause a subtraction.
- 19.2 Show the micro-operations and control signals in the same fashion as **Table 19.1** for the processor in **Figure 19.5** for the following instructions:

- Load Accumulator
- Store Accumulator
- Add to Accumulator
- AND to Accumulator
- Jump
- Jump if AC = 0
- Complement Accumulator

- 19.3 Assume that propagation delay along the bus and through the ALU of **Figure 19.6** are 20 and 100 ns, respectively. The time required for a register to copy data from the bus is 10 ns. What is the time that must be allowed for
 - a. data from one register to another?
 - b. the program counter?

19.4 Write the sequence of micro-operations required for the bus structure of [Figure 19.6](#) to add a number to the AC when the number is

- immediate operand;
- direct-address operand;
- indirect-address operand.

19.5 A stack is implemented as shown in [Figure 19.11](#) (see [Appendix G](#) for a discussion of stacks). Show the sequence of micro-operations for

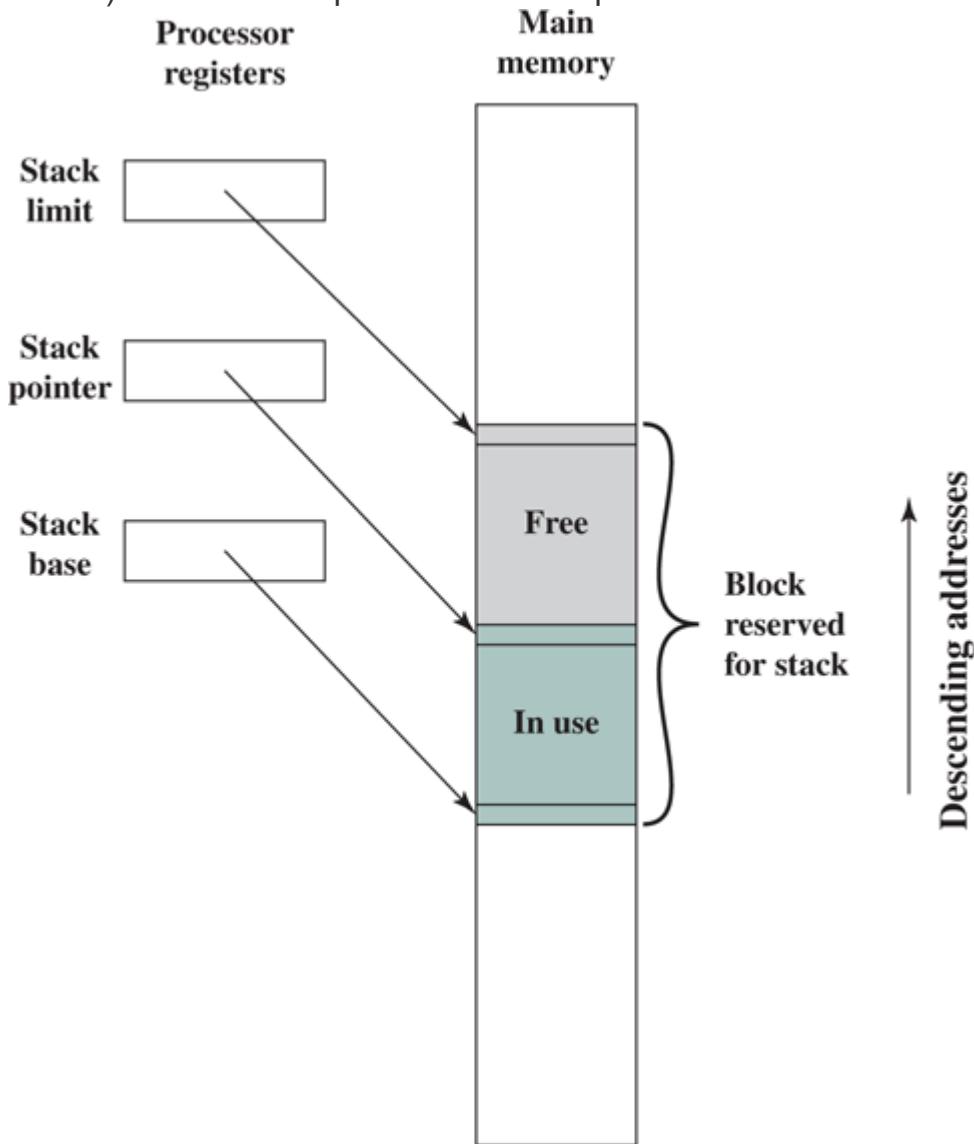

Figure 19.11 Typical Stack Organization (full/descending)

- popping;
- the stack

19.6 Describe the implementation of the multiply instruction in the hypothetical machine designed by Wilkes. Use narrative and a flowchart.

19.7 Assume a microinstruction set that includes a microinstruction with the following symbolic form:

$$\text{IF}(\text{AC}_0 = 1) \text{ THEN } \text{CAR} \leftarrow (\text{C}_{0-6}) \text{ ELSE } \text{CAR} \leftarrow (\text{CAR}) + 1$$

where AC is the sign bit of the accumulator and C are the first seven bits of the

microinstruction. Using this microinstruction, write a microprogram that implements a Branch Register Minus (BRM) machine instruction, which branches if the AC is negative. Assume that bits C_1 through C_n of the microinstruction specify a parallel set of micro-operations. Express the program symbolically.

19.8 A simple processor has four major phases to its instruction cycle: fetch, indirect, execute, and interrupt. Two 1-bit flags designate the current phase in a hardwired implementation.

- a. Why are these flags needed?
- b. Why are they not needed in a microprogrammed control unit?.

Learning Objectives

After studying this chapter, you should be able to:

- Summarize the types of parallel processor organizations.
- Present an overview of design features of symmetric multiprocessors.
- Understand the issue of cache coherence in a multiple processor system.
- Explain the key features of the MESI protocol.
- Explain the difference between implicit and explicit multithreading.
- Summarize key design issues for clusters.
- Explain the concept of nonuniform memory access.

Traditionally, the computer has been viewed as a sequential machine. Most

computer programming languages require the programmer to specify algorithms as sequences of instructions. Processors execute programs by executing machine instructions in a sequence and one at a time. Each instruction is executed in a sequence of operations (fetch instruction, fetch operands, perform operation, store results).

This view of the computer has never been entirely true. At the micro-operation level, multiple control signals are generated at the same time. Instruction pipelining, at least to the extent of overlapping fetch and execute operations, has been around for a long time. Both of these are examples of performing independent operations in parallel. This approach is taken further with superscalar organization, which exploits instruction-level parallelism. With a superscalar machine, there are multiple execution units within a single processor, and these may execute multiple instructions from the same program in parallel.

As computer technology has evolved, and as the cost of computer hardware has dropped, computer designers have sought more and more opportunities for parallelism, usually to enhance performance and, in some cases, to increase availability. After an overview, this chapter looks at some of the most prominent approaches to parallel organization. First, we examine symmetric multiprocessors (SMPs), one of the earliest and still the most common example of parallel organization. In an SMP organization, multiple processors share a common memory. This organization raises the issue of cache coherence, to which a separate section is devoted. Next, the chapter examines multithreaded processors and chip multiprocessors. Then we describe clusters, which consist of multiple independent computers organized in a cooperative fashion. Clusters have become increasingly common to support workloads that are beyond the capacity of a single SMP. Another approach to the use of multiple processors that we examine is that of nonuniform memory access (NUMA) machines. The NUMA approach is relatively new and not yet proven in the marketplace, but is often considered as an alternative to the SMP or cluster approach.

20.1 Multiple Processor Organizations

Types of Parallel Processor Systems

A taxonomy first introduced by Flynn [FLYN72] is still the most common way of categorizing systems with parallel processing capability. Flynn proposed the following categories of computer systems:

- **Single instruction, single data (SISD) stream:** A single processor executes a single instruction stream to operate on data stored in a single memory. Uniprocessors fall into this category.
- **Single instruction, multiple data (SIMD) stream:** A single machine instruction controls the simultaneous execution of a number of processing elements on a lockstep basis. Each processing element has an associated data memory, so that instructions are executed on different sets of data by different processors. Vector and array processors fall into this category, and are discussed in [Section 20.7](#).
- **Multiple instruction, single data (MISD) stream:** A sequence of data is transmitted to a set of processors, each of which executes a different instruction sequence. This structure is not commercially implemented.
- **Multiple instruction, multiple data (MIMD) stream:** A set of processors simultaneously execute different instruction sequences on different data sets. SMPs, clusters, and NUMA systems fit into this category.

With the MIMD organization, the processors are general purpose; each is able to process all of the instructions necessary to perform the appropriate data transformation. MIMDs can be further subdivided by the means in which the processors communicate ([Figure 20.1](#)). If the processors share a common memory, then each processor accesses programs and data stored in the shared memory, and processors communicate with each other via that memory. The most common form of such systems is known as a **symmetric multiprocessor (SMP)**, which we examine in [Section 20.2](#). In an SMP, multiple processors share a single memory or pool of memory by means of a shared bus or other interconnection mechanism; a distinguishing feature is that the memory access time to any region of memory is approximately the same for each processor. A more recent development is the **nonuniform memory access (NUMA)** organization, which is described in [Section 20.6](#). As the name suggests, the memory access time to different regions of memory may differ for a NUMA processor.

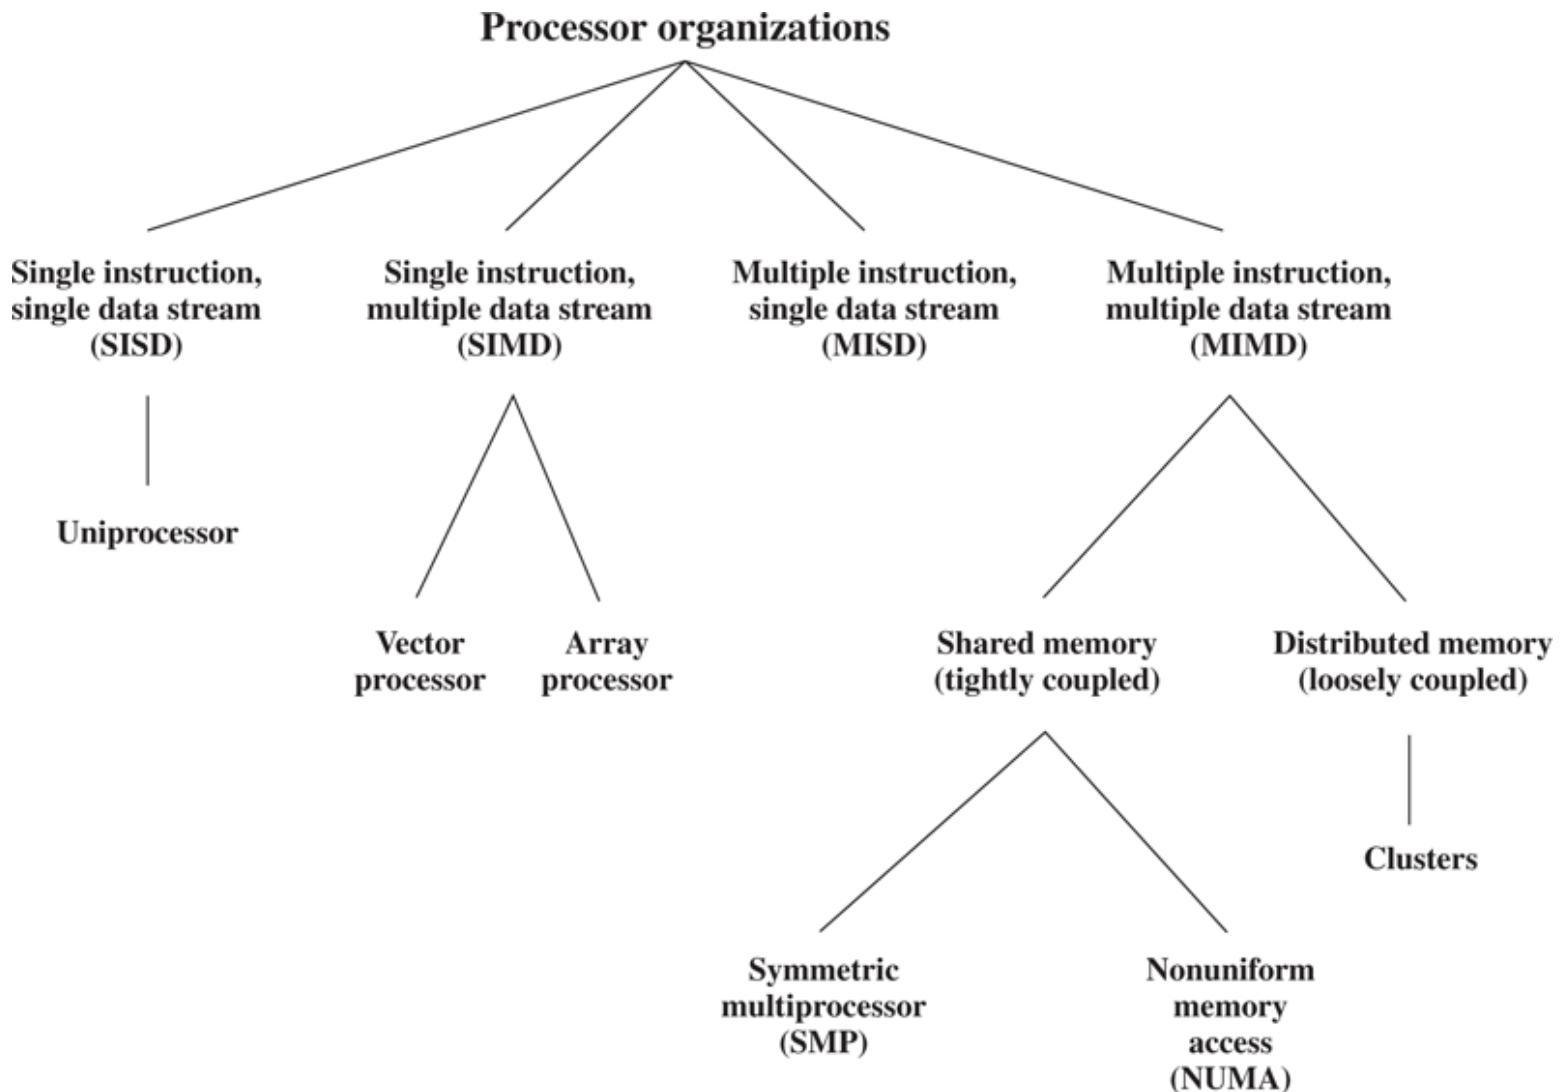

Figure 20.1 A Taxonomy of Parallel Processor Architectures

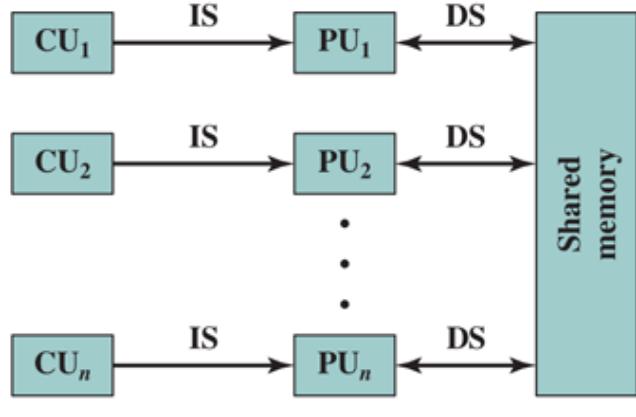

A collection of independent uniprocessors or SMPs may be interconnected to form a **cluster**. Communication among the computers is either via fixed paths or via some network facility.

Parallel Organizations

Figure 20.2 illustrates the general organization of the taxonomy of **Figure 20.1**. **Figure 20.2a** shows the structure of an SISD. There is some sort of control unit (CU) that provides an instruction stream (IS) to a processing unit (PU). The processing unit operates on a single data stream (DS) from a memory unit (MU). With an SIMD, there is still a single control unit, now feeding a single instruction stream to multiple PUs. Each PU may have its own dedicated memory (illustrated in **Figure 20.2b**), or there may be a shared memory. Finally, with the MIMD, there are multiple control units, each feeding a separate instruction stream to its own PU. The MIMD may be a shared-memory multiprocessor (**Figure 20.2c**) or a distributed-memory multicomputer (**Figure 20.2d**).

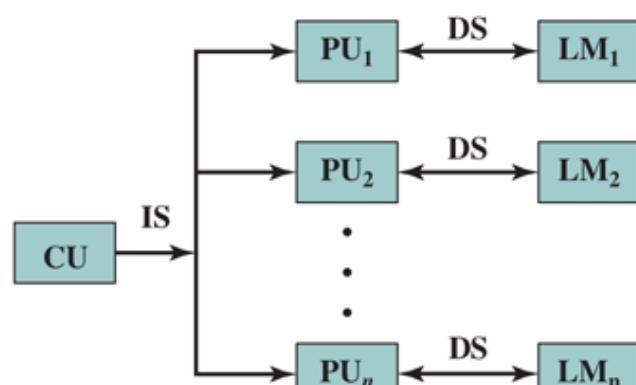

(a) SISD

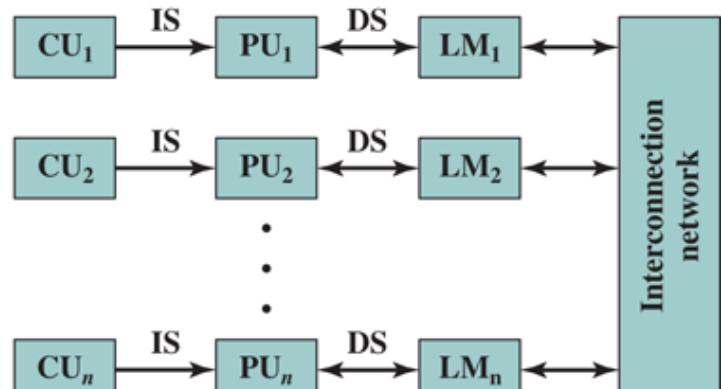

(c) MIMD (with shared memory)

CU = Control unit
IS = Instruction stream
PU = Processing unit
DS = Data stream
MU = Memory unit
LM = Local memory

SISD = Single instruction,
= single data stream
SIMD = Single instruction,
multiple data stream
MIMD = Multiple instruction,
multiple data stream

(b) SIMD (with distributed memory)

(d) MIMD (with distributed memory)

Figure 20.2 Alternative Computer Organizations

The design issues relating to SMPs, clusters, and NUMAs are complex, involving issues relating to physical organization, interconnection structures, interprocessor communication, operating system design, and application software techniques. Our concern here is primarily with organization, although we touch briefly on operating system design issues.

20.2 Symmetric Multiprocessors

Until fairly recently, virtually all single-user personal computers and most workstations contained a single general-purpose microprocessor. As demands for performance increase and as the cost of microprocessors continues to drop, vendors have introduced systems with an SMP organization. The term *SMP* refers to a computer hardware architecture and also to the operating system behavior that reflects that architecture. An SMP can be defined as a standalone computer system with the following characteristics:

1. There are two or more similar processors of comparable capability.
2. These processors share the same main memory and I/O facilities and are interconnected by a bus or other internal connection scheme, such that memory access time is approximately the same for each processor.
3. All processors share access to I/O devices, either through the same channels or through different channels that provide paths to the same device.
4. All processors can perform the same functions (hence the term *symmetric*).
5. The system is controlled by an integrated operating system that provides interaction between processors and their programs at the job, task, file, and data element levels.

Points 1 to 4 should be self-explanatory. Point 5 illustrates one of the contrasts with a loosely coupled multiprocessing system, such as a cluster. In the latter, the physical unit of interaction is usually a message or complete file. In an SMP, individual data elements can constitute the level of interaction, and there can be a high degree of cooperation between processes.

The operating system of an SMP schedules processes or threads across all of the processors. An SMP organization has a number of potential advantages over a uniprocessor organization, including the following:

- **Performance:** If the work to be done by a computer can be organized so that some portions of the work can be done in parallel, then a system with multiple processors will yield greater performance than one with a single processor of the same type ([Figure 20.3](#)).

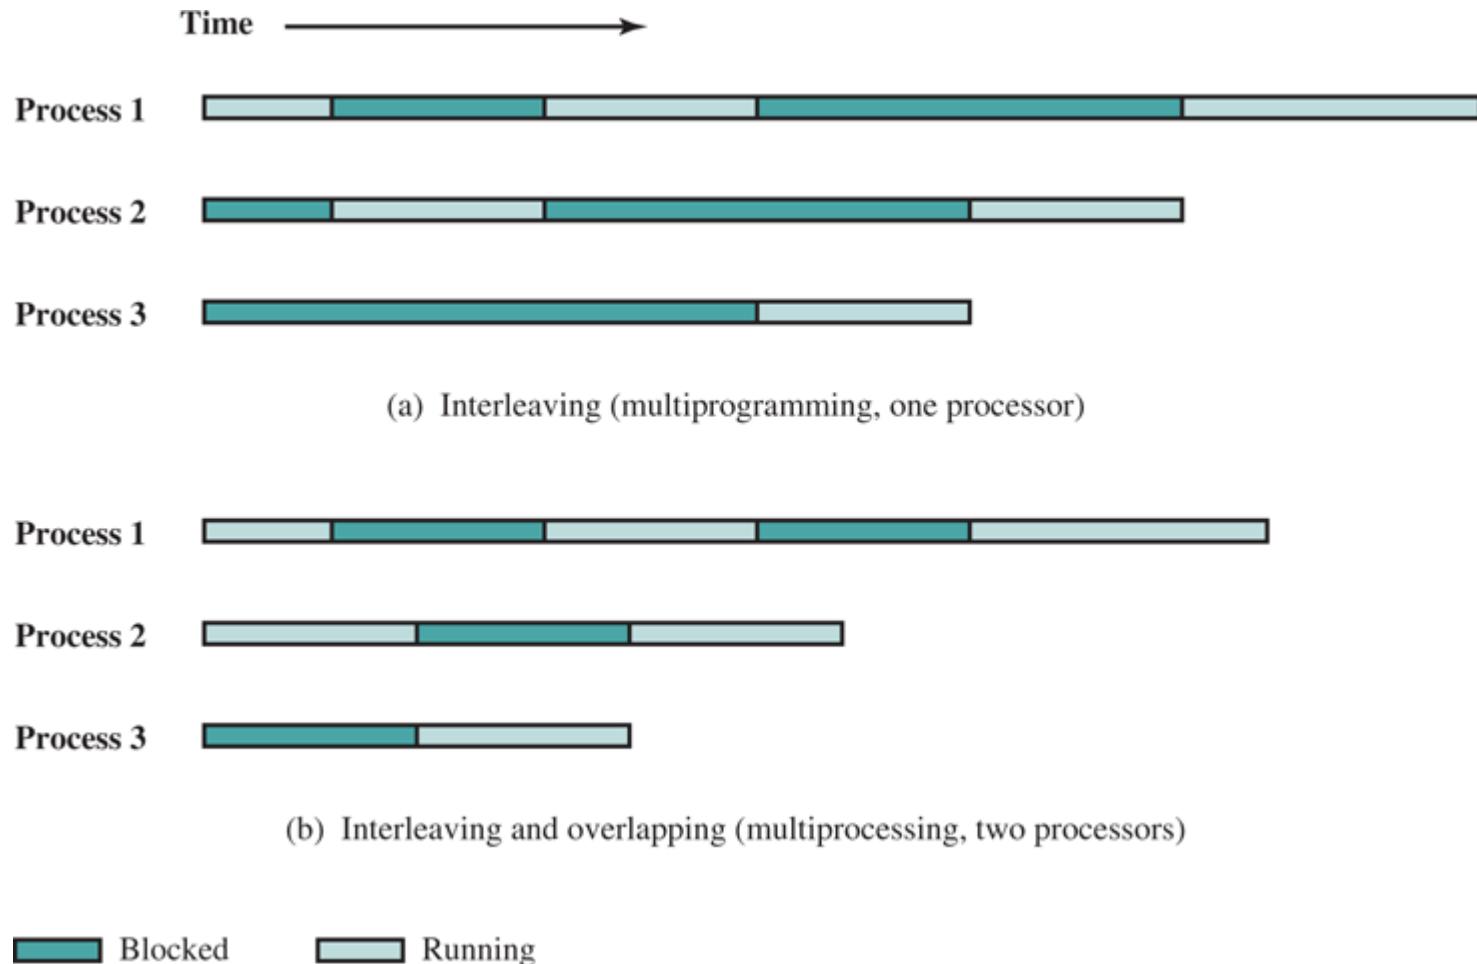

Figure 20.3 Multiprogramming and Multiprocessing

- **Availability:** In a symmetric multiprocessor, because all processors can perform the same functions, the failure of a single processor does not halt the machine. Instead, the system can continue to function at reduced performance.
- **Incremental growth:** A user can enhance the performance of a system by adding an additional processor.
- **Scaling:** Vendors can offer a range of products with different price and performance characteristics based on the number of processors configured in the system.

It is important to note that these are potential, rather than guaranteed, benefits. The operating system must provide tools and functions to exploit the parallelism in an SMP system.

An attractive feature of an SMP is that the existence of multiple processors is transparent to the user. The operating system takes care of scheduling threads or processes on individual processors, and of synchronization among processors.

Organization

Figure 20.4 depicts in general terms the organization of a multiprocessor system. There are two or more processors. Each processor is self-contained, including a control unit, ALU, registers, and, typically, one or more levels of cache. Each processor has access to a shared main memory and the I/O devices through some form of interconnection mechanism. The processors can communicate with each other through memory (messages and status information left in common data areas). It may also be possible for processors to exchange signals directly. The memory is often organized so that multiple simultaneous accesses to separate blocks of memory are possible. In some configurations, each processor may also have its own private main memory and I/O channels, in addition to the

shared resources.

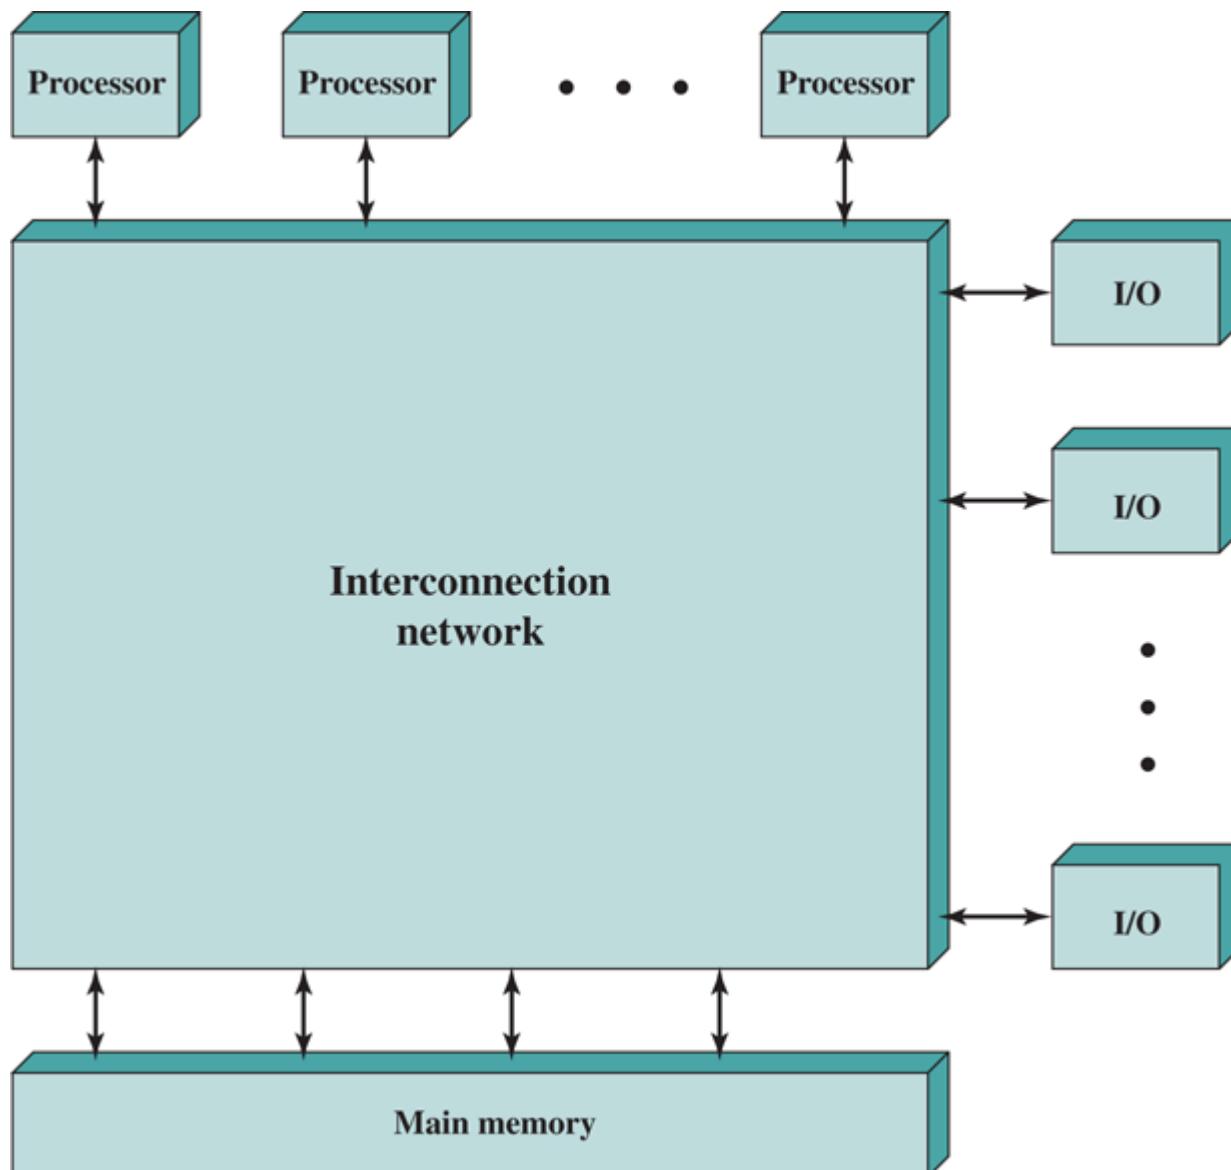

Figure 20.4 Generic Block Diagram of a Tightly Coupled Multiprocessor

The most common organization for personal computers, workstations, and servers is the time-shared bus. The time-shared bus is the simplest mechanism for constructing a multiprocessor system ([Figure 20.5](#)). The structure and interfaces are basically the same as for a single-processor system that uses a bus interconnection. The bus consists of control, address, and data lines. To facilitate DMA transfers from I/O subsystems to processors, the following features are provided:

- **Addressing:** It must be possible to distinguish modules on the bus to determine the source and destination of data.
- **Arbitration:** Any I/O module can temporarily function as “master.” A mechanism is provided to arbitrate competing requests for bus control, using some sort of priority scheme.
- **Time-sharing:** When one module is controlling the bus, other modules are locked out and must, if necessary, suspend operation until bus access is achieved.

These uniprocessor features are directly usable in an SMP organization. In this latter case, there are now multiple processors as well as multiple I/O processors all attempting to gain access to one or more memory modules via the bus.

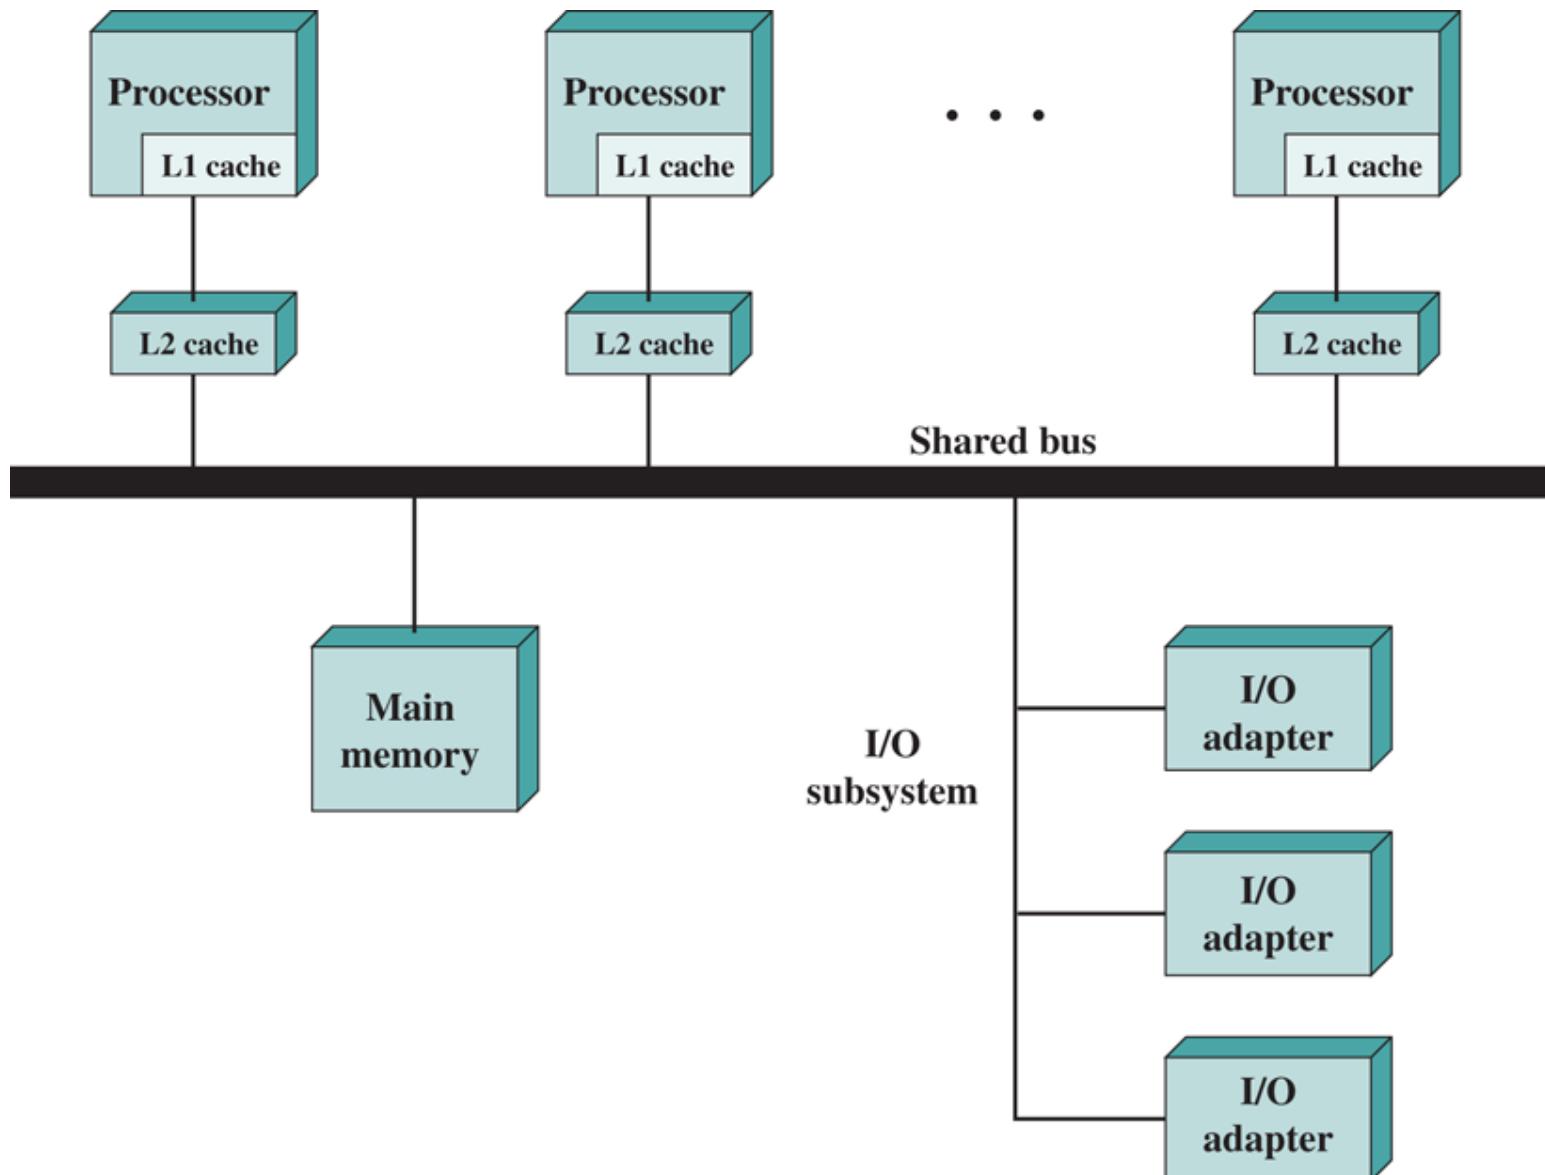

Figure 20.5 Symmetric Multiprocessor Organization

The bus organization has several attractive features:

- **Simplicity:** This is the simplest approach to multiprocessor organization. The physical interface and the addressing, arbitration, and time-sharing logic of each processor remain the same as in a single-processor system.
- **Flexibility:** It is generally easy to expand the system by attaching more processors to the bus.
- **Reliability:** The bus is essentially a passive medium, and the failure of any attached device should not cause failure of the whole system.

The main drawback to the bus organization is performance. All memory references pass through the common bus. Thus, the bus cycle time limits the speed of the system. To improve performance, it is desirable to equip each processor with a cache memory. This should reduce the number of bus accesses dramatically. Typically, workstation and PC SMPs have two levels of cache, with the L1 cache internal (same chip as the processor) and the L2 cache either internal or external. Some processors now employ a L3 cache as well.

The use of caches introduces some new design considerations. Because each local cache contains an image of a portion of memory, if a word is altered in one cache, it could conceivably invalidate a word in another cache. To prevent this, the other processors must be alerted that an update has taken place. This problem is known as the **cache coherence** problem and is typically addressed in hardware rather than by the operating system. We address this issue in [Section 20.3](#).

Multiprocessor Operating System Design Considerations

An SMP operating system manages processor and other computer resources so that the user perceives a single operating system controlling system resources. In fact, such a configuration should appear as a single-processor multiprogramming system. In both the SMP and uniprocessor cases, multiple jobs or processes may be active at one time, and it is the responsibility of the operating system to schedule their execution and to allocate resources. A user may construct applications that use multiple processes or multiple threads within processes, without regard to whether a single processor or multiple processors will be available. Thus, a multiprocessor operating system must provide all the functionality of a multiprogramming system plus additional features to accommodate multiple processors. Among the key design issues:

- **Simultaneous concurrent processes:** OS routines need to be reentrant to allow several processors to execute the same IS code simultaneously. With multiple processors executing the same or different parts of the OS, OS tables and management structures must be managed properly to avoid deadlock or invalid operations.
- **Scheduling:** Any processor may perform scheduling, so conflicts must be avoided. The scheduler must assign ready processes to available processors.
- **Synchronization:** With multiple active processes having potential access to shared address spaces or shared I/O resources, care must be taken to provide effective synchronization. Synchronization is a facility that enforces mutual exclusion and event ordering.
- **Memory management:** Memory management on a multiprocessor must deal with all of the issues found on uniprocessor machines, as discussed in [Chapter 9](#). In addition, the operating system needs to exploit the available hardware parallelism, such as multiported memories, to achieve the best performance. The paging mechanisms on different processors must be coordinated to enforce consistency when several processors share a page or segment, and to decide on page replacement.
- **Reliability and fault tolerance:** The operating system should provide graceful degradation in the face of processor failure. The scheduler and other portions of the operating system must recognize the loss of a processor and restructure management tables accordingly.

20.3 Cache Coherence and the MESI Protocol

In contemporary multiprocessor systems, it is customary to have one or two levels of cache associated with each processor. This organization is essential to achieve reasonable performance. It does, however, create a problem known as the *cache coherence* problem. The essence of the problem is this: Multiple copies of the same data can exist in different caches simultaneously, and if processors are allowed to update their own copies freely, an inconsistent view of memory can result. In [Chapter 5](#) we defined two common write policies: The two common write policies are:

- **Write back:** Write operations are usually made only to the cache. Main memory is only updated when the corresponding cache line is evicted from the cache.
- **Write through:** All write operations are made to main memory as well as to the cache, ensuring that main memory is always valid.

It is clear that a write-back policy can result in inconsistency. If two caches contain the same line, and the line is updated in one cache, the other cache will unknowingly have an invalid value. Subsequent reads to that invalid line produce invalid results. Even with the write-through policy, inconsistency can occur unless other caches monitor the memory traffic or receive some direct notification of the update.

In this section, we will briefly survey various approaches to the cache coherence problem and then focus on the approach that is most widely used: the MESI (modified/exclusive/shared/invalid) protocol. A version of this protocol is used on the x86 architecture.

For any cache coherence protocol, the objective is to let recently used local variables get into the appropriate cache and stay there through numerous reads and writes, while using the protocol to maintain consistency of shared variables that might be in multiple caches at the same time. Cache coherence approaches have generally been divided into software and hardware approaches. Some implementations adopt a strategy that involves both software and hardware elements. Nevertheless, the classification into software and hardware approaches is still instructive and is commonly used in surveying cache coherence strategies.

Software Solutions

Software cache coherence schemes attempt to avoid the need for additional hardware circuitry and logic by relying on the compiler and operating system to deal with the problem. Software approaches are attractive because the overhead of detecting potential problems is transferred from run time to compile time, and the design complexity is transferred from hardware to software. On the other hand, compile-time software approaches generally must make conservative decisions, leading to inefficient cache utilization.

Compiler-based coherence mechanisms perform an analysis on the code to determine which data items may become unsafe for caching, and they mark those items accordingly. The operating system or hardware then prevents noncacheable items from being cached.

The simplest approach is to prevent any shared data variables from being cached. This is too conservative, because a shared data structure may be exclusively used during some periods and may be effectively read-only during other periods. It is only during periods when at least one process may update the variable and at least one other process may access the variable that cache coherence is an issue.

More efficient approaches analyze the code to determine safe periods for shared variables. The compiler then inserts instructions into the generated code to enforce cache coherence during the

critical periods. A number of techniques have been developed for performing the analysis and for enforcing the results; see [LILJ93] and [STEN90] for surveys.

Hardware Solutions

Hardware-based solutions are generally referred to as cache coherence protocols. These solutions provide dynamic recognition at run time of potential inconsistency conditions. Because the problem is only dealt with when it actually arises, there is more effective use of caches, leading to improved performance over a software approach. In addition, these approaches are transparent to the programmer and the compiler, reducing the software development burden.

Hardware schemes differ in a number of particulars, including where the state information about data lines is held, how that information is organized, where coherence is enforced, and the enforcement mechanisms. In general, hardware schemes can be divided into two categories: **directory protocols** and **snoopy protocols**.

DIRECTORY PROTOCOLS

Directory protocols collect and maintain information about where copies of lines reside. Typically, there is a centralized controller that is part of the main memory controller, and a directory that is stored in main memory. The directory contains global state information about the contents of the various local caches. When an individual cache controller makes a request, the centralized controller checks and issues necessary commands for data transfer between memory and caches or between caches. It is also responsible for keeping the state information up to date; therefore, every local action that can affect the global state of a line must be reported to the central controller.

Typically, the controller maintains information about which processors have a copy of which lines. Before a processor can write to a local copy of a line, it must request exclusive access to the line from the controller. Before granting this exclusive access, the controller sends a message to all processors with a cached copy of this line, forcing each processor to invalidate its copy. After receiving acknowledgments back from each such processor, the controller grants exclusive access to the requesting processor. When another processor tries to read a line that is exclusively granted to another processor, it will send a miss notification to the controller. The controller then issues a command to the processor holding that line that requires the processor to do a write back to main memory. The line may now be shared for reading by the original processor and the requesting processor.

Directory schemes suffer from the drawbacks of a central bottleneck and the overhead of communication between the various cache controllers and the central controller. However, they are effective in large-scale systems that involve multiple buses or some other complex interconnection scheme.

SNOOPY PROTOCOLS

Snoopy protocols distribute the responsibility for maintaining cache coherence among all of the cache controllers in a multiprocessor. A cache must recognize when a line that it holds is shared with other caches. When an update action is performed on a shared cache line, it must be announced to all other caches by a broadcast mechanism. Each cache controller is able to “snoop” on the network to observe these broadcasted notifications, and react accordingly.

Snoopy protocols are ideally suited to a bus-based multiprocessor, because the shared bus provides a simple means for broadcasting and snooping. However, because one of the objectives of the use of local caches is to avoid bus accesses, care must be taken that the increased bus traffic required for

broadcasting and snooping does not cancel out the gains from the use of local caches.

Two basic approaches to the snoopy protocol have been explored: write invalidate and write update (or write broadcast). With a write-invalidate protocol, there can be multiple readers but only one writer at a time. Initially, a line may be shared among several caches for reading purposes. When one of the caches wants to perform a write to the line, it first issues a notice that invalidates that line in the other caches, making the line exclusive to the writing cache. Once the line is exclusive, the owning processor can make cheap local writes until some other processor requires the same line.

With a write-update protocol, there can be multiple writers as well as multiple readers. When a processor wishes to update a shared line, the word to be updated is distributed to all others, and caches containing that line can update it.

Neither of these two approaches is superior to the other under all circumstances. Performance depends on the number of local caches and the pattern of memory reads and writes. Some systems implement adaptive protocols that employ both write-invalidate and write-update mechanisms.

The write-invalidate approach is the most widely used in commercial multiprocessor systems, such as the x86 architecture. It marks the state of every cache line (using two extra bits in the cache tag) as modified, exclusive, shared, or invalid. For this reason, the write-invalidate protocol is called MESI. In the remainder of this section, we will look at its use among local caches across a multiprocessor. For simplicity in the presentation, we do not examine the mechanisms involved in coordinating among both level 1 and level 2 locally and at the same time coordinating across the distributed multiprocessor. This would not add any new principles but would greatly complicate the discussion.

The MESI Protocol

To provide cache consistency on an SMP, the data cache often supports a protocol known as MESI. For MESI, the data cache includes two status bits per tag, so that each line can be in one of four states:

- **Modified:** The line in the cache has been modified (different from main memory) and is available only in this cache.
- **Exclusive:** The line in the cache is the same as that in main memory and is not present in any other cache.
- **Shared:** The line in the cache is the same as that in main memory and may be present in another cache.
- **Invalid:** The line in the cache does not contain valid data.

Table 20.1 summarizes the meaning of the four states. **Figure 20.6** displays a state diagram for the MESI protocol. Keep in mind that each line of the cache has its own state bits and therefore its own realization of the state diagram. **Figure 20.6a** shows the transitions that occur due to actions initiated by the processor attached to this cache. **Figure 20.6b** shows the transitions that occur due to events that are snooped on the common bus. This presentation of separate state diagrams for processor-initiated and bus-initiated actions helps to clarify the logic of the MESI protocol. At any time a cache line is in a single state. If the next event is from the attached processor, then the transition is dictated by **Figure 20.6a**, and if the next event is from the bus the transition is dictated by **Figure 20.6b**. **Figure 20.7** summarizes the state relationship between lines in different caches, all of which map to the same block of memory.

Table 20.1 MESI Cache Line States

	M	E	S	I

	Modified	Exclusive	Shared	Invalid
This cache line valid?	Yes	Yes	Yes	No
The memory copy is ...	out of date	valid	valid	—
Copies exist in other caches?	No	No	Maybe	Maybe
A write to this line ...	does not go to bus	does not go to bus	goes to bus and updates cache	goes directly to bus

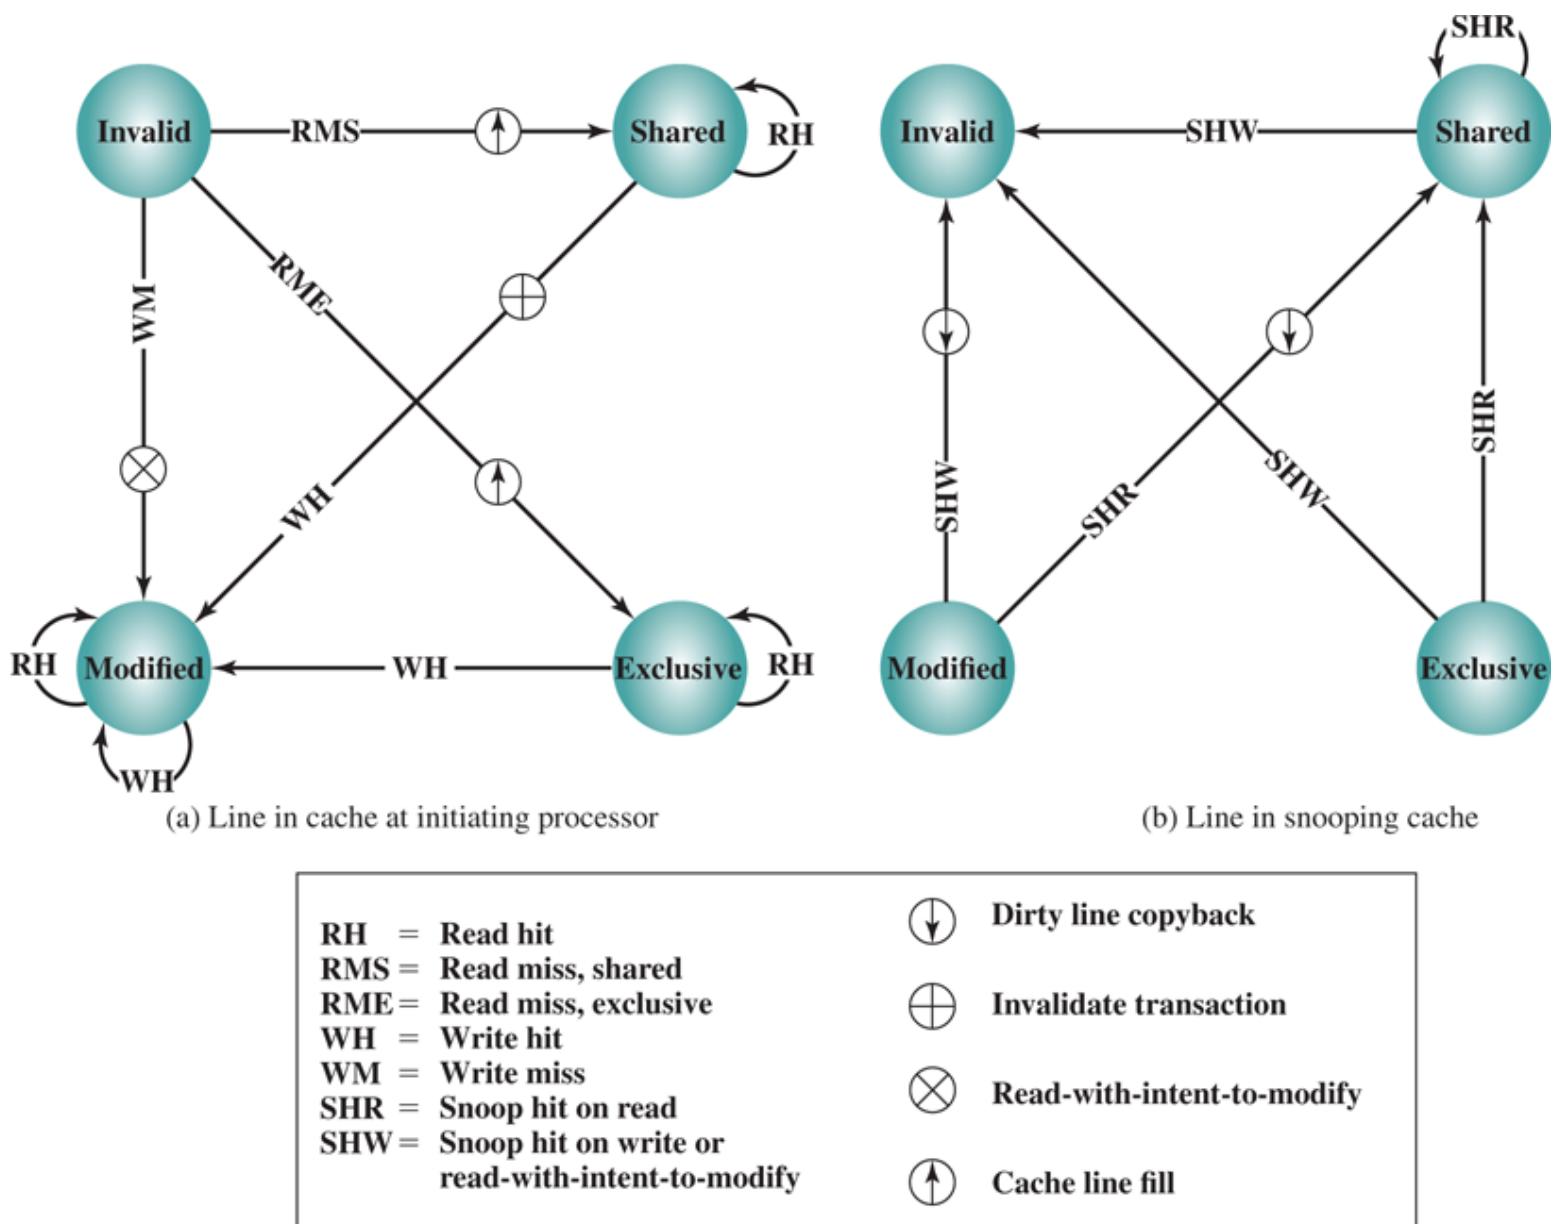

Figure 20.6 MESI State Transition Diagram

State of line in local cache that maps to memory block i	Allowable states for cache lines in other caches that map to memory block i			
Modified	Invalid			
Exclusive	Invalid			
Shared	Shared	Invalid		
Invalid	Modified	Exclusive	Shared	Invalid

Figure 20.7 Relationship Between Cache Lines in Cooperating Caches

We now examine the transitions in [Figure 20.6](#) in more detail.

READ MISS

When a read miss occurs in the local cache, the processor initiates a memory read to read the line of main memory containing the missing address. The processor inserts a signal on the bus that alerts all other processor/cache units to snoop the transaction. There are a number of possible outcomes:

- If one other cache has a clean (unmodified since read from memory) copy of the line in the exclusive state, it returns a signal indicating that it shares this line. The responding processor then transitions the state of its copy from exclusive to shared, and the initiating processor reads the line from main memory and transitions the line in its cache from invalid to shared.
- If one or more caches have a clean copy of the line in the shared state, each of them signals that it shares the line. The initiating processor reads the line and transitions the line in its cache from invalid to shared.
- If one other cache has a modified copy of the line, then that cache blocks the memory read and provides the line to the requesting cache over the shared bus. The responding cache then changes its line from modified to shared.¹ The line sent to the requesting cache is also received and processed by the memory controller, which stores the block in memory.

¹ In some implementations, the cache with the modified line signals the initiating processor to retry. Meanwhile, the processor with the modified copy seizes the bus, writes the modified line back to main memory, and transitions the line in its cache from modified to shared. Subsequently, the requesting processor tries again and finds that one or more processors have a clean copy of the line in the shared state, as described in the

preceding point.

- If no other cache has a copy of the line (clean or modified), then no signals are returned. The initiating processor reads the line and transitions the line in its cache from invalid to exclusive.

READ HIT

When a read hit occurs on a line currently in the local cache, the processor simply reads the required item. There is no state change: The state remains modified, shared, or exclusive.

WRITE MISS

When a write miss occurs in the local cache, the processor initiates a memory read to read the line of main memory containing the missing address. For this purpose, the processor issues a signal on the bus that means *read-with-intent-to-modify* (RWITM). When the line is loaded, it is immediately marked modified. With respect to other caches, two possible scenarios precede the loading of the line of data.

First, some other cache may have a modified copy of this line (state = modify). In this case, the alerted processor signals the initiating processor that another processor has a modified copy of the line. The initiating processor surrenders the bus and waits. The other processor gains access to the bus, writes the modified cache line back to main memory, and transitions the state of the cache line to invalid (because the initiating processor is going to modify this line). Subsequently, the initiating processor will again issue a signal to the bus of RWITM and then read the line from main memory, modify the line in the cache, and mark the line in the modified state.

The second scenario is that no other cache has a modified copy of the requested line. In this case, no signal is returned, and the initiating processor proceeds to read in the line and modify it. Meanwhile, if one or more caches have a clean copy of the line in the shared state, each cache invalidates its copy of the line, and if one cache has a clean copy of the line in the exclusive state, it invalidates its copy of the line.

WRITE HIT

When a write hit occurs on a line currently in the local cache, the effect depends on the current state of that line in the local cache:

- **Shared:** Before performing the update, the processor must gain exclusive ownership of the line. The processor signals its intent on the bus. Each processor that has a shared copy of the line in its cache transitions the sector from shared to invalid. The initiating processor then performs the update and transitions its copy of the line from shared to modified.
- **Exclusive:** The processor already has exclusive control of this line, and so it simply performs the update and transitions its copy of the line from exclusive to modified.
- **Modified:** The processor already has exclusive control of this line and has the line marked as modified, and so it simply performs the update.

MESI SIGNALING

It will help to clarify the state transition diagrams of [Figure 20.6](#) to develop flowcharts that show the exchange of signals between cooperating caches during a read or write operation. The following flowcharts assume an initiator system and one or more other participants, and refer to the state of a cache line in each system that all map to the same block of main memory.

Figure 20.8 covers the case of a memory read operation.² If the desired word is contained in a cache line of the initiator's cache, then the line must be in the M, E, or S state. In that case, the word is retrieved from the cache and returned to the processor. If the cache line is not present, then the initiator signals a read miss (RM) to the other participants. This indicates that it is going to perform a read memory operation to bring in the memory block containing the desired word after waiting for responding signals. Then, if necessary the initiator writes back a line of cache to make room for the incoming block.

² This figure and the next were provided by Professor Roger Kieckhafer of Michigan Technological University.

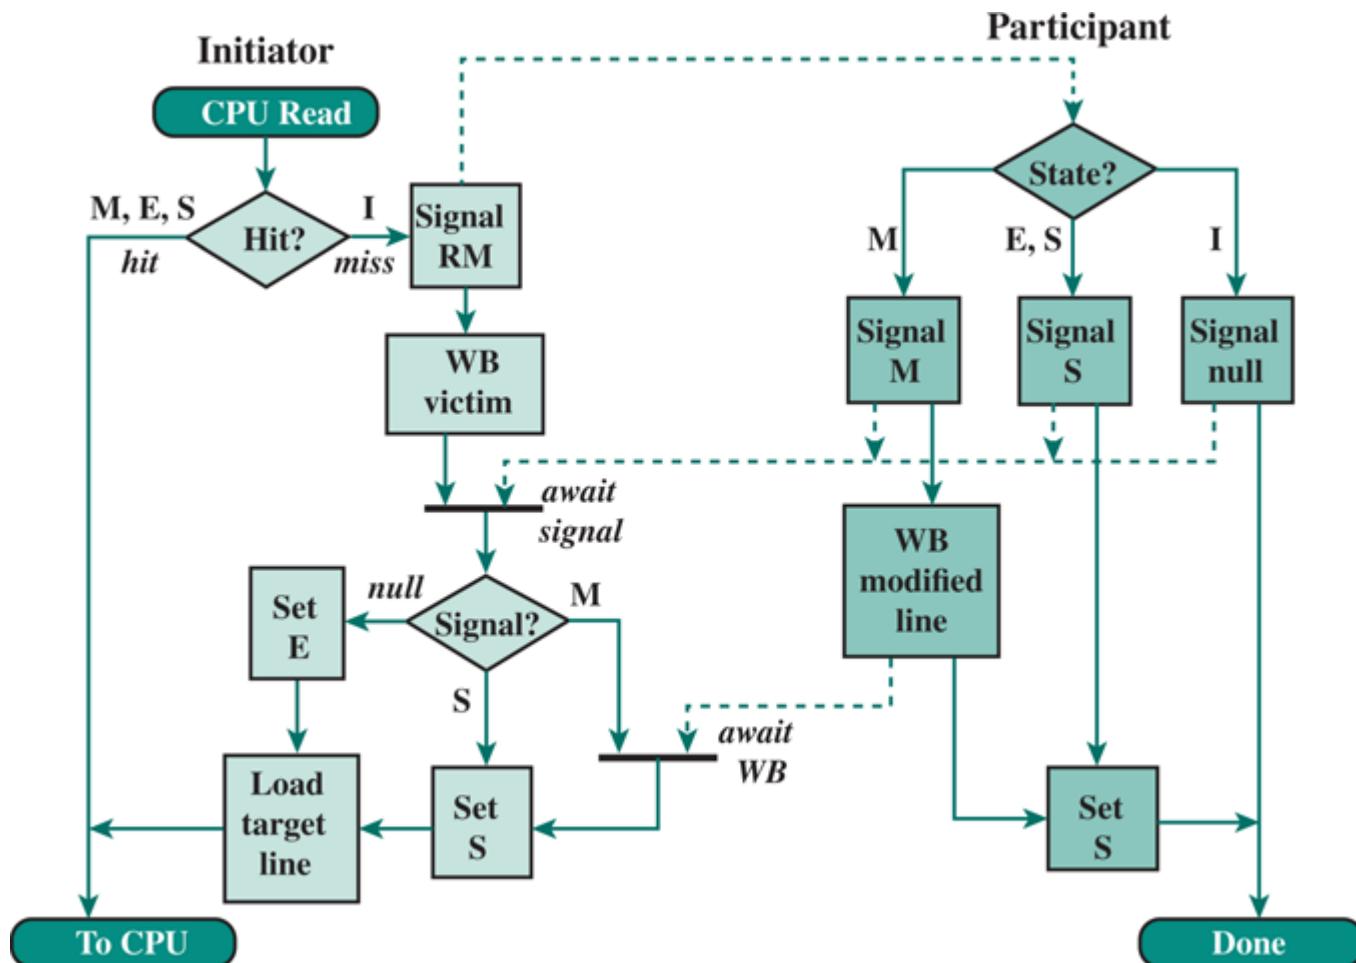

Figure 20.8 Initiator Reads from Writeback Cache

Source: Used with permission from Professor Roger Kieckhafer of Michigan Technological University

At the participant end, the participant checks to see if the requested block is in a line of its cache. If not, it signals back null and is done. If the participant has the desired line in either the E or S state, it signals S, because now the line will be shared with the initiator, and sets the line state to S. If the line is in the M state, it signals M to the initiator. Then the participant writes back the line to bring main memory up to date and move to an S state. If the initiator receives a signal M, it waits until the participant has written the line back to memory before proceeding. If the signal is M or S, the initiator sets the line to S and if the incoming signal is null it sets the state to E. Once the state is set, the target line is loaded.

Figure 20.8 indicates the interaction between an initiator and a single participant. If there are multiple other cache systems, the initiator needs to take into account all incoming signals. If an M signal is received, any other signals received should be S or null; the initiator responds to the M signal by

waiting for the WB signal. If there is no M signal but one or more S signals, then the initiator responds to that.

Figure 20.9 is the flowchart when the initiator performs a write to a write-back cache. If the block containing the word to be written is already in a line of the cache (hit), the initiator updates the line in the cache and sets the line state to M. It also signals a write hit to participants, who set that line to invalid. If the desired line is not in the cache, the initiator signals a write miss (WM) to the other participants. The rest of the flowchart is similar to that of **Figure 20.8**.

L1-L2 CACHE CONSISTENCY

We have so far described cache coherency protocols in terms of the cooperative activity among caches connected to the same bus or other SMP interconnection facility. Typically, these caches are L2 caches, and each processor also has an L1 cache that does not connect directly to the bus and therefore cannot engage in a snoopy protocol. Thus, some scheme is needed to maintain data integrity across both levels of cache and across all caches in the SMP configuration.

The strategy is to extend the MESI protocol (or any cache coherence protocol) to the L1 caches. Thus, each line in the L1 cache includes bits to indicate the state. In essence, the objective is the following: for any line that is present in both an L2 cache and its corresponding L1 cache, the L1 line state should track the state of the L2 line. A simple means of doing this is to adopt the write-through policy in the L1 cache; in this case the write through is to the L2 cache and not to the memory. The L1

write-through policy forces any modification to an L1 line out to the L2 cache and therefore makes it visible to other L2 caches. The use of the L1 write-through policy requires that the L1 content must be a subset of the L2 content. This in turn suggests that the associativity of the L2 cache should be equal to or greater than that of the L1 associativity. The L1 write-through policy is used in the IBM S/390 SMP.

If the L1 cache has a write-back policy, the relationship between the two caches is more complex. There are several approaches to maintaining, a topic beyond our scope.

20.4 Multithreading and Chip Multiprocessors

The most important measure of performance for a processor is the rate at which it executes instructions. This can be expressed as

$$\text{MIPS rate} = f \times \text{IPC}$$

where f is the processor clock frequency, in MHz, and IPC (instructions per cycle) is the average number of instructions executed per cycle. Accordingly, designers have pursued the goal of increased performance on two fronts: increasing clock frequency and increasing the number of instructions executed or, more properly, the number of instructions that complete during a processor cycle. As we have seen in earlier chapters, designers have increased IPC by using an instruction pipeline and then by using multiple parallel instruction pipelines in a superscalar architecture. With pipelined and multiple-pipeline designs, the principal problem is to maximize the utilization of each pipeline stage. To improve throughput, designers have created ever more complex mechanisms, such as executing some instructions in a different order from the way they occur in the instruction stream and beginning execution of instructions that may never be needed. But as was discussed in [Section 2.2](#), this approach may be reaching a limit due to complexity and power consumption concerns.

An alternative approach, which allows for a high degree of instruction-level parallelism without increasing circuit complexity or power consumption, is called multithreading. In essence, the instruction stream is divided into several smaller streams, known as threads, such that the threads can be executed in parallel.

The variety of specific multithreading designs, realized in both commercial systems and experimental systems, is vast. In this section, we give a brief survey of the major concepts.

Implicit and Explicit Multithreading

The concept of thread used in discussing multithreaded processors may or may not be the same as the concept of software threads in a multiprogrammed operating system. It will be useful to define terms briefly:

- **Process:** An instance of a program running on a computer. A process embodies two key characteristics:
 - **Resource ownership:** A process includes a virtual address space to hold the process image; the process image is the collection of program, data, stack, and attributes that define the process. From time to time, a process may be allocated control or ownership of resources, such as main memory, I/O channels, I/O devices, and files.
 - **Scheduling/execution:** The execution of a process follows an execution path (trace) through one or more programs. This execution may be interleaved with that of other processes. Thus, a process has an execution state (Running, Ready, etc.) and a dispatching priority and is the entity that is scheduled and dispatched by the operating system.
- **Process switch:** An operation that switches the processor from one process to another, by saving all the process control data, registers, and other information for the first and replacing them with the process information for the second.³

³ The term *context switch* is often found in OS literature and textbooks. Unfortunately, although most of the literature uses this term to mean what is here called a process switch, other sources use it to mean a thread switch. To avoid ambiguity, the term is not used in this book.

- **Thread:** A dispatchable unit of work within a process. It includes a processor context (which includes the program counter and stack pointer) and its own data area for a stack (to enable subroutine branching). A thread executes sequentially and is interruptible so that the processor can turn to another thread.
- **Thread switch:** The act of switching processor control from one thread to another within the same process. Typically, this type of switch is much less costly than a process switch.

Thus, a thread is concerned with scheduling and execution, whereas a process is concerned with both scheduling/execution and resource ownership. The multiple threads within a process share the same resources. This is why a thread switch is much less time consuming than a process switch. Traditional operating systems, such as earlier versions of unix, did not support threads. Most modern operating systems, such as Linux, other versions of unix, and Windows, do support threads. A distinction is made between user-level threads, which are visible to the application program, and kernel-level threads, which are visible only to the operating system. Both of these may be referred to as explicit threads, defined in software.

All of the commercial processors and most of the experimental processors so far have used explicit multithreading. These systems concurrently execute instructions from different explicit threads, either by interleaving instructions from different threads on shared pipelines or by parallel execution on parallel pipelines. Implicit multithreading refers to the concurrent execution of multiple threads extracted from a single sequential program. These implicit threads may be defined either statically by the compiler or dynamically by the hardware. In the remainder of this section we consider explicit multithreading.

Approaches to Explicit Multithreading

At minimum, a multithreaded processor must provide a separate program counter for each thread of execution to be executed concurrently. The designs differ in the amount and type of additional hardware used to support concurrent thread execution. In general, instruction fetching takes place on a thread basis. The processor treats each thread separately and may use a number of techniques for optimizing single-thread execution, including branch prediction, register renaming, and superscalar techniques. What is achieved is thread-level parallelism, which may provide for greatly improved performance when married to instruction-level parallelism.

Broadly speaking, there are four principal approaches to multithreading:

- **Interleaved multithreading:** This is also known as **fine-grained multithreading**. The processor deals with two or more thread contexts at a time, switching from one thread to another at each clock cycle. If a thread is blocked because of data dependencies or memory latencies, that thread is skipped and a ready thread is executed.
- **Blocked multithreading:** This is also known as **coarse-grained multithreading**. The instructions of a thread are executed successively until an event occurs that may cause delay, such as a cache miss. This event induces a switch to another thread. This approach is effective on an in-order processor that would stall the pipeline for a delay event such as a cache miss.
- **Simultaneous multithreading (SMT):** Instructions are simultaneously issued from multiple threads to the execution units of a superscalar processor. This combines the wide superscalar instruction issue capability with the use of multiple thread contexts.
- **Chip multiprocessing:** In this case, multiple cores are implemented on a single chip and each core handles separate threads. The advantage of this approach is that the available logic area on a chip is used effectively without depending on ever-increasing complexity in pipeline design. This is referred to as multicore; we examine this topic separately in [Chapter 21](#).

For the first two approaches, instructions from different threads are not executed simultaneously.

Instead, the processor is able to rapidly switch from one thread to another, using a different set of registers and other context information. This results in a better utilization of the processor's execution resources and avoids a large penalty due to cache misses and other latency events. The SMT approach involves true simultaneous execution of instructions from different threads, using replicated execution resources. Chip multiprocessing also enables simultaneous execution of instructions from different threads.

Figure 20.10, based on one in [UNGE02], illustrates some of the possible pipeline architectures that involve multithreading and contrasts these with approaches that do not use multithreading. Each horizontal row represents the potential issue slot or slots for a single execution cycle; that is, the width of each row corresponds to the maximum number of instructions that can be issued in a single clock cycle.⁴ The vertical dimension represents the time sequence of clock cycles. An empty (shaded) slot represents an unused execution slot in one pipeline. A no-op is indicated by N.

⁴ Issue slots are the position from which instructions can be issued in a given clock cycle. Recall from [Chapter 18](#) that instruction issue is the process of initiating instruction execution in the processor's functional units. This occurs when an instruction moves from the decode stage of the pipeline to the first execute stage of the pipeline.

The first three illustrations in **Figure 20.10** show different approaches with a scalar (i.e., single-issue) processor:

- **Single-threaded scalar:** This is the simple pipeline found in traditional RISC and CISC machines, with no multithreading.
- **Interleaved multithreaded scalar:** This is the easiest multithreading approach to implement. By switching from one thread to another at each clock cycle, the pipeline stages can be kept fully occupied, or close to fully occupied. The hardware must be capable of switching from one thread context to another between cycles.
- **Blocked multithreaded scalar:** In this case, a single thread is executed until a latency event occurs that would stop the pipeline, at which time the processor switches to another thread.

Figure 20.10c shows a situation in which the time to perform a thread switch is one cycle, whereas **Figure 20.10b** shows that thread switching occurs in zero cycles. In the case of interleaved multithreading, it is assumed that there are no control or data dependencies between threads, which simplifies the pipeline design and therefore should allow a thread switch with no delay. However, depending on the specific design and implementation, block multithreading may require a clock cycle to perform a thread switch, as illustrated in **Figure 20.10**. This is true if a fetched instruction triggers the thread switch and must be discarded from the pipeline [UNGE03].

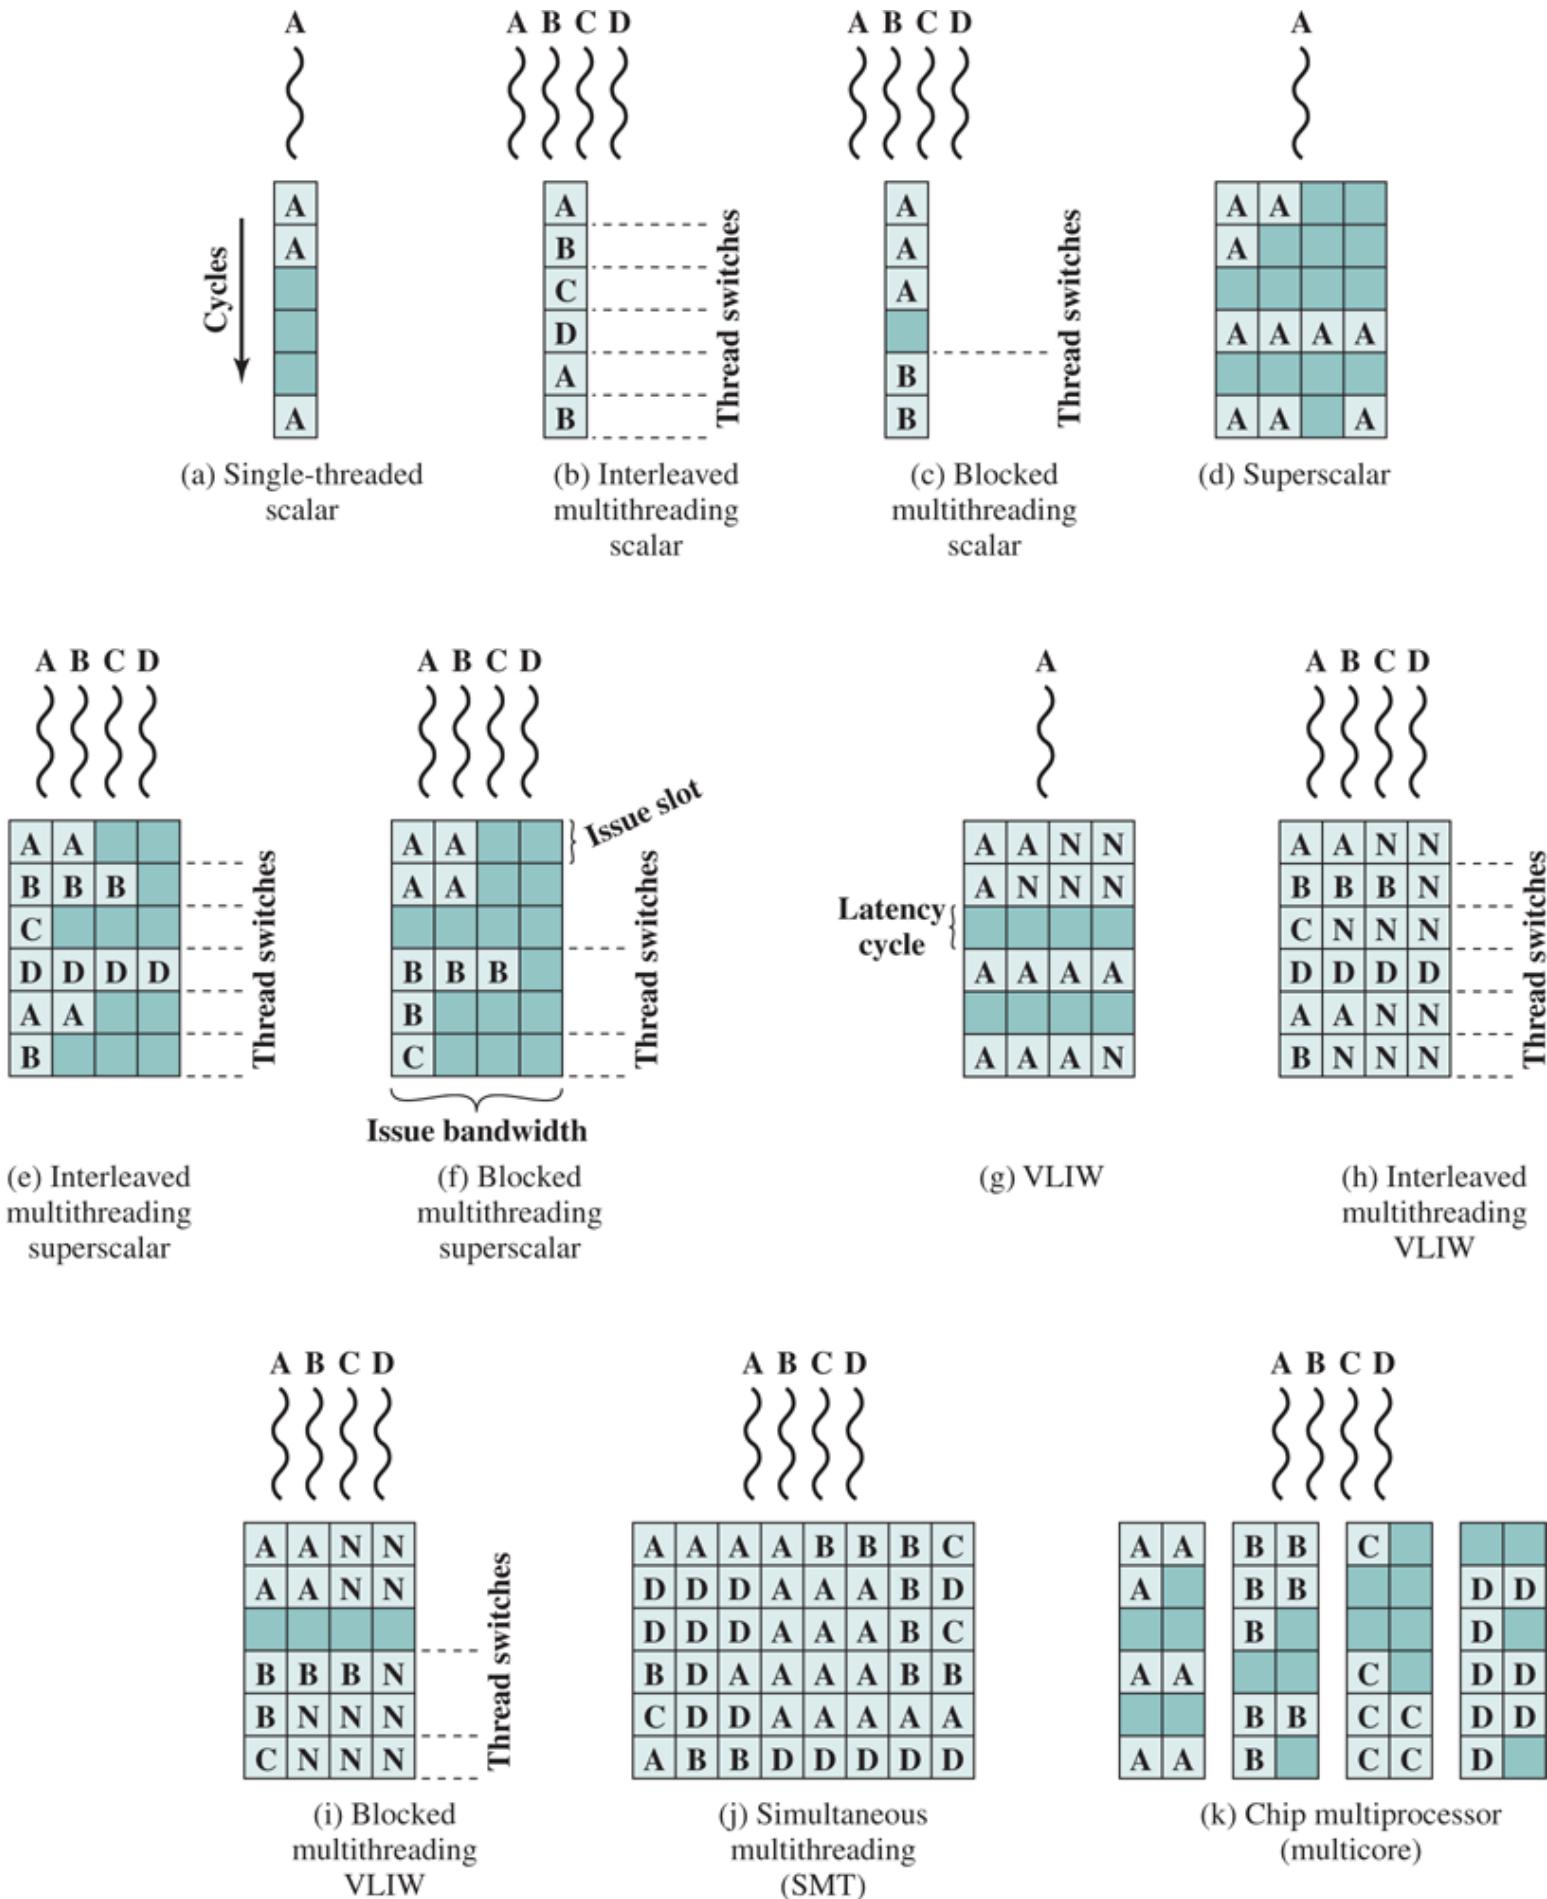

Figure 20.10 Approaches to Executing Multiple Threads

Although interleaved multithreading appears to offer better processor utilization than blocked

multithreading, it does so at the sacrifice of single-thread performance. The multiple threads compete for cache resources, which raises the probability of a cache miss for a given thread.

More opportunities for parallel execution are available if the processor can issue multiple instructions per cycle. [Figures 20.10d](#) through [20.10i](#) illustrate a number of variations among processors that have hardware for issuing four instructions per cycle. In all these cases, only instructions from a single thread are issued in a single cycle. The following alternatives are illustrated:

- **Superscalar:** This is the basic superscalar approach with no multithreading. Until relatively recently, this was the most powerful approach to providing parallelism within a processor. Note that during some cycles, not all of the available issue slots are used. During these cycles, less than the maximum number of instructions is issued; this is referred to as *horizontal loss*. During other instruction cycles, no issue slots are used; these are cycles when no instructions can be issued; this is referred to as *vertical loss*.
- **Interleaved multithreading superscalar:** During each cycle, as many instructions as possible are issued from a single thread. With this technique, potential delays due to thread switches are eliminated, as previously discussed. However, the number of instructions issued in any given cycle is still limited by dependencies that exist within any given thread.
- **Blocked multithreaded superscalar:** Again, instructions from only one thread may be issued during any cycle, and blocked multithreading is used.
- **Very long instruction word (VLIW):** A VLIW architecture, such as IA-64, places multiple instructions in a single word. Typically, a VLIW is constructed by the compiler, which places operations that may be executed in parallel in the same word. In a simple VLIW machine ([Figure 20.10g](#)), if it is not possible to completely fill the word with instructions to be issued in parallel, no-ops are used.
- **Interleaved multithreading VLIW:** This approach should provide similar efficiencies to those provided by interleaved multithreading on a superscalar architecture.
- **Blocked multithreading VLIW:** This approach should provide similar efficiencies to those provided by blocked multithreading on a superscalar architecture.

The final two approaches illustrated in [Figure 20.10](#) enable the parallel, simultaneous execution of multiple threads:

- **Simultaneous multithreading:** [Figure 20.10i](#) shows a system capable of issuing 8 instructions at a time. If one thread has a high degree of instruction-level parallelism, it may on some cycles be able fill all of the horizontal slots. On other cycles, instructions from two or more threads may be issued. If sufficient threads are active, it should usually be possible to issue the maximum number of instructions on each cycle, providing a high level of efficiency.
- **Chip multiprocessor (multicore):** [Figure 20.10k](#) shows a chip containing four cores, each of which has a two-issue superscalar processor. Each core is assigned a thread, from which it can issue up to two instructions per cycle. We discuss multicore computers in [Chapter 21](#).

Comparing [Figures 20.10i](#) and [20.10k](#), we see that a chip multiprocessor with the same instruction issue capability as an SMT cannot achieve the same degree of instruction-level parallelism. This is because the chip multiprocessor is not able to hide latencies by issuing instructions from other threads. On the other hand, the chip multiprocessor should outperform a superscalar processor with the same instruction issue capability, because the horizontal losses will be greater for the superscalar processor. In addition, it is possible to use multithreading within each of the cores on a chip multiprocessor, and this is done on some contemporary machines.

20.5 Clusters

An important and relatively recent development in computer system design is clustering. Clustering is an alternative to symmetric multiprocessing as an approach to providing high performance and high availability, and is particularly attractive for server applications. We can define a cluster as a group of interconnected, whole computers working together as a unified computing resource that can create the illusion of being one machine. The term *whole computer* means a system that can run on its own, apart from the cluster; in the literature, each computer in a cluster is typically referred to as a *node*.

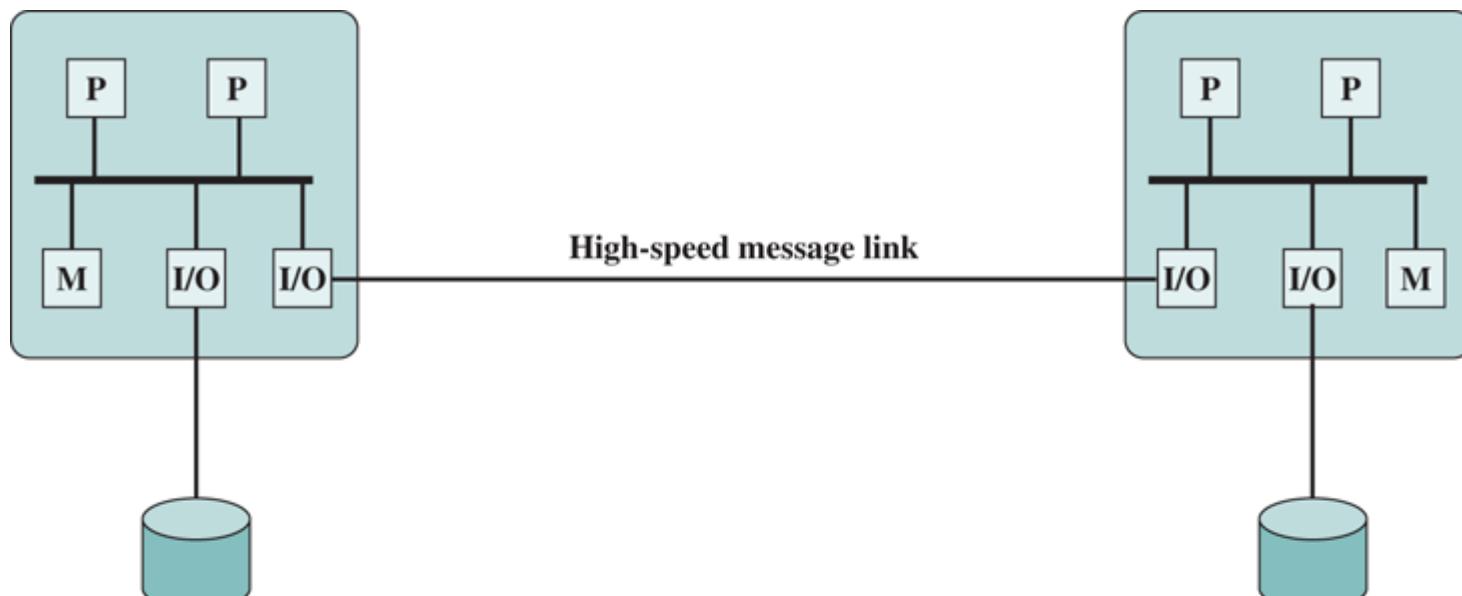

[BREW97] lists four benefits that can be achieved with clustering. These can also be thought of as objectives or design requirements:

- **Absolute scalability:** It is possible to create large clusters that far surpass the power of even the largest standalone machines. A cluster can have tens, hundreds, or even thousands of machines, each of which is a multiprocessor.
- **Incremental scalability:** A cluster is configured in such a way that it is possible to add new systems to the cluster in small increments. Thus, a user can start out with a modest system and expand it as needs grow, without having to go through a major upgrade in which an existing small system is replaced with a larger system.
- **High availability:** Because each node in a cluster is a standalone computer, the failure of one node does not mean loss of service. In many products, fault tolerance is handled automatically in software.
- **Superior price/performance:** By using commodity building blocks, it is possible to put together a cluster with equal or greater computing power than a single large machine, at much lower cost.

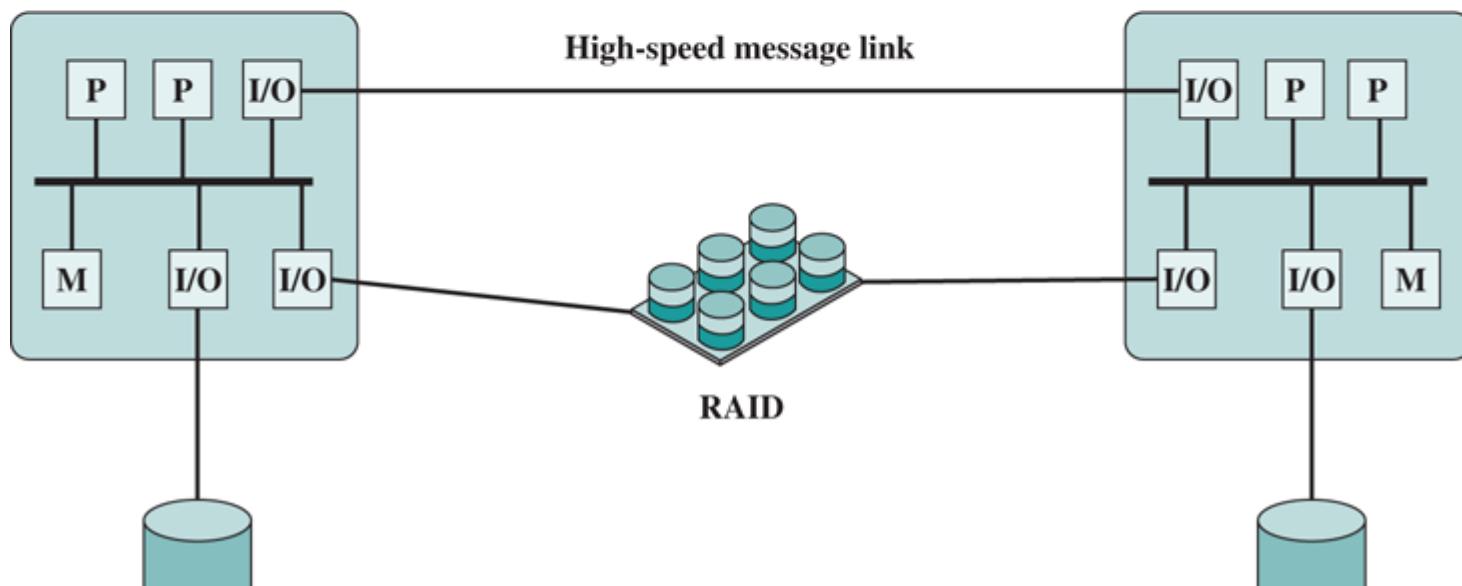

Cluster Configurations

In the literature, clusters are classified in a number of different ways. Perhaps the simplest classification is based on whether the computers in a cluster share access to the same disks. [Figure 20.11a](#) shows a two-node cluster in which the only interconnection is by means of a high-speed link that can be used for message exchange to coordinate cluster activity. The link can be a LAN that is shared with other computers that are not part of the cluster, or the link can be a dedicated interconnection facility. In the latter case, one or more of the computers in the cluster will have a link to a LAN or WAN so that there is a connection between the server cluster and remote client systems. Note that in the figure, each computer is depicted as being a multiprocessor. This is not necessary but does enhance both performance and availability.

In the simple classification depicted in [Figure 20.11](#), the other alternative is a shared-disk cluster. In this case, there generally is still a message link between nodes. In addition, there is a disk subsystem that is directly linked to multiple computers within the cluster. In this figure, the common disk subsystem is a RAID system. The use of RAID or some similar redundant disk technology is common in clusters so that the high availability achieved by the presence of multiple computers is not compromised by a shared disk that is a single point of failure.

(a) Standby server with no shared disk

(b) Shared Disk

Figure 20.11 Cluster Configurations

A clearer picture of the range of cluster options can be gained by looking at functional alternatives. **Table 20.2** provides a useful classification along functional lines, which we now discuss.

Table 20.2 Clustering Methods: Benefits and Limitations

Clustering Method	Description	Benefits	Limitations
Passive Standby	A secondary server takes over in case of primary server failure.	Easy to implement.	High cost because the secondary server is unavailable for other processing tasks.

Active Secondary:	The secondary server is also used for processing tasks.	Reduced cost because secondary servers can be used for processing.	Increased complexity.
Separate Servers	Separate servers have their own disks. Data is continuously copied from primary to secondary server.	High availability.	High network and server overhead due to copying operations.
Servers Connected to Disks	Servers are cabled to the same disks, but each server owns its disks. If one server fails, its disks are taken over by the other server.	Reduced network and server overhead due to elimination of copying operations.	Usually requires disk mirroring or RAID technology to compensate for risk of disk failure.
Servers Share Disks	Multiple servers simultaneously share access to disks.	Low network and server overhead. Reduced risk of downtime caused by disk failure.	Requires lock manager software. Usually used with disk mirroring or RAID technology.

A common, older method known as **passive standby**, is simply to have one computer handle all of the processing load while the other computer remains inactive, standing by to take over in the event of a failure of the primary. To coordinate the machines, the active, or primary, system periodically sends a “heartbeat” message to the standby machine. Should these messages stop arriving, the standby assumes that the primary server has failed and puts itself into operation. This approach increases availability but does not improve performance. Further, if the only information that is exchanged between the two systems is a heartbeat message, and if the two systems do not share common disks, then the standby provides a functional backup but has no access to the databases managed by the primary.

The passive standby is generally not referred to as a cluster. The term *cluster* is reserved for multiple interconnected computers that are all actively doing processing while maintaining the image of a single system to the outside world. The term **active secondary** is often used in referring to this configuration. Three classifications of clustering can be identified: separate servers, shared nothing, and shared memory.

In one approach to clustering, each computer is a **separate server** with its own disks, and there are no disks shared between systems ([Figure 20.11a](#)). This arrangement provides high performance as well as high availability. In this case, some type of management or scheduling software is needed to assign incoming client requests to servers so that the load is balanced and high utilization is achieved. It is desirable to have a failover capability, which means that if a computer fails while executing an application, another computer in the cluster can pick up and complete the application. For this to happen, data must constantly be copied among systems so that each system has access to the current data of the other systems. The overhead of this data exchange ensures high availability at the cost of a performance penalty.

To reduce the communications overhead, most clusters now consist of servers connected to common disks (**Figure 20.11b**). In one variation on this approach, called **shared nothing**, the common disks are partitioned into volumes, and each volume is owned by a single computer. If that computer fails, the cluster must be reconfigured so that some other computer has ownership of the volumes of the failed computer.

It is also possible to have multiple computers share the same disks at the same time (called the **shared disk** approach), so that each computer has access to all of the volumes on all of the disks. This approach requires the use of some type of locking facility to ensure that data can only be accessed by one computer at a time.

20.6 Nonuniform Memory Access

In terms of commercial products, the two common approaches to providing a multiple-processor system to support applications are SMPs and clusters. For some years, another approach, known as nonuniform memory access (NUMA), has been the subject of research and commercial NUMA products are now available.

Before proceeding, we should define some terms often found in the NUMA literature.

- **Uniform memory access (UMA):** All processors have access to all parts of main memory using loads and stores. The memory access time of a processor to all regions of memory is the same. The access times experienced by different processors are the same. The SMP organization discussed in [Sections 20.2](#) and [20.3](#) is UMA.
- **Nonuniform memory access (NUMA):** All processors have access to all parts of main memory using loads and stores. The memory access time of a processor differs depending on which region of main memory is accessed. The last statement is true for all processors; however, for different processors, which memory regions are slower and which are faster differs.
- **Cache-coherent NUMA (CC-NUMA):** A NUMA system in which cache coherence is maintained among the caches of the various processors.

A NUMA system without cache coherence is more or less equivalent to a cluster. The commercial products that have received much attention recently are CC-NUMA systems, which are quite distinct from both SMPs and clusters. Usually, but unfortunately not always, such systems are in fact referred to in the commercial literature as CC-NUMA systems. This section is concerned only with CC-NUMA systems.

Motivation

With an SMP system, there is a practical limit to the number of processors that can be used. An effective cache scheme reduces the bus traffic between any one processor and main memory. As the number of processors increases, this bus traffic also increases. Also, the bus is used to exchange cache-coherence signals, further adding to the burden. At some point, the bus becomes a performance bottleneck. Performance degradation seems to limit the number of processors in an SMP configuration to somewhere between 16 and 64 processors. For example, Silicon Graphics' Power Challenge SMP is limited to 64 R10000 processors in a single system; beyond this number performance degrades substantially.

The processor limit in an SMP is one of the driving motivations behind the development of cluster systems. However, with a cluster, each node has its own private main memory; applications do not see a large global memory. In effect, coherence is maintained in software rather than hardware. This memory granularity affects performance and, to achieve maximum performance, software must be tailored to this environment. One approach to achieving large-scale multiprocessing while retaining the flavor of SMP is NUMA.

The objective with NUMA is to maintain a transparent system-wide memory while permitting multiple multiprocessor nodes, each with its own bus or other internal interconnect system.

Organization

[Figure 20.12](#) depicts a typical CC-NUMA organization. There are multiple independent nodes, each of which is, in effect, an SMP organization. Thus, each node contains multiple processors, each with its own L1 and L2 caches, plus main memory. The node is the basic building block of the overall

CC-NUMA organization. For example, each Silicon Graphics Origin node includes two MIPS R10000 processors; each Sequent NUMA-Q node includes four Pentium II processors. The nodes are interconnected by means of some communications facility, which could be a switching mechanism, a ring, or some other networking facility.

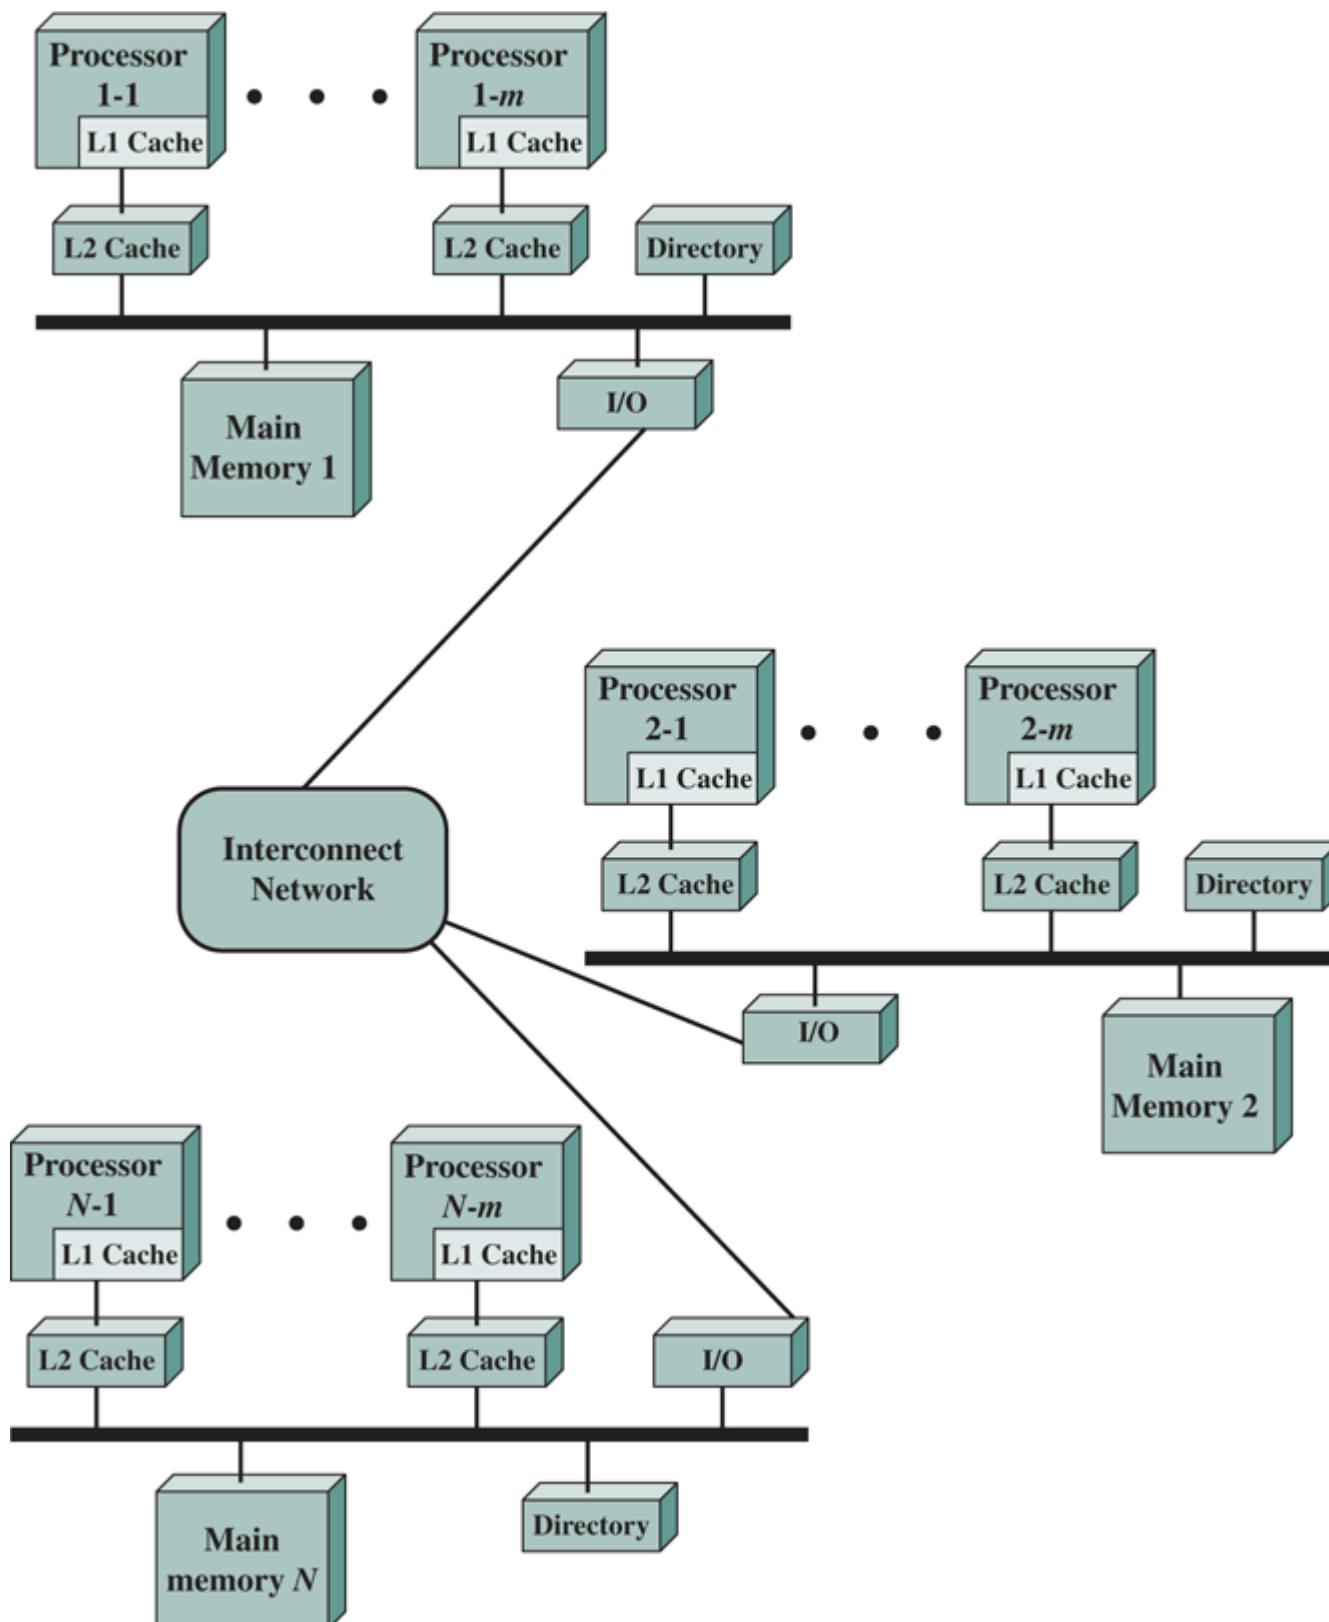

Figure 20.12 CC-NUMA Organization

Each node in the CC-NUMA system includes some main memory. From the point of view of the processors, however, there is only a single addressable memory, with each location having a unique system-wide address. When a processor initiates a memory access, if the requested memory location

is not in that processor's cache, then the L2 cache initiates a fetch operation. If the desired line is in the local portion of the main memory, the line is fetched across the local bus. If the desired line is in a remote portion of the main memory, then an automatic request is sent out to fetch that line across the interconnection network, deliver it to the local bus, and then deliver it to the requesting cache on that bus. All of this activity is automatic and transparent to the processor and its cache.

In this configuration, cache coherence is a central concern. Although implementations differ as to details, in general terms we can say that each node must maintain some sort of directory that gives it an indication of the location of various portions of memory and also cache status information. To see how this scheme works, we give an example taken from [PFIS98]. Suppose that processor 3 on node 2 (P2-3) requests a memory location 798, which is in the memory of node 1. The following sequence occurs:

1. P2-3 issues a read request on the snoopy bus of node 2 for location 798.
2. The directory on node 2 sees the request and recognizes that the location is in node 1.
3. Node 2's directory sends a request to node 1, which is picked up by node 1's directory.
4. Node 1's directory, acting as a surrogate of P2-3, requests the contents of 798, as if it were a processor.
5. Node 1's main memory responds by putting the requested data on the bus.
6. Node 1's directory picks up the data from the bus.
7. The value is transferred back to node 2's directory.
8. Node 2's directory places the data back on node 2's bus, acting as a surrogate for the memory that originally held it.
9. The value is picked up and placed in P2-3's cache and delivered to P2-3.

The preceding sequence explains how data are read from a remote memory using hardware mechanisms that make the transaction transparent to the processor. On top of these mechanisms, some form of cache coherence protocol is needed. Various systems differ on exactly how this is done. We make only a few general remarks here. First, as part of the preceding sequence, node 1's directory keeps a record that some remote cache has a copy of the line containing location 798. Then, there needs to be a cooperative protocol to take care of modifications. For example, if a modification is done in a cache, this fact can be broadcast to other nodes. Each node's directory that receives such a broadcast can then determine if any local cache has that line and, if so, cause it to be purged. If the actual memory location is at the node receiving the broadcast notification, then that node's directory needs to maintain an entry indicating that that line of memory is invalid and remains so until a write back occurs. If another processor (local or remote) requests the invalid line, then the local directory must force a write back to update memory before providing the data.

NUMA Pros and Cons

The main advantage of a CC-NUMA system is that it can deliver effective performance at higher levels of parallelism than SMP, without requiring major software changes. With multiple NUMA nodes, the bus traffic on any individual node is limited to a demand that the bus can handle. However, if many of the memory accesses are to remote nodes, performance begins to break down. There is reason to believe that this performance breakdown can be avoided. First, the use of L1 and L2 caches is designed to minimize all memory accesses, including remote ones. If much of the software has good temporal locality, then remote memory accesses should not be excessive. Second, if the software has good spatial locality, and if virtual memory is in use, then the data needed for an application will reside on a limited number of frequently-used pages that can be initially loaded into the memory local to the running application. The Sequent designers report that such spatial locality does appear in representative applications [LOVE96]. Finally, the virtual memory scheme can be enhanced by including in the operating system a page migration mechanism that will move a virtual memory page

to a node that is frequently using it; the Silicon Graphics designers report success with this approach [WHIT97].

Even if the performance breakdown due to remote access is addressed, there are two other disadvantages for the CC-NUMA approach [PFIS98]. First, a CC-NUMA does not transparently look like an SMP; software changes will be required to move an operating system and applications from an SMP to a CC-NUMA system. These include page allocation, already mentioned, process allocation, and load balancing by the operating system. A second concern is that of availability. This is a rather complex issue and depends on the exact implementation of the CC-NUMA system; the interested reader is referred to [PFIS98].

nonuniform memory access (NUMA)
passive standby
platform as a service (PaaS)
service aggregation
service arbitrage
service intermediation
snoopy protocol
software as a service (SaaS)
symmetric multiprocessor (SMP)
uniform memory access (UMA)
uniprocessor

Review Questions

- 20.1 List and briefly define three types of computer system organization.
- 20.2 What are the chief characteristics of an SMP?
- 20.3 What are some of the potential advantages of an SMP compared with a uniprocessor?
- 20.4 What are some of the key OS design issues for an SMP?
- 20.5 What is the difference between software and hardware cache coherent schemes?
- 20.6 What is the meaning of each of the four states in the MESI protocol?
- 20.7 What are some of the key benefits of clustering?
- 20.8 What is the difference between failover and fallback?
- 20.9 What are the differences among UMA, NUMA, and CC-NUMA?

Problems

20.1 Let α be the percentage of program code that can be executed simultaneously by n processors in a computer system. Assume that the remaining code must be executed sequentially by a single processor. Each processor has an execution rate of x MIPS.

- a. Derive an expression for the effective MIPS rate when using the system for exclusive execution of this program, in terms of n , α , and x .
- b. If $n = 16$ and $x = 4$ MIPS, determine the value of α that will yield a system performance of 40 MIPS.

20.2 A multiprocessor with eight processors has 20 attached tape drives. There are a large number of jobs submitted to the system that each require a maximum of four tape drives to complete execution. Assume that each job starts running with only three tape drives for a long period before requiring the fourth tape drive for a short period toward the end of its operation. Also assume an endless supply of such jobs.

- a. Assume the scheduler in the OS will not start a job unless there are four tape drives available. When a job is started, four drives are assigned immediately and are not released until the job finishes. What is the maximum number of jobs that can be in progress at once? What are the maximum and minimum number of tape drives that may be left idle as a result of this policy?
- b. Suggest an alternative policy to improve tape drive utilization and at the same time avoid system deadlock. What is the maximum number of jobs that can be in progress at once? What are the bounds on the number of idling tape drives?

20.3 Can you foresee any problem with the write-once cache approach on bus-based multiprocessors? If so, suggest a solution.

20.4 Consider a situation in which two processors in an SMP configuration, over time, require access to the same line of data from main memory. Both processors have a cache and use the MESI protocol. Initially, both caches have an invalid copy of the line. **Figure 20.13** depicts the consequence of a read of line x by Processor P1. If this is the start of a sequence of accesses, draw the subsequent figures for the following sequence:

1. P2 reads x .
2. P1 writes to x (for clarity, label the line in P1's cache x').
3. P1 writes to x (label the line in P1's cache x'').
4. P2 reads x .

20.5 **Figure 20.14** shows the state diagrams of two possible cache coherence protocols. Deduce and explain each protocol, and compare each to MESI.

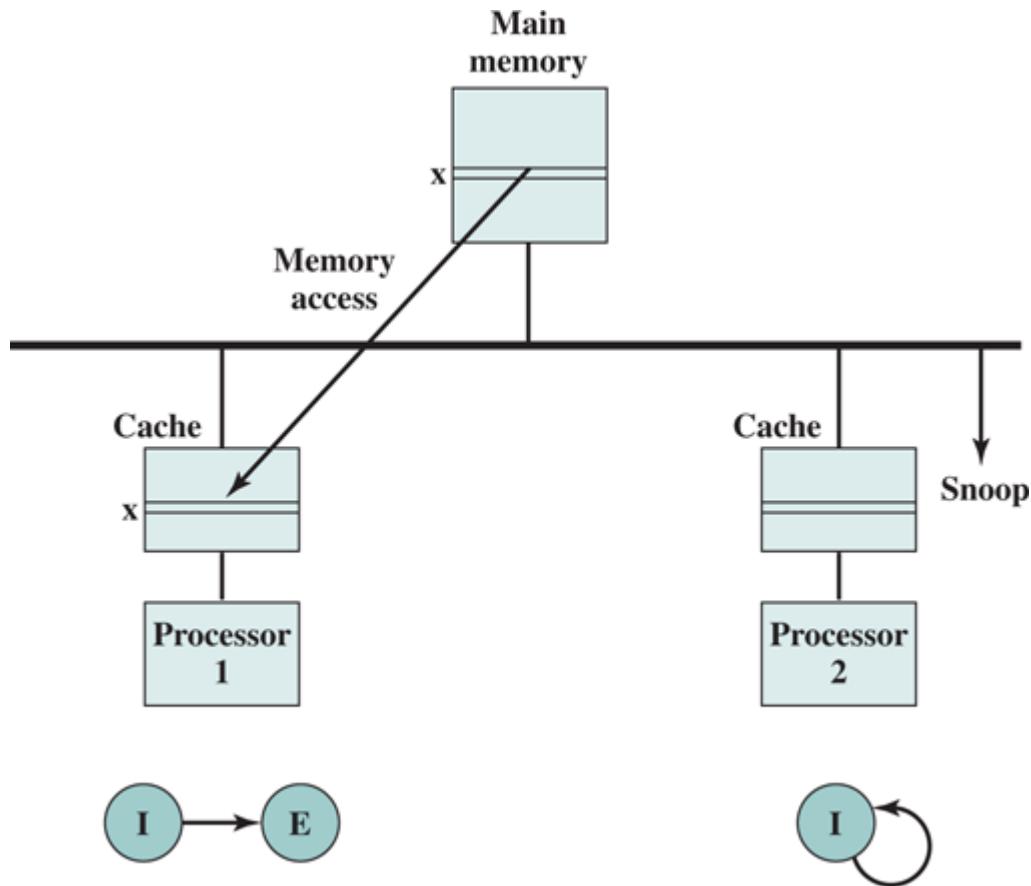

Figure 20.13 MESI Example: Processor 1 Reads Line x

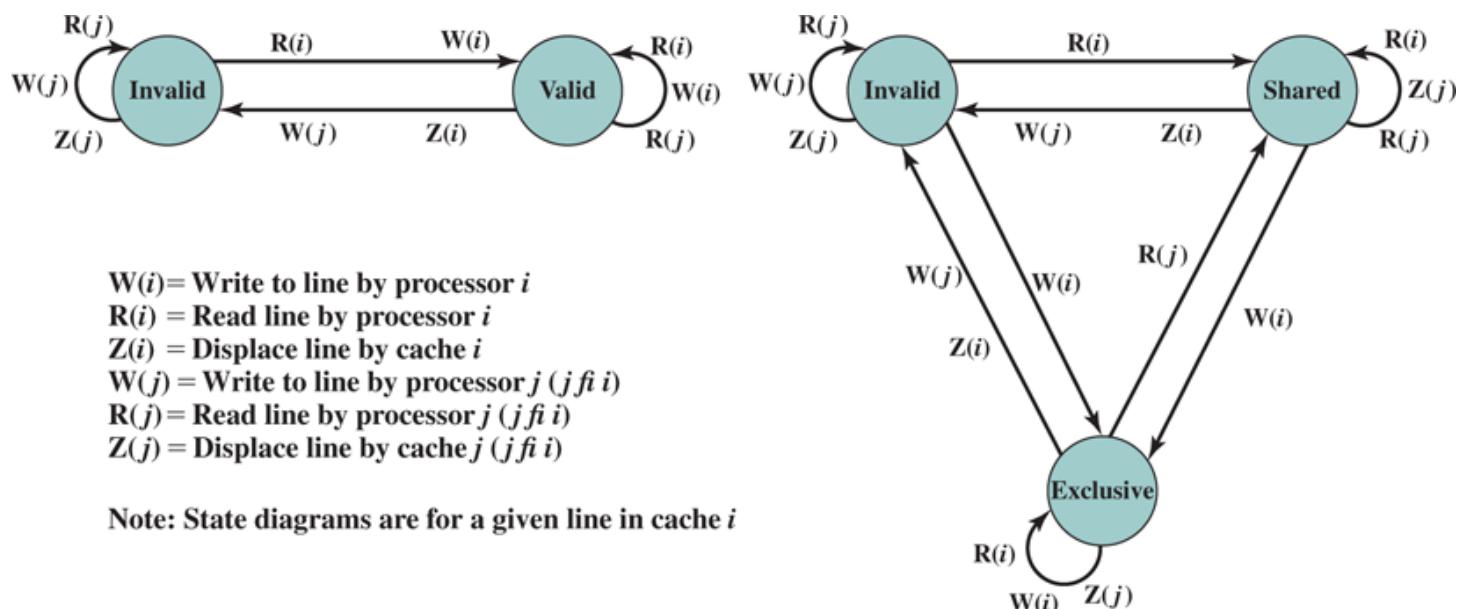

Figure 20.14 Two Cache Coherence Protocols

20.6 Consider an SMP with both L1 and L2 caches using the MESI protocol. As explained in [Section 20.3](#), one of four states is associated with each line in the L2 cache. Are all four states also needed for each line in the L1 cache? If so, why? If not, explain which state or states can be eliminated.

20.7 An earlier version of the IBM mainframe, the S/390 G4, used three levels of cache. As with the z990, only the first level was on the processor chip [called the processor unit (PU)]. The L2

cache was also similar to the z990. An L3 cache was on a separate chip that acted as a memory controller, and was interposed between the L2 caches and the memory cards. **Table 20.3** shows the performance of a three-level cache arrangement for the IBM S/390. The purpose of this problem is to determine whether the inclusion of the third level of cache seems worthwhile. Determine the access penalty (average number of PU cycles) for a system with only an L1 cache, and normalize that value to 1.0. Then determine the normalized access penalty when both an L1 and L2 cache are used, and the access penalty when all three caches are used. Note the amount of improvement in each case and state your opinion on the value of the L3 cache.

Table 20.3 Typical Cache Hit Rate on S/390 SMP Configuration [MAK97]

Memory Subsystem	Access Penalty (PU cycles)	Cache Size	Hit Rate (%)
L1 cache	1	32 KB	89
L2 cache	5	256 KB	5
L3 cache	14	2 MB	3
Memory	32	8 GB	3

20.8

- Consider a uniprocessor with separate data and instruction caches, with hit ratios of H_d and H_i , respectively. Access time from processor to cache is c clock cycles, and transfer time for a block between memory and cache is b clock cycles. Let f_i be the fraction of memory accesses that are for instructions, and f_d is the fraction of dirty lines in the data cache among lines replaced. Assume a write-back policy and determine the effective memory access time in terms of the parameters just defined.
- Now assume a bus-based SMP in which each processor has the characteristics of part (a). Every processor must handle cache invalidation in addition to memory reads and writes. This affects effective memory access time. Let f_{inv} be the fraction of data references that cause invalidation signals to be sent to other data caches. The processor sending the signal requires t clock cycles to complete the invalidation operation. Other processors are not involved in the invalidation operation. Determine the effective memory access time.

20.9 What organizational alternative is suggested by each of the illustrations in **Figure 20.15** ?

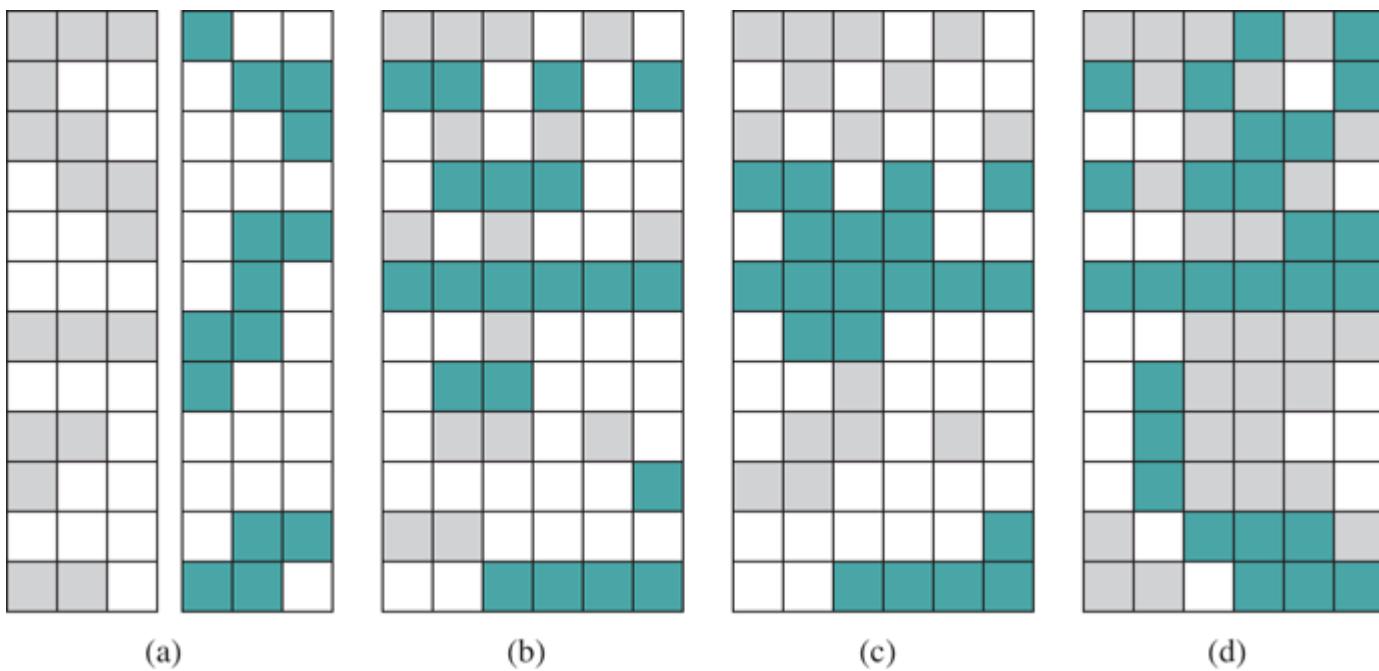

Figure 20.15 Diagram for Problem 20.9

20.10 In [Figure 20.10](#), some of the diagrams show horizontal rows that are partially filled. In other cases, there are rows that are completely blank. These represent two different types of loss of efficiency. Explain.

20.11 Consider the pipeline depiction in [Figure 16.13b](#), which is redrawn in [Figure 20.16a](#), with the fetch and decode stages ignored, to represent the execution of thread A. [Figure 20.16b](#) illustrates the execution of a separate thread B. In both cases, a simple pipelined processor is used.

- Show an instruction issue diagram, similar to [Figure 20.10a](#), for each of the two threads.
- Assume that the two threads are to be executed in parallel on a chip multiprocessor, with each of the two cores on the chip using a simple pipeline. Show an instruction issue diagram similar to [Figure 20.10k](#). Also show a pipeline execution diagram in the style of [Figure 20.16](#).
- Assume a two-issue superscalar architecture. Repeat part (b) for an interleaved multithreading superscalar implementation, assuming no data dependencies. *Note:* There is no unique answer; you need to make assumptions about latency and priority.
- Repeat part (c) for a blocked multithreading superscalar implementation.
- Repeat for a four-issue SMT architecture.

Figure 20.16 Two Threads of Execution

20.12 An application program is executed on a nine-computer cluster. A benchmark program took time T on this cluster. Further, it was found that 25% of T was time in which the application was running simultaneously on all nine computers. The remaining time, the application had to run on a single computer.

- Calculate the effective speedup under the aforementioned condition as compared to executing the program on a single computer. Also calculate α , the percentage of code that has been parallelized (programmed or compiled so as to use the cluster mode) in the preceding program.
- Suppose that we are able to effectively use 17 computers rather than 9 computers on the parallelized portion of the code. Calculate the effective speedup that is achieved.

20.13 The following FORTRAN program is to be executed on a computer, and a parallel version is to be executed on a 32-computer cluster.

```

L1:      DO 10 I = 1, 1024
L2:          SUM(I) = 0
L3:          DO 20 J = 1, I
L4: 20                  SUM(I) = SUM(I) + I
L5: 10  CONTINUE

```

Suppose lines 2 and 4 each take two machine cycle times, including all processor and memory-access activities. Ignore the overhead caused by the software loop control statements (lines 1, 3, 5) and all other system overhead and resource conflicts.

- What is the total execution time (in machine cycle times) of the program on a single computer?
- Divide the I-loop iterations among the 32 computers as follows: Computer 1 executes the first 32 iterations ($I = 1$ to 32), processor 2 executes the next 32 iterations, and so on. What are the execution time and speedup factor compared with part (a)? (Note that the computational workload, dictated by the J-loop, is unbalanced among the computers.)
- Explain how to modify the parallelizing to facilitate a balanced parallel execution of all the computational workload over 32 computers. By a balanced load is meant an equal number of additions assigned to each computer with respect to both loops.
- What is the minimum execution time resulting from the parallel execution on 32 computers? What is the resulting speedup over a single computer?

20.14 Consider the following two versions of a program to add two vectors:

```

L1:      DO 10 I = 1, N
L2:      A(I) = B(I) + C(I)
L3: 10  CONTINUE
L4:      SUM = 0
L5:      DO 20J = 1, N
L6:      SUM = SUM + A(J)
L7: 20  CONTINUE

```

```

DOALL K = 1, M
DO 10 I = L(K-1)+1, KL
A(I) = B(I)+C(I)
10  CONTINUE
SUM(K) = 0
DO 20 J = 1, L
SUM(K) = SUM(K) + A(L(K-1)+J)
20  CONTINUE
ENDALL

```

- The program on the left executes on a uniprocessor. Suppose each line of code L2, L4, and L6 takes one processor clock cycle to execute. For simplicity, ignore the time required for the other lines of code. Initially all arrays are already loaded in main memory and the short program fragment is in the instruction cache. How many clock cycles are required to execute this program?
- The program on the right is written to execute on a multiprocessor with M processors. We partition the looping operations into M sections with $L = N / M$ elements per section.

DOALL declares that all M sections are executed in parallel. The result of this program is to produce M partial sums. Assume that k clock cycles are needed for each interprocessor communication operation via the shared memory and that therefore the addition of each partial sum requires k cycles. An l -level binary adder tree can merge all the partial sums, where $l = \log_2 M$. How many cycles are needed to produce the final sum?

- Suppose $N = 2^{20}$ elements in the array and $M = 256$. What is the speedup achieved by using the multiprocessor? Assume $k = 200$. What percentage is this of the theoretical speedup of a factor of 256?

Learning Objectives

After studying this chapter, you should be able to:

- Understand the **hardware performance issues** that have driven the move to multicore computers.
- Understand the **software performance issues** posed by the use of multithreaded multicore computers.
- Present an overview of the two principal approaches to **heterogeneous multicore organization**.
- Have an appreciation of the use of **multicore organization** on embedded systems, PCs and servers, and mainframes.

A **multicore processor**, also known as a **chip multiprocessor**, combines two or more processor units (called cores) on a single piece of silicon (called a die).

Typically, each core consists of all of the components of an independent processor, such as registers, ALU, pipeline hardware, and control unit, plus L1 instruction and data caches. In addition to the multiple cores, contemporary multicore chips also include L2 cache and, increasingly, L3 cache. The most highly integrated multicore processors, known as systems on chip (SoCs), also include memory and peripheral controllers.

This chapter provides an overview of multicore systems. We begin with a look at the hardware performance factors that led to the development of multicore computers and the software challenges of exploiting the power of a multicore system. Next, we look at multicore organization. Finally, we examine three examples of multicore products, covering personal computer and workstation systems (Intel), embedded systems (ARM), and mainframes (IBM).

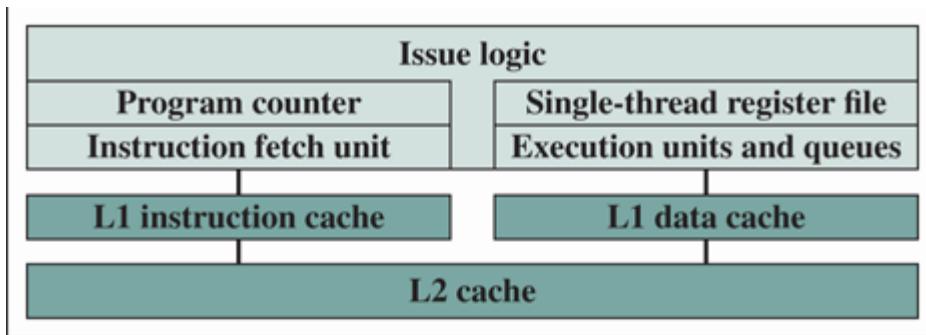

21.1 Hardware Performance Issues

As we discuss in [Chapter 2](#), microprocessor Microprocessor systems have experienced a steady increase in execution performance for decades. This increase is due to a number of factors, including increase in clock frequency, increase in transistor density, and refinements in the organization of the processor on the chip.

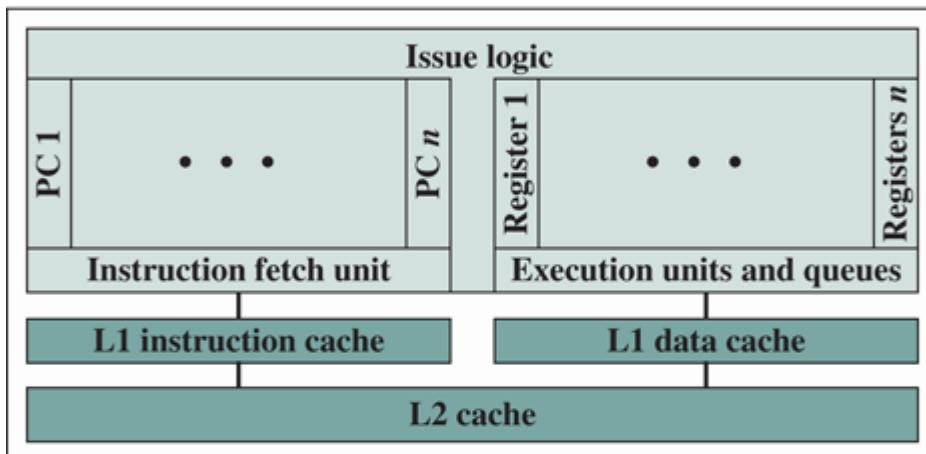

Increase in Parallelism and Complexity

The organizational changes in processor design have primarily been focused on exploiting ILP, so that more work is done in each clock cycle. These changes include, in chronological order ([Figure 21.1](#)):

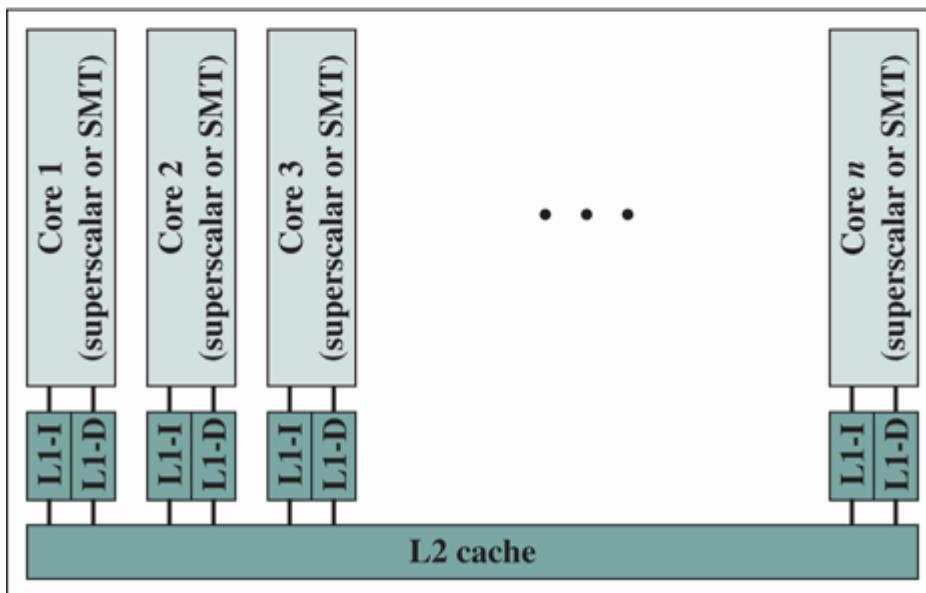

- **Pipelining:** Individual instructions are executed through a pipeline of stages so that while one instruction is executing in one stage of the pipeline, another instruction is executing in another stage of the pipeline.
- **Superscalar:** Multiple pipelines are constructed by replicating execution resources. This enables parallel execution of instructions in parallel pipelines, so long as hazards are avoided.
- **Simultaneous multithreading (SMT):** Register banks are expanded so that multiple threads can share the use of pipeline resources.

(a) Superscalar

(b) Simultaneous multithreading

(c) Multicore

Figure 21.1 Alternative Chip Organizations

With each of these innovations, designers have over the years attempted to increase the performance of the system by adding complexity. In the case of pipelining, simple three-stage pipelines were replaced by pipelines with five stages. Intel's Pentium 4 "Prescott" core had 31 stages for some instructions.

There is a practical limit to how far this trend can be taken, because with more stages, there is the need for more logic, more interconnections, and more control signals.

With superscalar organization, increased performance can be achieved by increasing the number of parallel pipelines. Again, there are diminishing returns as the number of pipelines increases. More logic is required to manage hazards and to stage instruction resources. Eventually, a single thread of execution reaches the point where hazards and resource dependencies prevent the full use of the multiple pipelines available. Also, compiled binary code rarely exposes enough ILP to take advantage of more than about six parallel pipelines.

This same point of diminishing returns is reached with SMT, as the complexity of managing multiple threads over a set of pipelines limits the number of threads and number of pipelines that can be effectively utilized. SMT's advantage lies in the fact that two (or more) program streams can be searched for available ILP.

There is a related set of problems dealing with the design and fabrication of the computer chip. The increase in complexity to deal with all of the logical issues related to very long pipelines, multiple superscalar pipelines, and multiple SMT register banks means that increasing amounts of the chip area are occupied with coordinating and signal transfer logic. This increases the difficulty of designing, fabricating, and debugging the chips. The increasingly difficult engineering challenge related to processor logic is one of the reasons that an increasing fraction of the processor chip is devoted to the simpler memory logic. Power issues, discussed next, provide another reason.

Power Consumption

To maintain the trend of higher performance as the number of transistors per chip rises, designers have resorted to more elaborate processor designs (pipelining, superscalar, SMT) and to high clock frequencies. Unfortunately, power requirements have grown exponentially as chip density and clock frequency have risen. This was shown in [Figure 2.2](#).

One way to control power density is to use more of the chip area for cache memory. Memory transistors are smaller and have a power density an order of magnitude lower than that of logic (see [Figure 21.2](#)). As chip transistor density has increased, the percentage of chip area devoted to memory has grown, and is now often half the chip area. Even so, there is still a considerable amount of chip area devoted to processing logic.

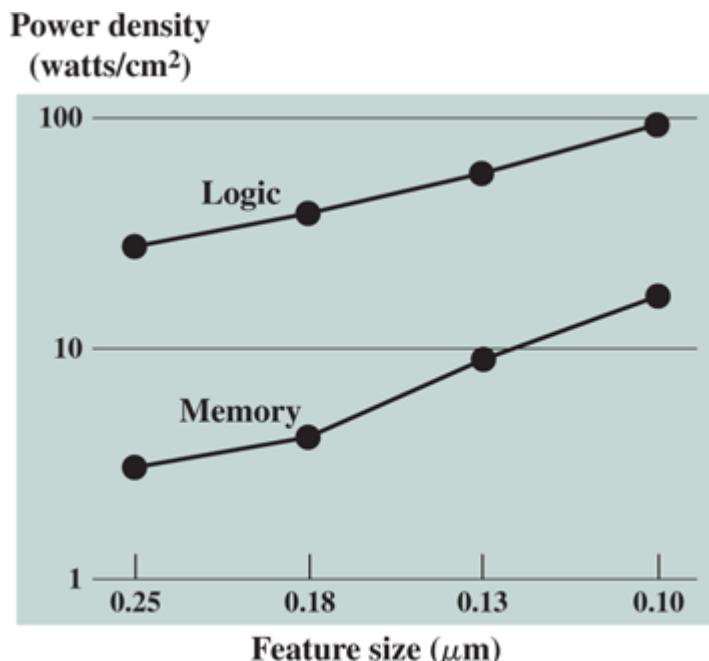

Figure 21.2 Power and Memory Considerations

How to use all those logic transistors is a key design issue. As discussed earlier in this section, there are limits to the effective use of such techniques as superscalar and SMT. In general terms, the experience of recent decades has been encapsulated in a rule of thumb known as [Pollack's rule](#) [POLL99], which states that performance increase is roughly proportional to the square root of increase in complexity. In other words, if you double the logic in a processor core, then it delivers only 40% more performance. In principle, the use of multiple cores has the potential to provide near-linear performance improvement with the increase in the number of cores—but only for software that can take advantage.

Power considerations provide another motive for moving toward a multicore organization. Because the chip has such a huge amount of cache memory, it becomes unlikely that any one thread of execution can effectively use all that memory. Even with SMT, multithreading is done in a relatively limited fashion and cannot therefore fully exploit a gigantic cache, whereas a number of relatively independent threads or processes has a greater opportunity to take full advantage of the cache memory.

21.2 Software Performance Issues

A detailed examination of the software performance issues related to multicore organization is beyond our scope. In this section, we first provide an overview of these issues, and then look at an example of an application designed to exploit multicore capabilities.

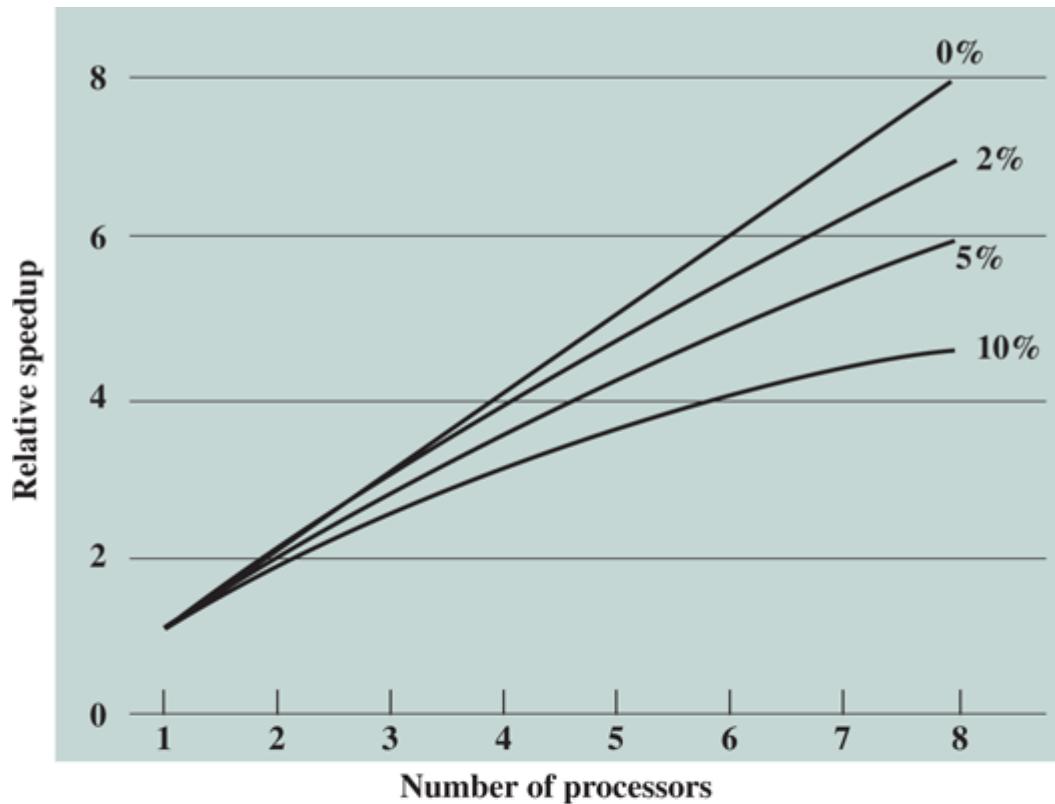

Software on Multicore

The potential performance benefits of a multicore organization depend on the ability to effectively exploit the parallel resources available to the application. Let us focus first on a single application running on a multicore system. Recall from [Chapter 2](#) that Amdahl's law states that:

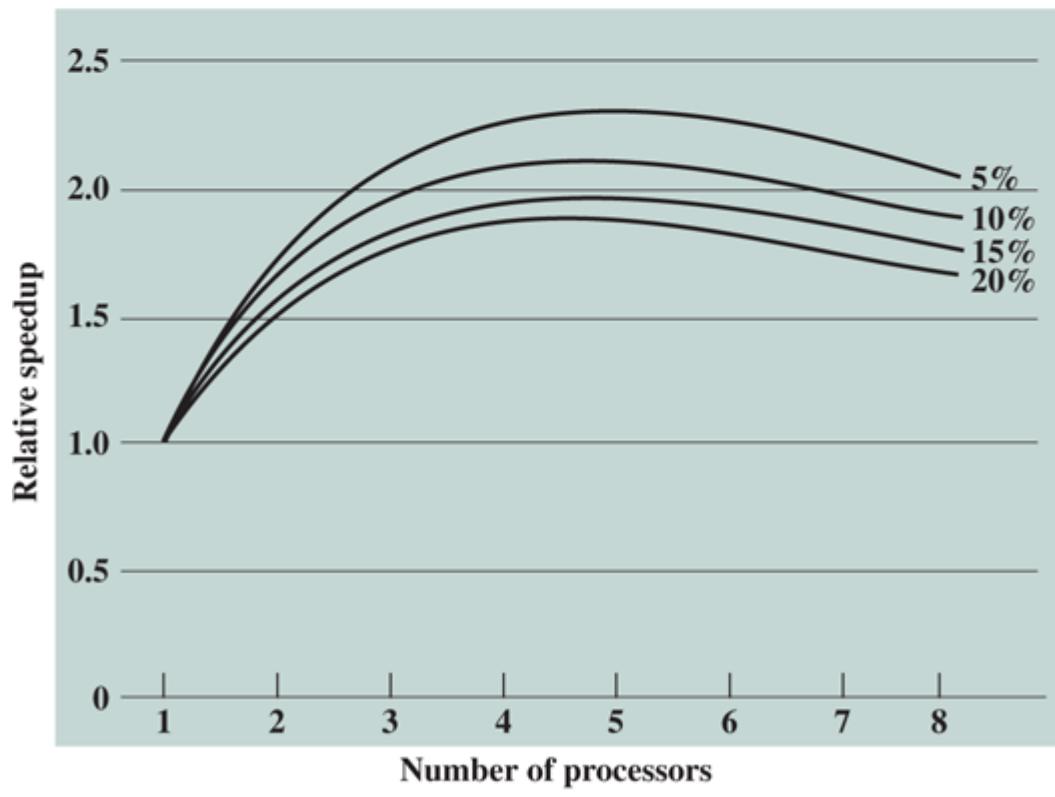

$$\begin{aligned} \text{Speed up} &= \frac{\text{time to execute program on a single processor}}{\cancel{\text{time to execute program on } N \text{ parallel processors}}} \\ &= \frac{1}{(1 - f) + \frac{f}{N}} \end{aligned} \tag{21.1}$$

The law assumes a program in which a fraction $(1 - f)$ of the execution time involves code that is inherently sequential and a fraction f that involves code that is infinitely parallelizable with no scheduling overhead.

This law appears to make the prospect of a multicore organization attractive. But as [Figure 21.3a](#) shows, even a small amount of serial code has a noticeable impact. If only 10% of the code is inherently serial ($f=0.9$), running the program on a multicore system with eight processors yields a performance gain of only a factor of 4.7. In addition, software typically incurs overhead as a result of communication and distribution of work among multiple processors, and as a result of cache coherence overhead. This overhead results in a curve where performance peaks and then begins to degrade because of the increased burden of the overhead of using multiple processors (e.g., coordination and OS management). [Figure 21.3b](#), from [MCDO05], is a representative example.

(a) Speedup with 0%, 2%, 5%, and 10% sequential portions

(b) Speedup with overheads

Figure 21.3 Performance Effect of Multiple Cores

However, software engineers have been addressing this problem and there are numerous applications in which it is possible to effectively exploit a multicore system. [MCDO05] analyzes the effectiveness of multicore systems on a set of database applications, in which great attention was paid to reducing the serial fraction within hardware architectures, operating systems, middleware, and the database application software. [Figure 21.4](#) shows the result. As this example shows, database

management systems and database applications are one area in which multicore systems can be used effectively. Many kinds of servers can also effectively use the parallel multicore organization, because servers typically handle numerous relatively independent transactions in parallel.

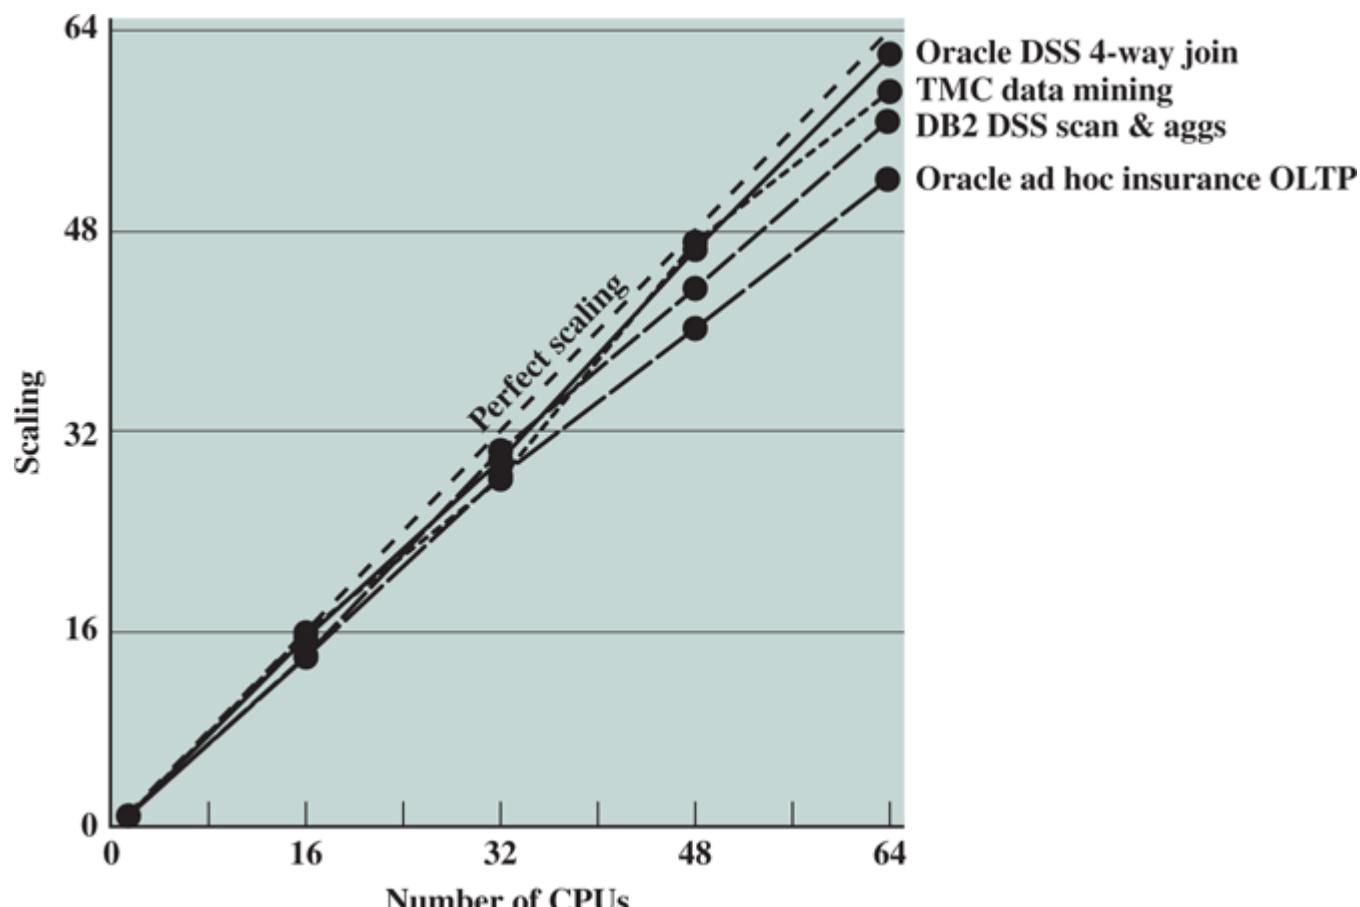

Figure 21.4 Scaling of Database Workloads on Multiple-Processor Hardware

In addition to general-purpose server software, a number of classes of applications benefit directly from the ability to scale throughput with the number of cores. [MCDO06] lists the following examples:

- **Multithreaded native applications (thread-level parallelism):** Multithreaded applications are characterized by having a small number of highly threaded processes.
- **Multiprocess applications (process-level parallelism):** Multiprocess applications are characterized by the presence of many single-threaded processes.
- **Java applications:** Java applications embrace threading in a fundamental way. Not only does the Java language greatly facilitate multithreaded applications, but the Java Virtual Machine is a multithreaded process that provides scheduling and memory management for Java applications.
- **Multi-instance applications (application-level parallelism):** Even if an individual application does not scale to take advantage of a large number of threads, it is still possible to gain from multicore architecture by running multiple instances of the application in parallel. If multiple application instances require some degree of isolation, virtualization technology (for the hardware of the operating system) can be used to provide each of them with its own separate and secure domain.

Before turning to an example, we elaborate on the topic of thread-level parallelism by introducing the concept of **threading granularity**, which can be defined as the minimal unit of work that can be beneficially parallelized. In general, the finer the granularity the system enables, the less constrained is the programmer in parallelizing a program. Consequently, finer grain threading systems allow parallelization in more situations than coarse-grained ones. The choice of the target granularity of an architecture involves an inherent tradeoff. On the one hand, the finer grain systems are preferable

because of the flexibility they afford to the programmer. On the other hand, the finer the threading granularity, the more significant part of the execution is taken by the threading system overhead.

Application Example: Valve Game Software

Valve is an entertainment and technology company that has developed a number of popular games as well as the Source engine, one of the most widely played game engines available. Source is an animation engine used by Valve for its games and licensed to other game developers.

Valve has reprogrammed the Source engine software to use multithreading to exploit the scalability of multicore processor chips from Intel and AMD [REIM06]. The revised Source engine code provides more powerful support for Valve games such as *Half Life 2*.

From Valve's perspective, threading granularity options are defined as follows [HARR06]:

- **Coarse-grained threading:** Individual modules, called systems, are assigned to individual processors. In the Source engine case, this means putting rendering on one processor, AI (artificial intelligence) on another, physics on another, and so on. This is straightforward. In essence, each major module is single threaded and the principal coordination involves synchronizing all the threads with a timeline thread.
- **Fine-grained threading:** Many similar or identical tasks are spread across multiple processors. For example, a loop that iterates over an array of data can be split up into a number of smaller parallel loops in individual threads that can be scheduled in parallel.
- **Hybrid threading:** This involves the selective use of fine-grain threading for some systems and single threading for other systems.

Valve found that through coarse threading, it could achieve up to twice the performance across two processors compared to executing on a single processor. But this performance gain could only be achieved with contrived cases. For real-world gameplay, the improvement was on the order of a factor of 1.2. Valve also found that effective use of fine-grain threading was difficult. The time per work unit can be variable, and managing the timeline of outcomes and consequences involved complex programming.

Valve found that a hybrid threading approach was the most promising and would scale the best as multicore systems with eight or sixteen processors became available. Valve identified systems that operate very effectively when assigned to a single processor permanently. An example is sound mixing, which has little user interaction, is not constrained by the frame configuration of windows, and works on its own set of data. Other modules, such as scene rendering, can be organized into a number of threads so that the module can execute on a single processor but achieve greater performance as it is spread out over more and more processors.

Figure 21.5 illustrates the thread structure for the rendering module. In this hierarchical structure, higher-level threads spawn lower-level threads as needed. The rendering module relies on a critical part of the Source engine, the world list, which is a database representation of the visual elements in the game's world. The first task is to determine what are the areas of the world that need to be rendered. The next task is to determine what objects are in the scene as viewed from multiple angles. Then comes the processor-intensive work. The rendering module has to work out the rendering of each object from multiple points of view, such as the player's view, the view of TV monitors, and the point of view of reflections in water.

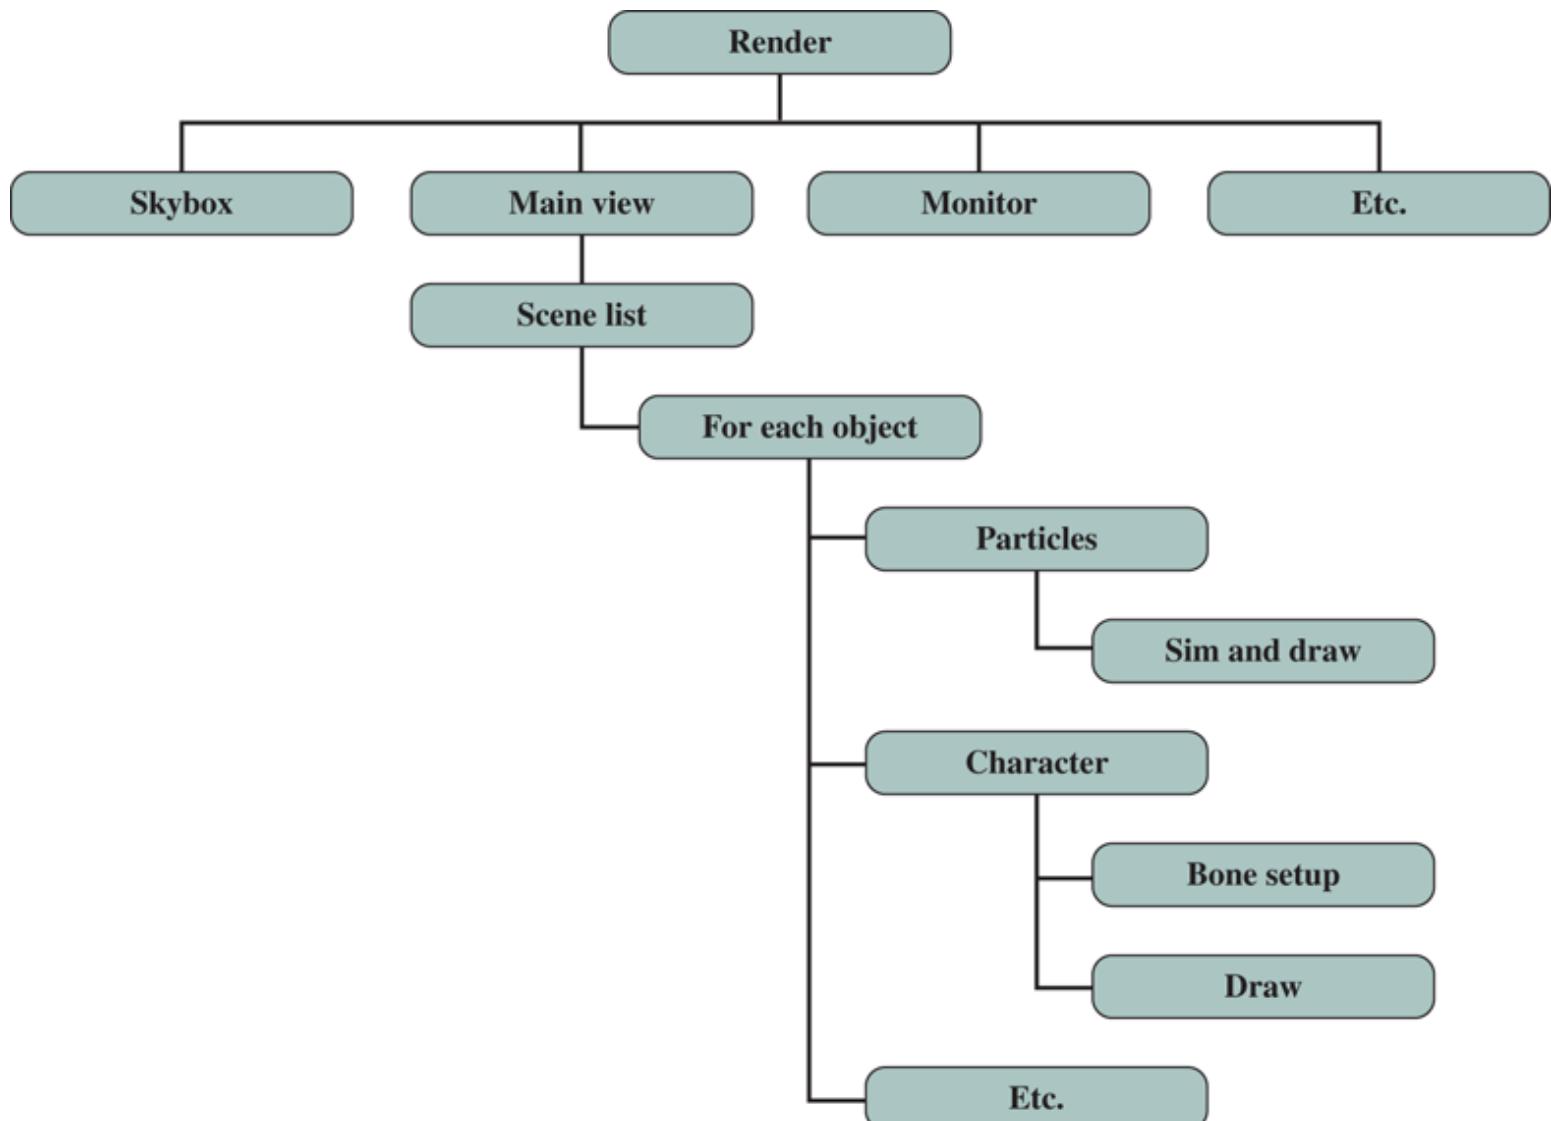

Figure 21.5 Hybrid Threading for Rendering Module

Some of the key elements of the threading strategy for the rendering module are listed in [LEON07] and include the following:

- Construct scene-rendering lists for multiple scenes in parallel (e.g., the world and its reflection in water).
- Overlap graphics simulation.
- Compute character bone transformations for all characters in all scenes in parallel.
- Allow multiple threads to draw in parallel.

The designers found that simply locking key databases, such as the world list, for a thread was too inefficient. Over 95% of the time, a thread is trying to read from a data set, and only 5% of the time at most is spent in writing to a data set. Thus, a concurrency mechanism known as the single-writer-multiple-readers model works effectively.

21.3 Multicore Organization

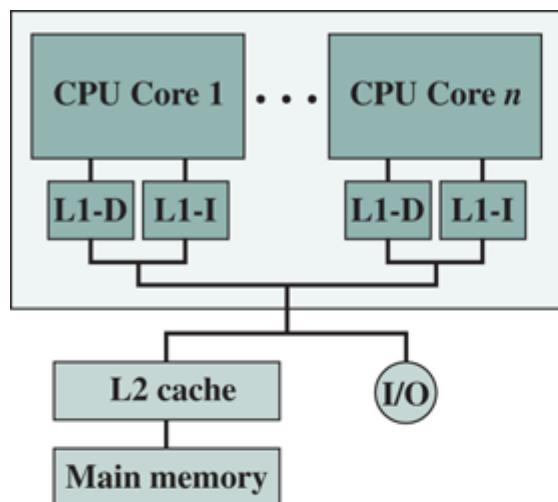

At a top level of description, the main variables in a multicore organization are as follows:

- The number of core processors on the chip
- The number of levels of cache memory
- How cache memory is shared among cores
- Whether simultaneous multithreading (SMT) is employed
- The types of cores

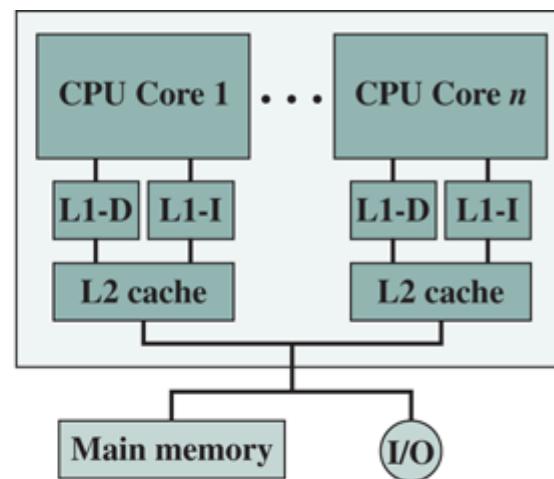

We explore all but the last of these considerations in this section, deferring a discussion of types of cores to the next section.

Levels of Cache

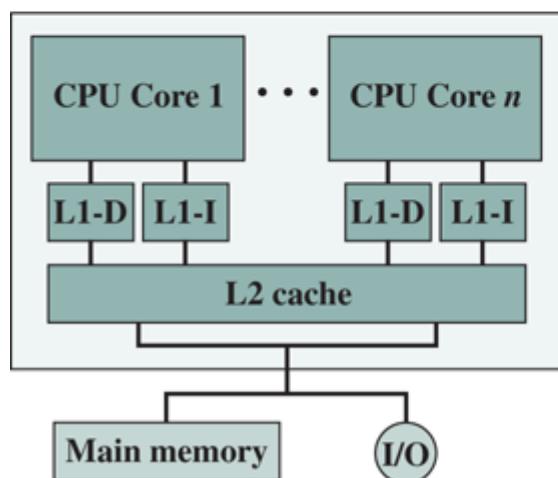

Figure 21.6 shows four general organizations for multicore systems. **Figure 21.6a** is an organization found in some of the earlier multicore computer chips, and is still seen in some embedded chips. In this organization, the only on-chip cache is L1 cache, with each core having its own dedicated L1 cache. Almost invariably, the L1 cache is divided into instruction and data caches for performance reasons, while L2 and higher-level caches are unified. An example of this organization is the ARM11 MPCore.

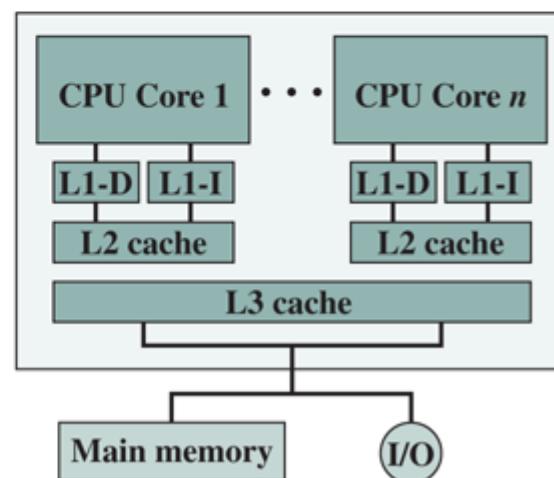

(a) Dedicated L1 cache

(b) Dedicated L2 cache

(c) Shared L2 cache

(d) Shared L3 cache

Figure 21.6 Multicore Organization Alternatives

The organization of **Figure 21.6b** is also one in which there is no on-chip cache sharing. In this, there is enough area available on the chip to allow for L2 cache. An example of this organization is the AMD Opteron. **Figure 21.6c** shows a similar allocation of chip space to memory, but with the use of a shared L2 cache. The Intel Core Duo has this organization. Finally, as the amount of cache memory available on the chip continues to grow, performance considerations dictate splitting off a separate, shared L3 cache (**Figure 21.6d**), with dedicated L1 and L2 caches for each core processor. The Intel Core i7 is an example of this organization.

The use of a shared higher-level cache on the chip has several advantages over exclusive reliance on dedicated caches:

1. Constructive interference can reduce overall miss rates. That is, if a thread on one core accesses a main memory location, this brings the line containing the referenced location into the shared cache. If a thread on another core soon thereafter accesses the same memory block, the memory locations will already be available in the shared on-chip cache.
2. A related advantage is that data shared by multiple cores is not replicated at the shared cache level.
3. With proper line replacement algorithms, the amount of shared cache allocated to each core is

- dynamic, so that threads that have less locality (larger working sets) can employ more cache.
- 4. Inter-core communication is easy to implement, via shared memory locations.
 - 5. The use of a shared higher-level cache confines the cache coherency problem to the lower cache levels, which may provide some additional performance advantage.

A potential advantage to having only dedicated L2 caches on the chip is that each core enjoys more rapid access to its private L2 cache. This is advantageous for threads that exhibit strong locality.

As both the amount of memory available and the number of cores grow, the use of a shared L3 cache combined with dedicated percore L2 caches in [Figure 21.6d](#) seems likely to provide better performance than simply a massive shared L2 cache or very large dedicated L2 caches with no on-chip L3. An example of this latter arrangement is the Xeon E5-2600/4600 chip processor ([Figure 8.16](#)).

Simultaneous Multithreading

Another organizational design decision in a multicore system is whether the individual cores will implement **simultaneous multithreading (SMT)**. For example, the Intel Core Duo uses pure superscalar cores, whereas the Intel Core i7 uses SMT cores. SMT has the effect of scaling up the number of hardware-level threads that the multicore system supports. Thus, a multicore system with four cores and SMT that supports four simultaneous threads in each core appears the same to the application level as a multicore system with 16 cores. As software is developed to more fully exploit parallel resources, an SMT approach appears to be more attractive than a purely superscalar approach.

21.4 Heterogeneous Multicore Organization

The quest to make optimal use of the silicon real estate on a processor chip is never ending. As clock speeds and logic densities increase, designers must balance many design elements in their attempts to maximize performance and minimize power consumption. We have so far examined a number of such approaches, including the following:

1. Increase the percentage of the chip devoted to cache memory.
2. Increase the number of levels of cache memory.
3. Change the length (increase or decrease) and functional components of the instruction pipeline.
4. Employ simultaneous multithreading.
5. Use multiple cores.

A typical case for the use of multiple cores is a chip with multiple identical cores, known as **homogenous multicore organization**. To achieve better results, in terms of performance and/or power consumption, an increasingly popular design choice is **heterogeneous multicore organization**, which refers to a processor chip that includes more than one kind of core. In this section, we look at two approaches to heterogeneous multicore organization.

Different Instruction Set Architectures

The approach that has received the most industry attention is the use of cores that have distinct ISAs. Typically, this involves mixing conventional cores, referred to in this context as CPUs, with specialized cores optimized for certain types of data or applications. Most often, the additional cores are optimized to deal with vector and matrix data processing.

CPU/GPU MULTICORE

The most prominent trend in terms of heterogeneous multicore design is the use of both CPUs and graphics processing units (GPUs) on the same chip. Briefly, GPUs are characterized by the ability to support thousands of parallel execution threads. Thus, GPUs are well matched to applications that process large amounts of vector and matrix data. Initially aimed at improving the performance of graphics applications, thanks to easy-to-adopt programming models such as CUDA (Compute Unified Device Architecture), these new processors are increasingly being applied to improve the performance of general-purpose and scientific applications that involve large numbers of repetitive operations on structured data.

To deal with the diversity of target applications in today's computing environment, multicore containing both GPUs and CPUs has the potential to enhance performance. This heterogeneous mix, however, presents issues of coordination and correctness.

Figure 21.7 is a typical multicore processor organization. Multiple CPUs and GPUs share on-chip resources, such as the last-level cache (LLC), interconnection network, and memory controllers. Most critical is the way in which cache management policies provide effective sharing of the LLC. The differences in cache sensitivity and memory access rate between CPUs and GPUs create significant challenges to the efficient sharing of the LLC.

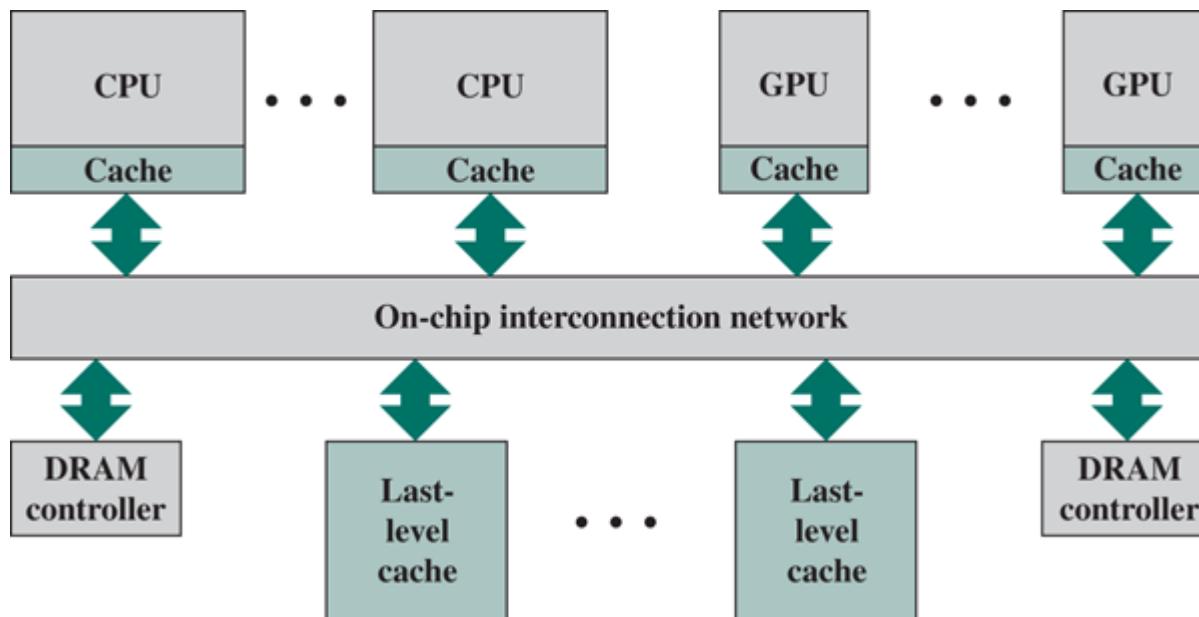

Figure 21.7 Heterogenous Multicore Chip Elements

Table 21.1 illustrates the potential performance benefit of combining CPUs and GPUs for scientific applications. This table shows the basic operating parameters of an AMD chip, the A10 5800K [ALTS12]. For floating-point calculations, the CPU's performance at 121.6 GFLOPS is dwarfed by the GPU, which offers 614 GFLOPS to applications that can utilize the resource effectively.

Table 21.1 Operating Parameters of AMD 5100K Heterogeneous Multicore Processor

FLOPS=floating-point operations per second.

FLOPS / core = number of parallel floating-point operations that can be performed.

	CPU	GPU
Clock frequency (GHz)	3.8	0.8
Cores	4	384
FLOPS/core	8	2
GFLOPS	121.6	614.4

Whether it is scientific applications or traditional graphics processing, the key to leveraging the added GPU processors is to consider the time needed to transfer a block of data to the GPU, process it, then return the results to the main application thread. In earlier implementations of chips that incorporated GPUs, physical memory is partitioned between CPU and GPU. If an application thread is running on a CPU that demands GPU processing, the CPU explicitly copies the data to the GPU memory. The GPU completes the computation and then copies the result back to CPU memory. Issues of cache coherence across CPU and GPU memory caches do not arise because the memory is partitioned. On the other hand, the physical handing of data back and forth results in a performance penalty.

A number of research and development efforts are underway to improve performance over that described in the preceding paragraph, of which the most notable is the initiative by the Heterogeneous System Architecture (HSA) Foundation. Key features of the HSA approach include the following:

1. The entire virtual memory space is visible to both CPU and GPU. Both CPU and GPU can access and allocate any location in the system's virtual memory space.
2. The virtual memory system brings in pages to physical main memory as needed.
3. A coherent memory policy ensures that CPU and GPU caches both see an up-to-date view of data.
4. A unified programming interface that enables users to exploit the parallel capabilities of the GPUs within programs that rely on CPU execution as well.

The overall objective is to allow programmers to write applications that exploit the serial power of CPUs and the parallel-processing power of GPUs seamlessly with efficient coordination at the OS and hardware level. As mentioned, this is an ongoing area of research and development.

CPU/DSP MULTICORE

Another common example of a heterogeneous multicore chip is a mixture of CPUs and digital signal processors (DSPs). A DSP provides ultra-fast instruction sequences (shift and add; multiply and add), which are commonly used in math-intensive digital signal processing applications. DSPs are used to process analog data from sources such as sound, weather satellites, and earthquake monitors. Signals are converted into digital data and analyzed using various algorithms such as Fast Fourier Transform. DSP cores are widely used in myriad devices, including cellphones, sound cards, fax machines, modems, hard disks, and digital TVs.

As a good representative example, **Figure 21.8** shows a recent version of Texas Instruments (TI) K2H SoC platform [TI12]. This heterogeneous multicore processor delivers power-efficient processing solutions for high-end imaging applications. TI lists the performance as delivering up to 352 GMACS, 198 GFLOPS, and 19,600 MIPS. GMACS stands for giga (billions of) multiply-accumulate operations per second, a common measure of DSP performance. Target applications for these systems include industrial automation, video surveillance, high-end inspection systems, industrial printers/scanners, and currency/counterfeit detection.

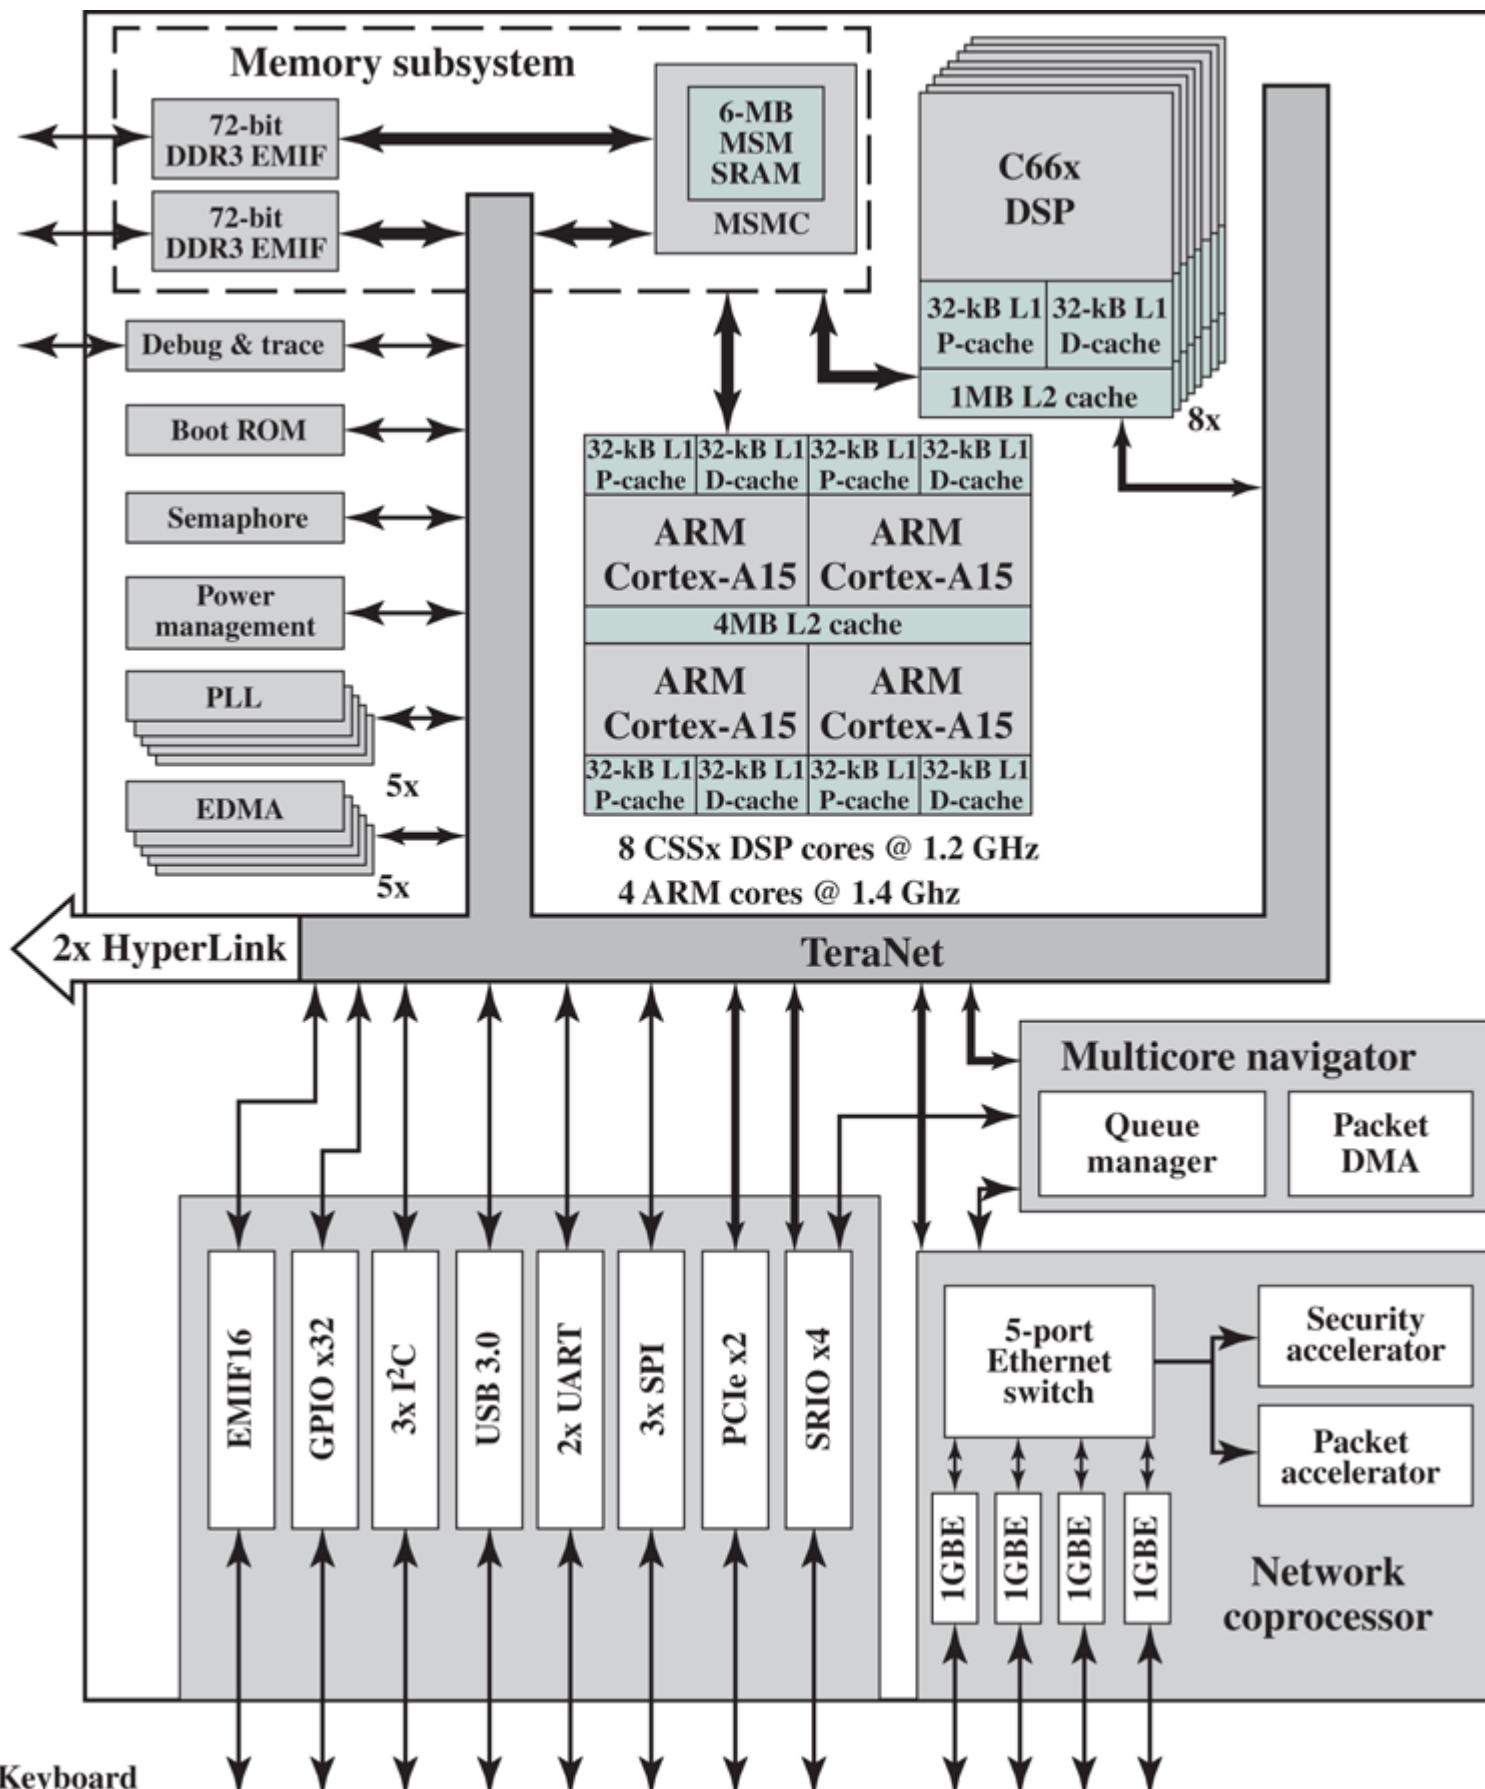

Figure 21.8 Texas Instruments 66AK2H12 Heterogenous Multicore Chip

The TI chip includes four ARM Cortex-A15 cores and eight TI C66x DSP cores.

Each DSP core contains 32 kB of L1 data cache and 32 kB of L1 program (instruction) cache. In addition, each DSP has 1 MB of dedicated SRAM memory that can be configured as all L2 cache, all

main memory, or a mix of the two. The portion configured as main memory functions as a “local” main memory, referred to simply as *SRAM*. This local main memory can be used for temporary data, avoiding the need for traffic between cache and off-chip memory. The L2 cache of each of the eight DSP cores is dedicated rather than shared with the other DSP cores. This is typical for a multicore DSP organization: Each DSP works on a separate block of data in parallel, so there is little need for data sharing.

Each ARM Cortex-A15 CPU core has 32-kB L1 data and program caches, and the four cores share a 4-MB L2 cache.

The 6-MB multicore shared memory (MSM) is always configured as all SRAM. That is, it behaves like main memory rather than cache. It can be configured to feed directly the L1 DSP and CPU caches, or to feed the L2 DSP and CPU caches. This configuration decision depends on the expected application profile. The multicore shared memory controller (MSMC) manages traffic among ARM cores, DSP, DMA, other mastering peripherals, and the external memory interface (EMIF). MSMC controls access to the MSM, which is accessible by all the cores and the mastering peripherals on the device.

Equivalent Instruction Set Architectures

Another recent approach to heterogeneous multicore organization is the use of multiple cores that have equivalent ISAs but vary in performance or power efficiency. The leading example of this is ARM’s big.Little architecture, which we examine in this section.

Figure 21.9 illustrates this architecture. The figure shows a multicore processor chip containing two high-performance Cortex-A15 cores and two lower-performance, lower-power-consuming Cortex-A7 cores. The A7 cores handle less computation-intense tasks, such as background processing, playing music, sending texts, and making phone calls. The A15 cores are invoked for high intensity tasks, such as for video, gaming, and navigation.

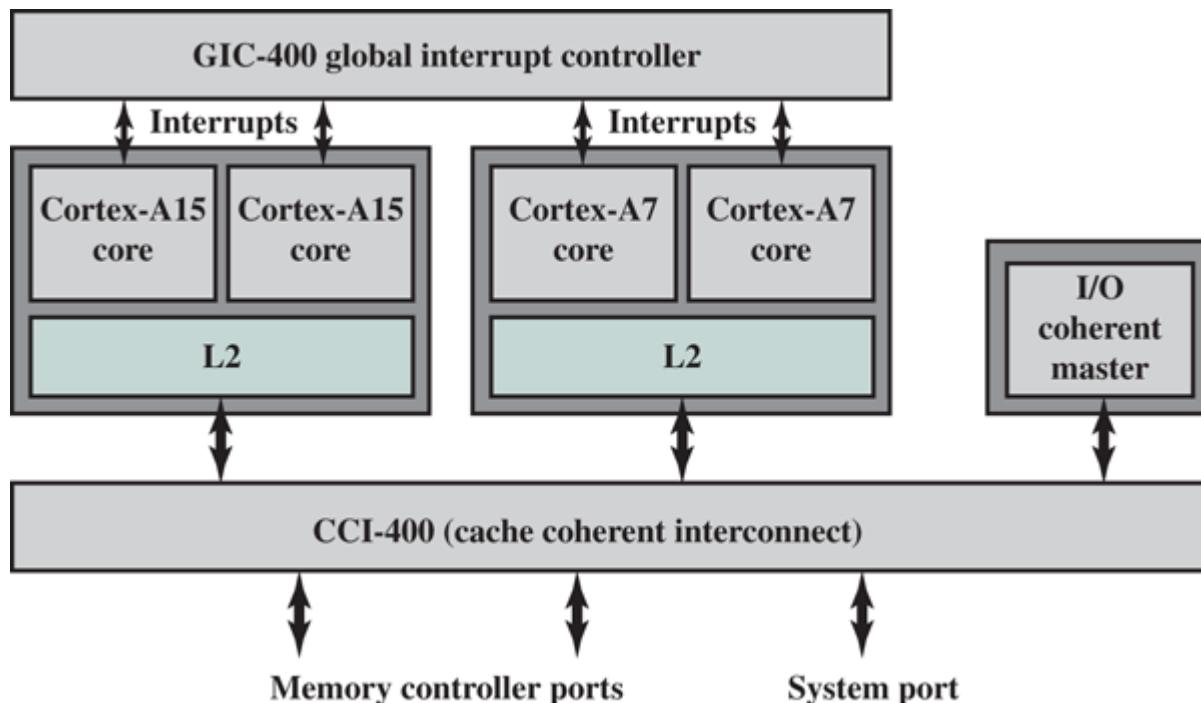

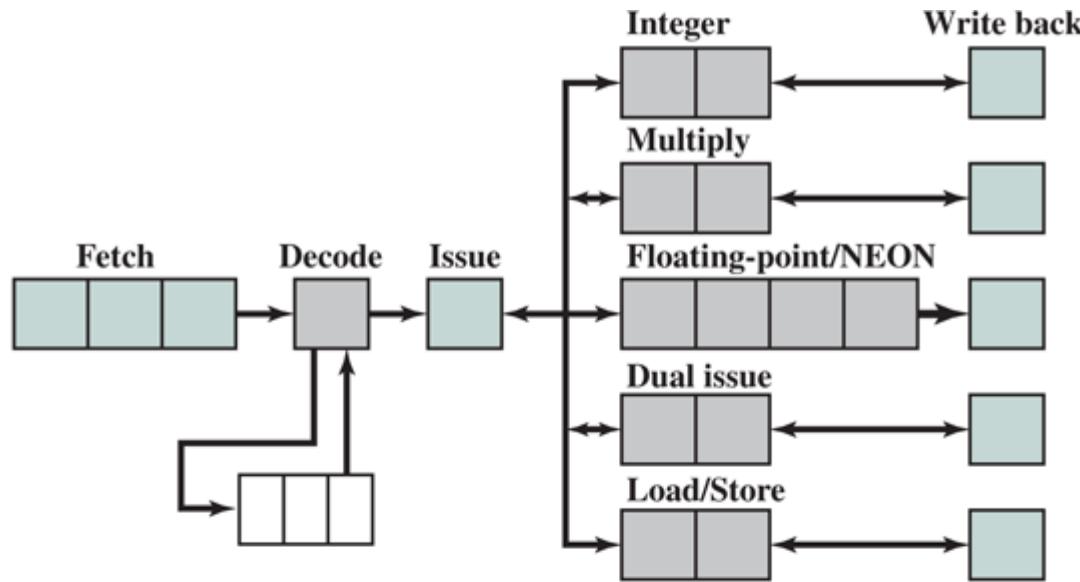

Figure 21.9 big.Little Chip Components

The big.Little architecture is aimed at the smartphone and tablet market. These are devices whose performance demands from users are increasing at a much faster rate than the capacity of batteries or

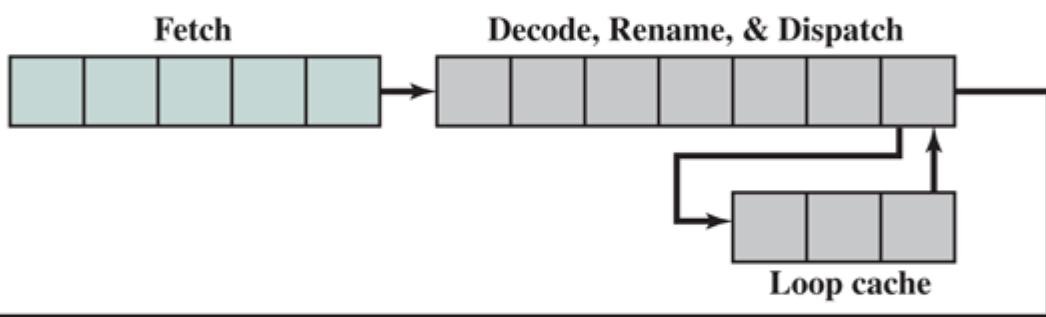

the power savings from semiconductor process advances. The usage pattern for smartphones and tablets is quite dynamic. Periods of processing-intense tasks, such as gaming and web browsing, alternate with typically longer periods of low processing-intensity tasks, such as texting, e-mail, and audio. The big.Little architecture takes advantage of this variation in required performance. The A15 is designed for maximum performance within the mobile power budget. The A7 processor is designed for maximum efficiency and high enough performance to address all but the most intense periods of work.

A7 AND A15 CHARACTERISTICS

The A7 is far simpler and less powerful than the A15. But its simplicity requires far fewer transistors than does the A15's complexity—and fewer transistors require less energy to operate. The differences between the A7 and A15 cores are seen most clearly by examining their instruction pipelines, as shown in [Figure 21.10](#).

(a) Cortex A-7 Pipeline

(b) Cortex A-15 Pipeline

Figure 21.10 Cortex A-7 and A-15 Pipelines

The A7 is an in-order CPU with a pipeline length of 8 to 10 stages. It has a single queue for all of its execution units, and two instructions can be sent to its five execution units per clock cycle. The A15, on the other hand, is an out-of-order processor with a pipeline length of 15 to 24 stages. Each of its eight execution units has its own multistage queue, and three instructions can be processed per clock cycle.

The energy consumed by the execution of an instruction is partially related to the number of pipeline stages it must traverse. Therefore, a significant difference in energy consumption between Cortex-A15 and Cortex-A7 comes from the different pipeline complexity. Across a range of benchmarks, the Cortex-A15 delivers roughly twice the performance of the Cortex-A7 per unit MHz, and the Cortex-A7 is roughly three times as energy efficient as the Cortex-A15 in completing the same workloads [JEFF12]. The performance tradeoff is illustrated in [Figure 21.11](#) [STEV13].

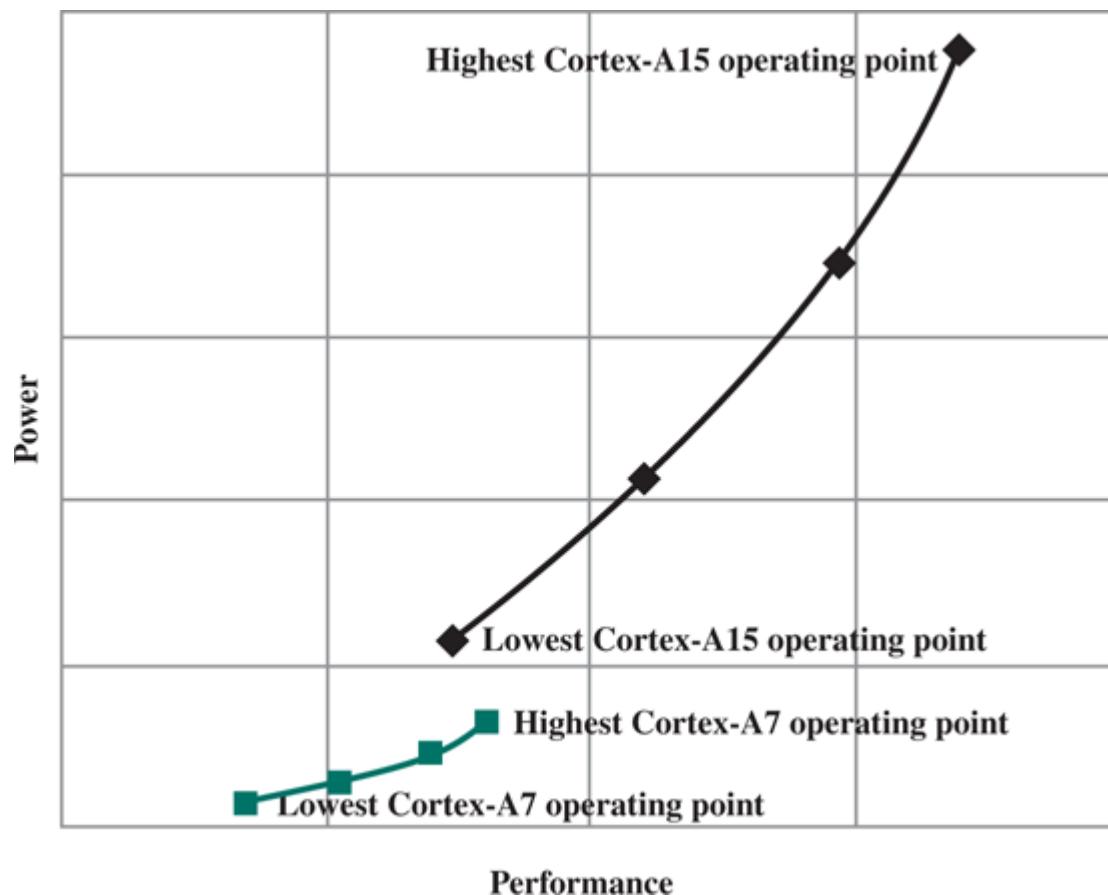

Figure 21.11 Cortex-A7 and A15 Performance Comparison

SOFTWARE PROCESSING MODELS

The big.Little architecture can be configured to use one of two software processing models: migration and multiprocessing (MP). The software models differ mainly in the way they allocate work to big or Little cores during runtime execution of a workload.

In the migration model, big and Little cores are paired. To the OS kernel scheduler, each big/Little pair is visible as a single core. Power management software is responsible for migrating software contexts between the two cores. This model is a natural extension of the dynamic voltage and frequency scaling (DVFS) operating points provided by current mobile platforms to allow the OS to match the performance of the platform to the performance required by the application. In today's smartphone SoCs, DVFS drivers like `cpu_freq` sample the OS performance at regular and frequent intervals, and the DVFS governor decides whether to shift to a higher or lower operating point or remain at the current operating point. As shown in [Figure 21.11](#), both the A7 and the A15 can execute at four distinct operating points. The DVFS software can effectively dial in to one of the operating points on the curve, setting a specific CPU clock frequency and voltage level.

These operating points affect the voltage and frequency of a single CPU cluster; however, in a big.Little system there are two CPU clusters with independent voltage and frequency domains. This allows the big cluster to act as a logical extension of the DVFS operating points provided by the Little

processor cluster. In a big.Little system under a migration mode of control, when Cortex-A7 is executing, the DVFS driver can tune the performance of the CPU cluster to higher levels. Once Cortex-A7 is at its highest operating point, if more performance is required, a task migration can be invoked that picks up the OS and applications and moves them to the Cortex-A15. In today's smartphone SoCs, DVFS drivers like `cpu_freq` sample the OS performance at regular and frequent intervals, and the DVFS governor decides whether to shift to a higher or lower operating point or remain at the current operating point.

The migration model is simple but requires that one of the CPUs in each pair is always idle. The MP model allows any mixture of A15 and A7 cores to be powered on and executing simultaneously. Whether a big processor needs to be powered on is determined by performance requirements of tasks currently executing. If there are demanding tasks, then a big processor can be powered on to execute them. Low demand tasks can execute on a Little processor. Finally, any processors that are not being used can be powered down. This ensures that cores, big or Little, are only active when they are needed, and that the appropriate core is used to execute any given workload.

The MP model is somewhat more complicated to implement but is also more efficient in its use of resources. It assigns tasks appropriately and enables more cores to be running simultaneously when the demand warrants it.

Cache Coherence and the MOESI Model

Typically, a heterogeneous multicore processor will feature dedicated L2 cache assigned to the different processor types. We see this in the general depiction of a CPU/GPU scheme in [Figure 21.7](#). Because the CPU and GPU are engaged in quite different tasks, it makes sense that each has its own L2 cache, shared among the similar CPUs. We also see this in the big.Little architecture ([Figure 21.9](#)), in which the A7 cores share an L2 cache and the A15 cores share a separate L2 cache.

When multiple caches exist, there is a need for a cache-coherence scheme to avoid access to invalid data. Cache coherency may be addressed with software-based techniques. In the case where the cache contains stale data, the cached copy may be invalidated and reread from memory when needed again. When memory contains stale data due to a write-back cache containing dirty data, the cache may be cleaned by forcing write back to memory. Any other cached copies that may exist in other caches must be invalidated. This software burden consumes too many resources in a SoC chip, leading to the use of hardware cache-coherent implementations, especially in heterogeneous multicore processors.

As described in [Chapter 20](#), there are two main approaches to hardware-implemented cache coherence: directory protocols and snoopy protocols. ARM has developed a hardware coherence capability called ACE (Advanced Extensible Interface Coherence Extensions) that can be configured to implement either the directory or the snoopy approach, or even a combination. ACE has been designed to support a wide range of coherent masters with differing capabilities. ACE supports coherency between dissimilar processors such as the Cortex-A15 and Cortex-A7 processors, enabling ARM big.Little technology. It supports I/O coherency for un-cached masters, supports masters with differing cache line sizes, differing internal cache state models, and masters with write-back or write-through caches. As another example, ACE is implemented in the memory subsystem memory controller (MSMC) in the TI SoC chip of [Figure 21.8](#). MSMC supports hardware cache coherence between the ARM CorePac L1/L2 caches and EDMA/IO peripherals for shared SRAM and DDR spaces. This feature allows the sharing of MSMC SRAM and DDR data spaces by these masters on the chip, without having to use explicit software cache maintenance techniques.

ACE makes use of a five-state cache model. In each cache, each line is either Valid or Invalid. If a line

is Valid, it can be in one of four states, defined by two dimensions. A line may contain data that are Shared or Unique. A Shared line contains data from a region of external (main) memory that is potentially sharable. A Unique line contains data from a region of memory that is dedicated to the core owning this cache. And the line is either Clean or Dirty, generally meaning either memory contains the latest, most up-to-date data and the cache line is merely a copy of memory, or if it's Dirty then the cache line is the latest, most up-to-date data and it must be written back to memory at some stage. The one exception to the above description is when multiple caches share a line and it's Dirty. In this case, all caches must contain the latest data value at all times, but only one may be in the Shared/Dirty state, the others being held in the Shared/Clean state. The Shared/Dirty state is thus used to indicate which cache has responsibility for writing the data back to memory, and Shared/Clean is more accurately described as meaning data is shared but there is no need to write it back to memory.

The ACE states correspond to a cache coherency model with five states, known as MOESI ([Figure 21.12](#)). [Table 21.2](#) compares the MOESI model with the MESI model described in [Chapter 20](#).

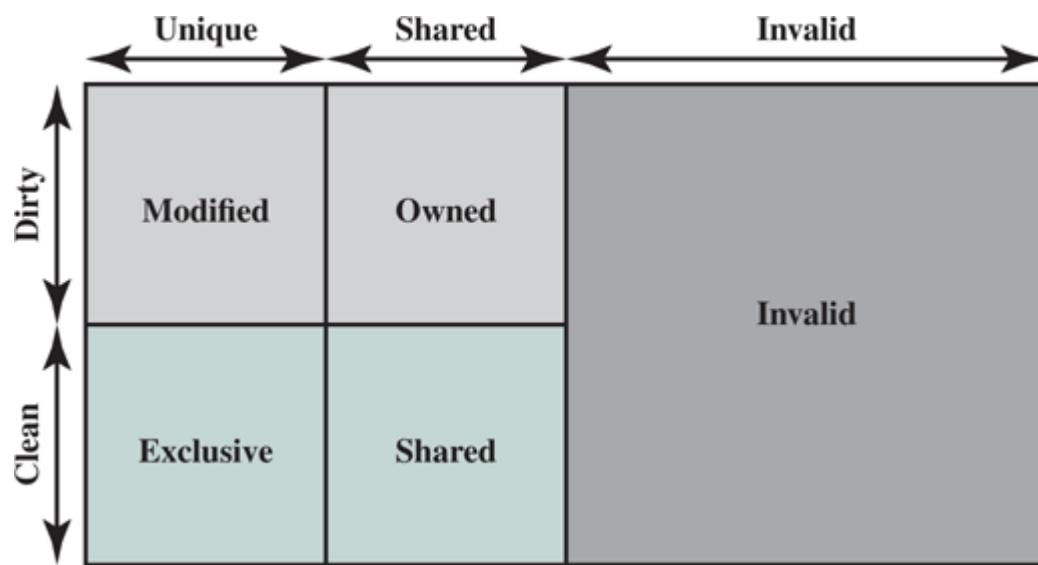

Figure 21.12 ARM ACE Cache Line States

Table 21.2 Comparison of States in Snoop Protocols

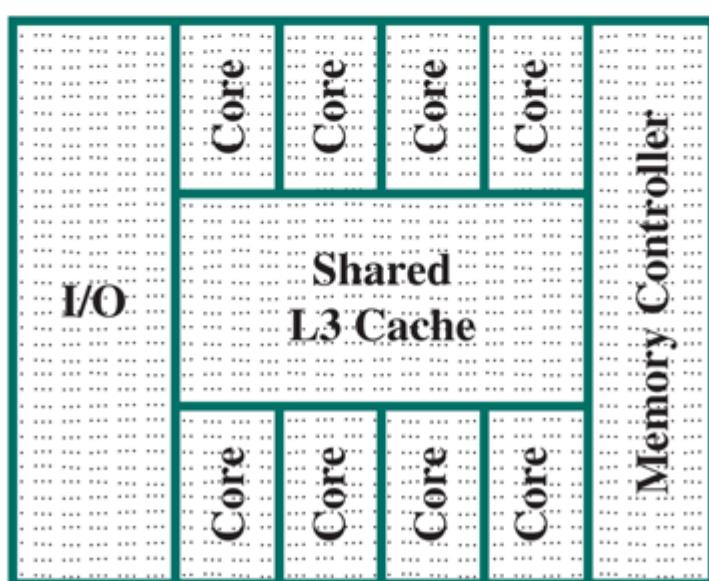

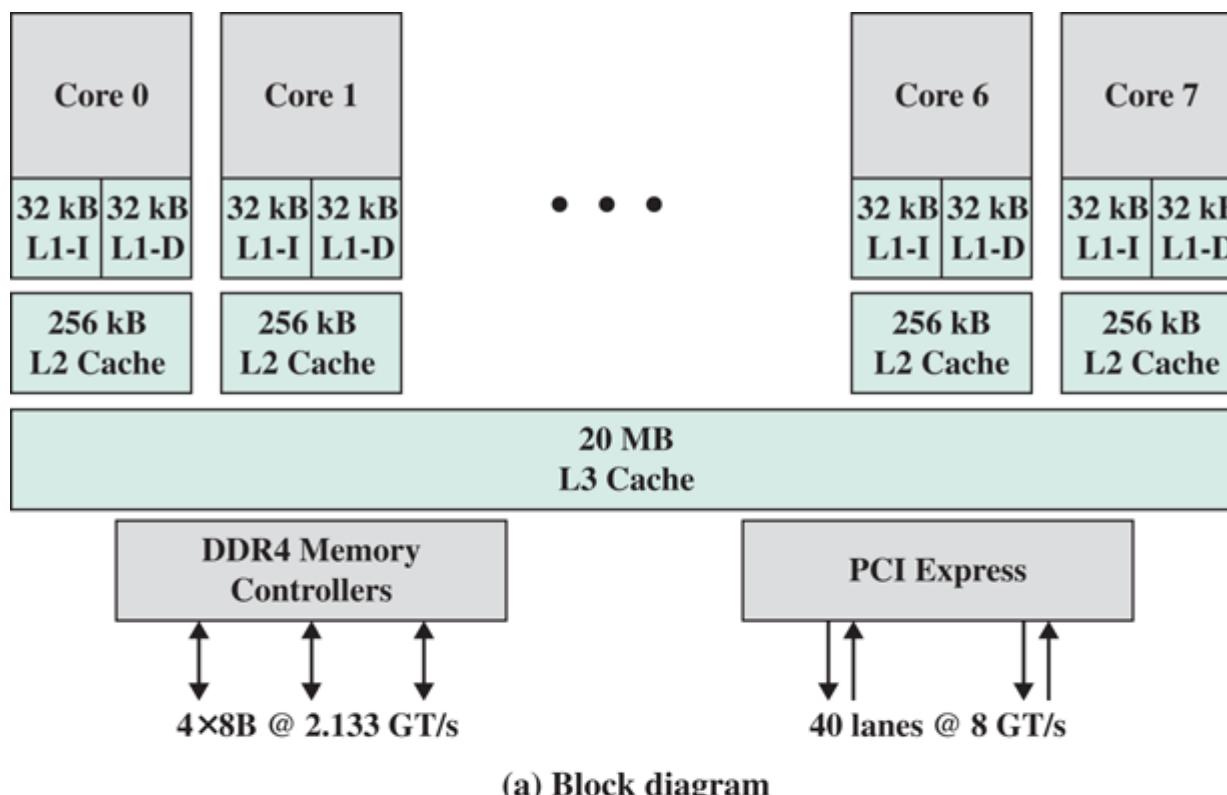

(a) MESIM				
	Modified	Exclusive	Shared	Invalid
Clean/Dirty	Dirty	Clean	Clean	N/A
Unique?	Yes	Yes	No	N/A
Can write?	Yes	Yes	No	N/A
Can forward?	Yes	Yes	Yes	N/A
Comments	Must write back to share or replace	Transitions to M on write	Shared implies clean, can forward	Cannot read

(b) MOESI					
	Modified	Owned	Exclusive	Shared	Invalid
Clean/Dirty	Dirty	Dirty	Clean	Either	N/A
Unique?	Yes	Yes	Yes	No	N/A
Can write?	Yes	Yes	Yes	No	N/A
Can forward?	Yes	Yes	Yes	No	N/A
Comments	Can share without write back	Must write back to transition	Transitions to M on write	Shared, can be dirty or clean	Cannot read

21.5 INTEL Core i7-5960X

Intel has introduced a number of multicore products in recent years. In this section, we look at the Intel Core i7-5960X.

The general structure of the Intel Core i7-5960X is shown in [Figure 21.13](#). Each core has its own **dedicated L2 cache** and the eight cores share a 20-MB **L3 cache**. One mechanism Intel uses to make its caches more effective is prefetching, in which the hardware examines memory access patterns and attempts to fill the caches speculatively with data that's likely to be requested soon.

(b) Physical layout on chip

Figure 21.13 Intel Core i7-5960X Block Diagram

The Core i7-5960X chip supports two forms of external communications to other chips. The **DDR4 memory controller** brings the memory controller for the DDR main memory¹ onto the chip. The interface supports four channels that are 8 bytes wide for a total bus width of 256 bits, for an aggregate data rate of up to 64 GB/s. With the memory controller on the chip, the Front Side Bus is eliminated.

¹ The DDR synchronous RAM memory is discussed in [Chapter 6](#).

The **PCI Express** is a peripheral bus. It enables high-speed communications among connected processor chips. The PCI Express link operates at 8 GT/s (transfers per second). At 40 bits per transfer, that adds up to 40 GB/s.

21.6 ARM Cortex-A15 MPCore

We have already seen two examples of heterogeneous multicore processors using ARM cores, in [Section 21.4](#): the big.Little architecture, which uses a combination of ARM Cortex-A7 and Cortex-A15 cores; and the Texas Instruments DSP SoC architecture, which combines Cortex-A15 cores with TI DSP cores. In this section, we introduce the Cortex-A15 MPCore multicore chip, which is a homogeneous multicore processor using multiple A15 cores. The A15 MPCore is a high-performance chip targeted at applications including mobile computing, high-end digital home servers, and wireless infrastructure.

[Figure 21.14](#) presents a block diagram of the Cortex-A15 MPCore. The key elements of the system are as follows:

- **Generic interrupt controller (GIC):** Handles interrupt detection and interrupt prioritization. The GIC distributes interrupts to individual cores.
- **Debug unit and interface:** The debug unit enables an external debug host to: stop program execution; examine and alter process and coprocessor state; examine and alter memory and input/output peripheral state; and restart the processor.
- **Generic timer:** Each core has its own private timer that can generate interrupts.
- **Trace:** Supports performance monitoring and program trace tools.
- **Core:** A single ARM Cortex-15 core.
- **L1 cache:** Each core has its own dedicated L1 data cache and L1 instruction cache.
- **L2 cache:** The shared L2 memory system services L1 instruction and data cache misses from each core.
- **Snoop control unit (SCU):** Responsible for maintaining L1/L2 cache coherency.

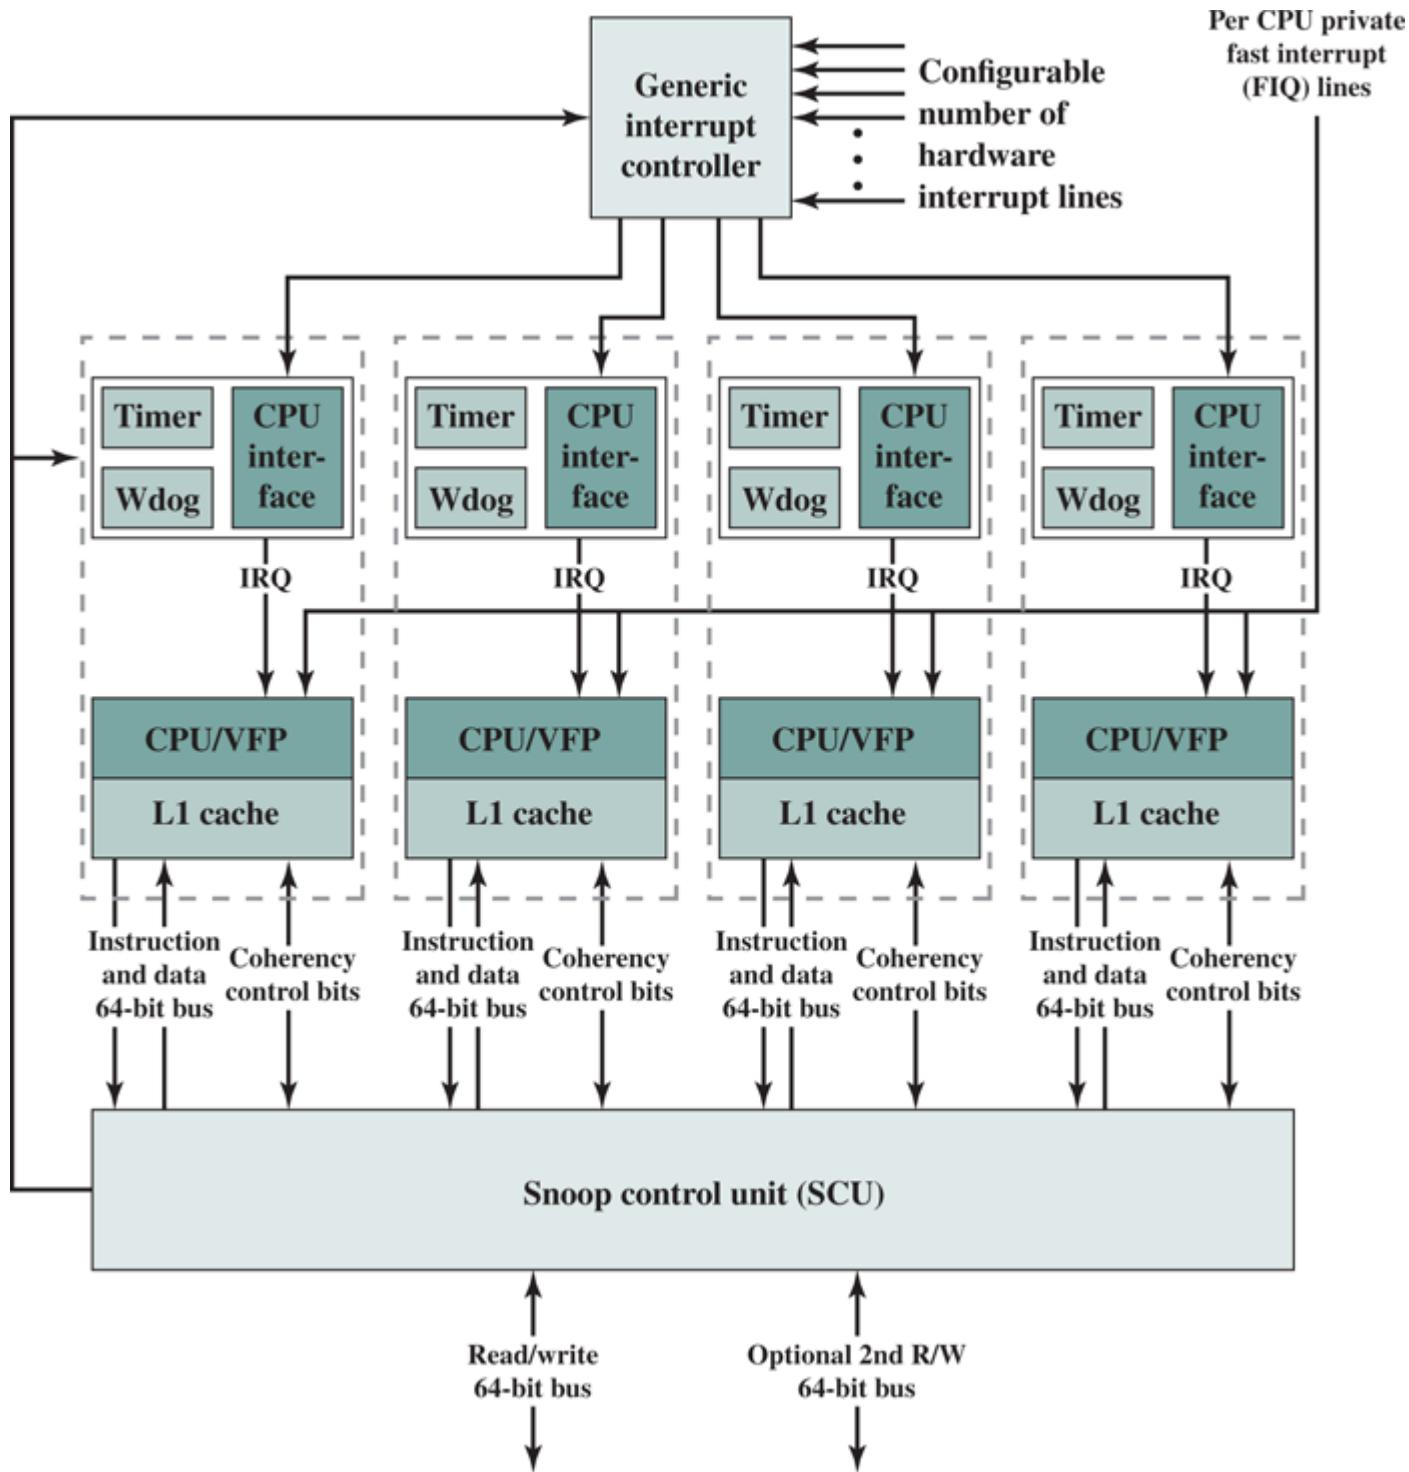

Figure 21.14 ARM Cortex-A15 MPCore Chip Block Diagram

Interrupt Handling

The GIC collates interrupts from a large number of sources. It provides:

- Masking of interrupts
- Prioritization of the interrupts
- Distribution of the interrupts to the target A15 cores
- Tracking the status of interrupts
- Generation of interrupts by software

The GIC is a single functional unit that is placed in the system alongside A15 cores. This enables the number of interrupts supported in the system to be independent of the A15 core design. The GIC is memory mapped; that is, control registers for the GIC are defined relative to a main memory base

address. The GIC is accessed by the A15 cores using a private interface through the SCU.

The GIC is designed to satisfy two functional requirements:

- Provide a means of routing an interrupt request to a single CPU or multiple CPUs, as required.
- Provide a means of interprocessor communication so that a thread on one CPU can cause activity by a thread on another CPU.

As an example that makes use of both requirements, consider a multithreaded application that has threads running on multiple processors. Suppose the application allocates some virtual memory. To maintain consistency, the operating system must update memory translation tables on all processors. The OS could update the tables on the processor where the virtual memory allocation took place, and then issue an interrupt to all the other processors running this application. The other processors could then use this interrupt's ID to determine that they need to update their memory translation tables.

The GIC can route an interrupt to one or more CPUs in the following three ways:

- An interrupt can be directed to a specific processor only.
- An interrupt can be directed to a defined group of processors. The MPCore views the first processor to accept the interrupt, typically the least loaded, as being best positioned to handle the interrupt.
- An interrupt can be directed to all processors.

From the point of view of software running on a particular CPU, the OS can generate an interrupt to all but self, to self, or to specific other CPUs. For communication between threads running on different CPUs, the interrupt mechanism is typically combined with shared memory for message passing. Thus, when a thread is interrupted by an interprocessor communication interrupt, it reads from the appropriate block of shared memory to retrieve a message from the thread that triggered the interrupt. A total of 16 interrupt IDs per CPU are available for interprocessor communication.

From the point of view of an A15 core, an interrupt can be:

- **Inactive:** An Inactive interrupt is one that is nonasserted, or which in a multiprocessing environment has been completely processed by that CPU but can still be either Pending or Active in some of the CPUs to which it is targeted, and so might not have been cleared at the interrupt source.
- **Pending:** A Pending interrupt is one that has been asserted, and for which processing has not started on that CPU.
- **Active:** An Active interrupt is one that has been started on that CPU, but processing is not complete. An Active interrupt can be pre-empted when a new interrupt of higher priority interrupts A15 core interrupt processing.

Interrupts come from the following sources:

- **Interprocessor interrupts (IPIs):** Each CPU has private interrupts, ID0-ID15, that can only be triggered by software. The priority of an IPI depends on the receiving CPU, not the sending CPU.
- **Private timer and/or watchdog interrupts:** These use interrupt IDs 29 and 30.
- **Legacy FIQ line:** In legacy IRQ mode, the legacy FIQ pin, on a per CPU basis, bypasses the Interrupt Distributor logic and directly drives interrupt requests into the CPU.
- **Hardware interrupts:** Hardware interrupts are triggered by programmable events on associated interrupt input lines. CPUs can support up to 224 interrupt input lines. Hardware interrupts start at ID32.

Figure 21.15 is a block diagram of the GIC. The GIC is configurable to support between 0 and 255 hardware interrupt inputs. The GIC maintains a list of interrupts, showing their priority and status. The Interrupt Distributor transmits to each CPU Interface the highest Pending interrupt for that interface. It receives back the information that the interrupt has been acknowledged, and can then change the

status of the corresponding interrupt. The CPU Interface also transmits End of Interrupt (EOI) information, which enables the Interrupt Distributor to update the status of this interrupt from Active to Inactive.

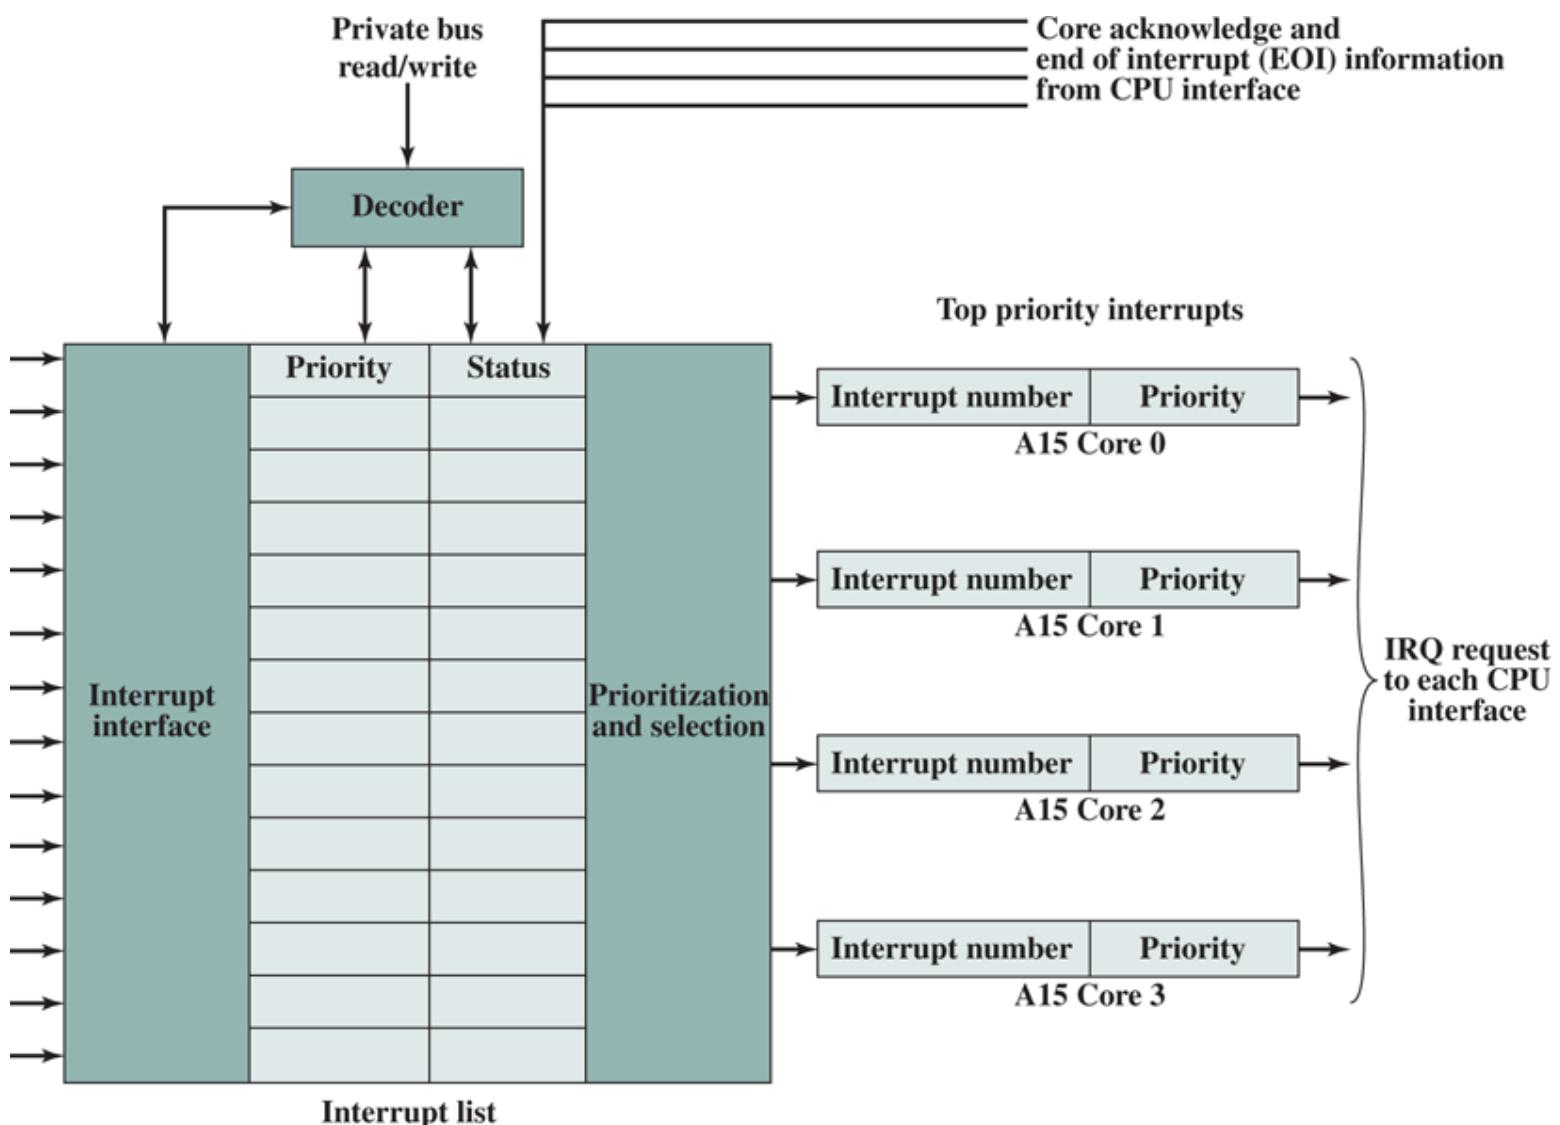

Figure 21.15 Generic Interrupt Controller Block Diagram

Cache Coherency

The MPCore's Snoop Control Unit (SCU) is designed to resolve most of the traditional bottlenecks related to access to shared data and the scalability limitation introduced by coherence traffic.

L1 CACHE COHERENCY

The L1 cache coherency scheme is based on the MESI protocol described in [Chapter 20](#). The SCU monitors operations with shared data to optimize MESI state migration. The SCU introduces three types of optimization: direct data intervention, duplicated tag RAMs, and migratory lines.

Direct data intervention (DDI) enables copying clean data from one CPU L1 data cache to another CPU L1 data cache without accessing external memory. This reduces read after read activity from the Level 1 cache to the Level 2 cache. Thus, a local L1 cache miss is resolved in a remote L1 cache rather than from access to the shared L2 cache.

Recall that main memory location of each line within a cache is identified by a tag for that line. The

tags can be implemented as a separate block of RAM of the same length as the number of lines in the cache. In the SCU, **duplicated tag RAMs** are duplicated versions of L1 tag RAMs used by the SCU to check for data availability before sending coherency commands to the relevant CPUs. Coherency commands are sent only to CPUs that must update their coherent data cache. This reduces the power consumption and performance impact from snooping into and manipulating each processor's cache on each memory update. Having tag data available locally lets the SCU limit cache manipulations to processors that have cache lines in common.

The **migratory lines** feature enables moving dirty data from one CPU to another without writing to L2 and reading the data back in from external memory. The operation can be described as follows. In a typical MESI protocol, when one processor has a modified line and another processor attempts to read that line, the following actions occur:

1. The line contents are transferred from the modified line to the processor that initiated the read.
2. The line contents are written back to main memory.
3. The line is put in the shared state in both caches.

L2 Cache Coherency

The SCU uses hybrid MESI and MOESI protocols to maintain coherency between the individual L1 data caches and the L2 cache. The L2 memory system contains a snoop tag array that is a duplicate copy of each of the L1 data cache directories. The snoop tag array reduces the amount of snoop traffic between the L2 memory system and the L1 memory system. Any line that resides in the snoop tag array in the Modified/Exclusive state belongs to the L1 memory system. Any access that hits against a line in this state must be serviced by the L1 memory system and passed to the L2 memory system. If the line is invalid or in the shared state in the snoop tag array, then the L2 cache can supply the data. The SCU contains buffers that can handle direct cache-to-cache transfers between cores without reading or writing any data on the ACE. Lines can migrate back and forth without any change to the MOESI state of the line in the L2 cache. Shareable transactions on the ACP are also coherent, so the snoop tag arrays are queried as a result of ACP transactions. For reads where the shareable line resides in one of the L1 data caches in the Modified/Exclusive state, the line is transferred from the L1 memory system to the L2 memory system and passed back on the ACP.

21.7 IBM z13 Mainframe

In this section, we look at a mainframe computer organization that uses multicore processor chips. The example we use is the IBM z13 mainframe computer [LASC16, BART15], which began shipping in late 2015. [Section 8.8](#) provides a general overview of the z13, together with a discussion of its I/O structure.

Organization

The principal building block of the z13 is the processor node. Two nodes are connected together with an inter-node S-Bus and housed in a drawer that fits into a slot of the mainframe cabinet. A-Bus interfaces connect these two nodes with nodes in other drawers. A z13 configuration can have up to four drawers.

The key components of a node are shown in [Figure 21.16](#):

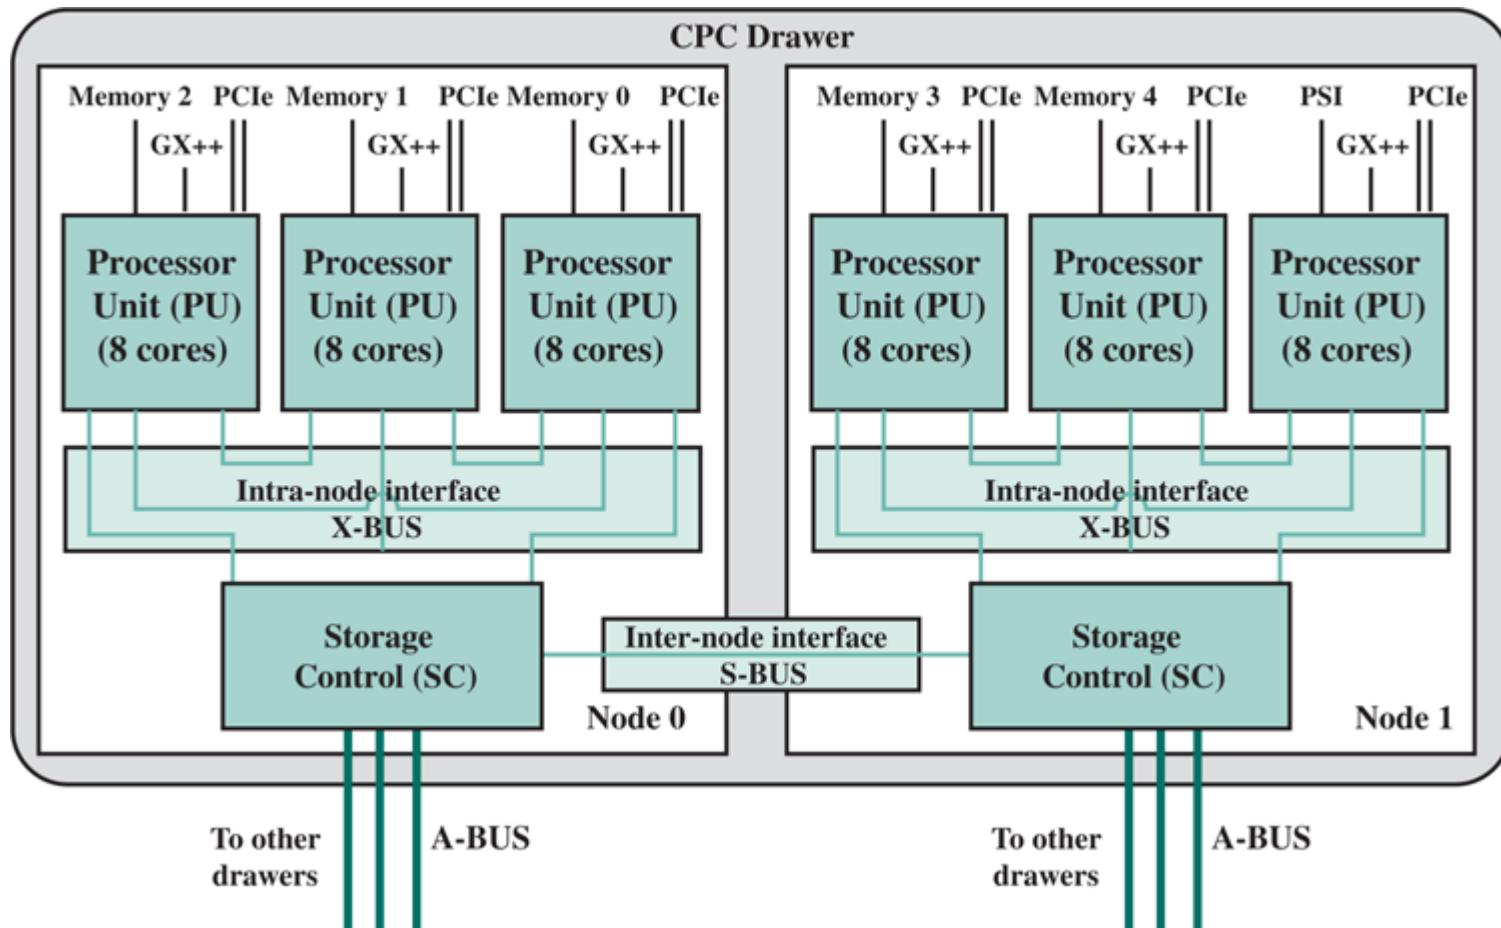

Figure 21.16 IBM z13 Drawer Structure

- **Processor unit (PU):** There are three PU chips, each containing eight 5-GHz processor cores plus three levels of cache. The PUs have external connections to main memory via memory control units and to I/O via host channel adapters. Thus, each node includes 24 cores.
- **Storage control (SC):** The two SC chips contain an additional level of cache (L4) plus interconnection logic for connecting to other nodes.
- **DRAM memory slots:** providing up to 1.28 GB of main memory.
- **PCIe slots:** Slots for connection to PCIe I/O drawers.
- **GX + + :** Slots for connection to InfiniBand.

- **S-Bus:** Connection to other nodes in this drawer.
- **A-Bus:** Connection to other drawers.
- **Processor support interface (PSI):** connects to system control logic.

The microprocessor core features a wide superscalar, out-of-order pipeline that can decode six z/Architecture CISC instructions per clock cycle (< 0.18ns) and execute up to ten instructions per cycle. Execution can occur out of program order. The instruction execution path is predicted by branch direction and target prediction logic. Each core includes four integer units, two load/store units, two binary floating-point units, two decimal floating-point units, and two vector floating-point units.

Cache Structure

The zEC12 incorporates a four-level cache structure. We look at each level in turn ([Figure 21.17](#)).

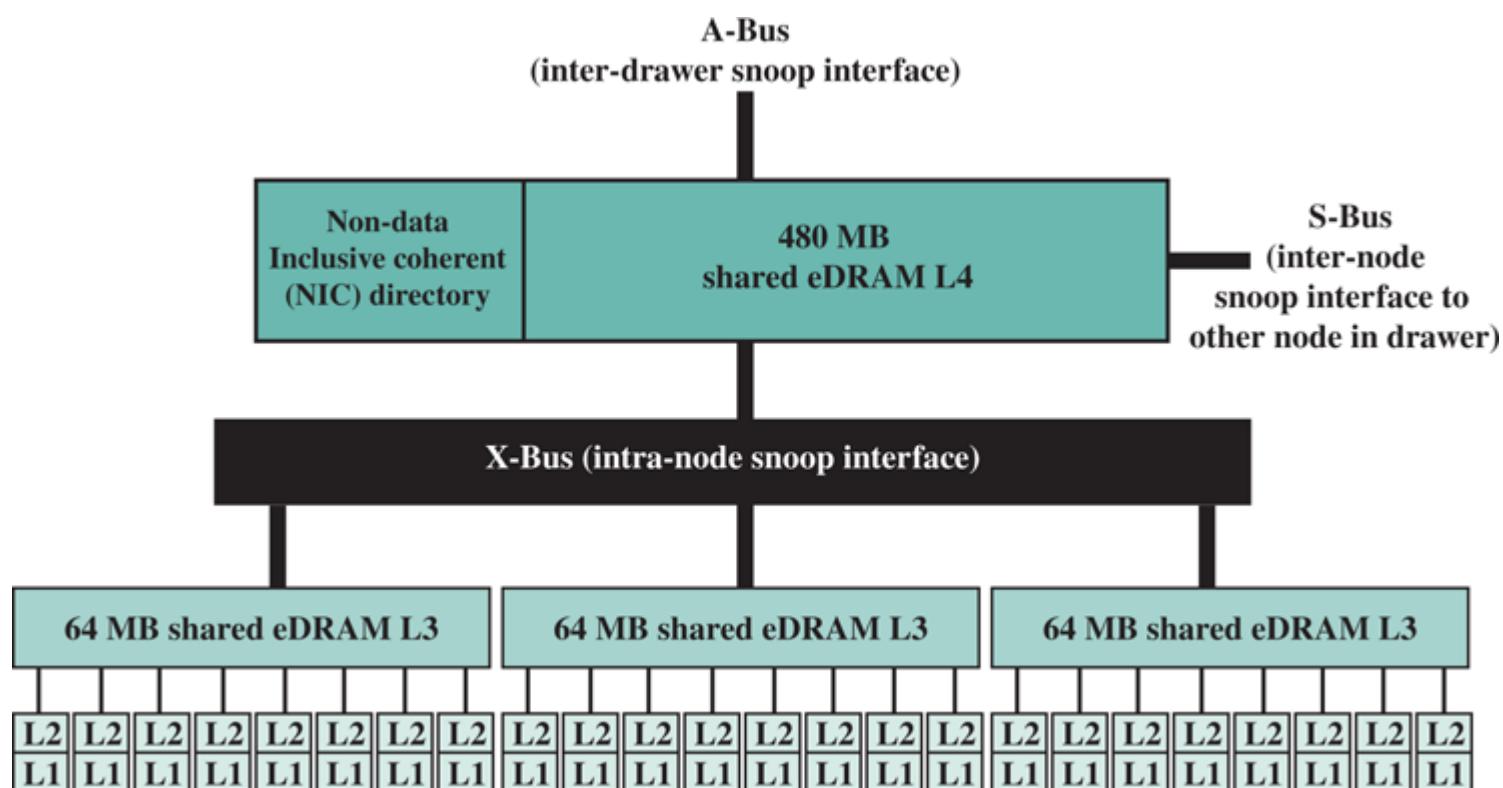

Figure 21.17 IBM z13 Cache Hierarchy in Single Node

Each core has a dedicated 96-kB L1 I-cache and a 128-kB L1 D-cache. The L1 cache is designed as a write-through cache to L2, that is, altered data are also stored to the next level of memory. These caches are eight-way set associative.

Each core also has a dedicated 2-MB L2, split equally into 1-MB data cache and 1-MB instruction cache. The L2 caches are write-through to L3, and eight-way set associative.

Each eight-core processor unit chip includes a 64-MB L3 cache shared by all eight cores. Because L1 and L2 caches are write-through, the L3 cache must process every store generated by the eight cores on its chip. This feature maintains data availability during a core failure. The L3 cache is 16-way set associative. The z13 implements embedded DRAM (eDRAM) as L3 cache memory on the chip. While this eDRAM memory is slower than static RAM (SRAM) traditionally used to implement cache memory, the eDRAM can hold significantly more bits in a given surface area. For many workloads, having more memory closer to the core is more important than having fast memory.

The three PUs in a node share a 480-MB L4 cache. The L4 cache is on a chip that also includes a

non-data inclusive coherent (NIC) directory that points to L3-owned lines that have not been included in L4 cache. The principal motivation for incorporating a level 4 cache is that the very high clock speed of the core processors results in a significant mismatch with main memory speed. The fourth cache layer is needed to keep the cores running efficiently. The large shared L3 and L4 caches are suited to transaction-processing workloads exhibiting a high degree of data sharing and task swapping. The L4 cache is 30-way set associative. The SC chip, which houses the L4 cache, also acts as a cross-point switch for L4-to-L4 traffic to up to the other node in the same drawer and two other drawers by bidirectional data buses. The L4 cache is the coherence manager, meaning that all memory fetches must be in the L4 cache before that data can be used by the processor.

All four caches use a line size of 256 bytes.

The z13 is an interesting study in design trade-offs and the difficulty in exploiting the increasingly powerful processors available with current technology. The large L4 cache is intended to drive the need for access to main memory down to the bare minimum. However, the distance to the off-chip L4 cache costs a number of instruction cycles. Thus, the on-chip area devoted to cache is as large as possible, even to the point of having fewer cores than possible on the chip. The L1 caches are small, to minimize distance from the core and ensure that access can occur in one cycle. Each L2 cache is dedicated to a single core, in an attempt to maximize the amount of cached data that can be accessed without resorting to a shared cache. The L3 cache is shared by all four cores on a chip and is as large as possible, to minimize the need to go to the L4 cache.

Because all of the nodes of the z13 share the workload, all of the L4 caches form a single L4 cache memory. Thus, access to L4 means not only going off-chip but perhaps off-drawer, further increasing access delay. This means relatively large distances exist between the higher-level caches in the processors and the L4 cache content. Still, accessing L4 cache data on another node is faster than accessing DRAM on the other node, which is why the L4 caches work this way.

To overcome the delays that are inherent to this design and to save cycles to access the off-node L4 content, the designers try to keep instructions and data as close to the cores as possible by directing as much work as possible of a given logical partition workload to the cores located in the same node as the L4 cache. This is achieved by having the system and the z/OS dispatcher work together to keep as much work as possible within the boundaries of as few cores and L4 cache space (which is best within a node boundary) as can be achieved without affecting throughput and response times. Preventing the resource manager/scheduler and the dispatcher from assigning workloads to processors where they might run less efficiently, contributes to overcoming latency in a high-frequency processor design such as the z13.

threading granularity

Review Questions

21.1 Summarize the differences among simple instruction pipelining, superscalar, and simultaneous multithreading.

21.2 Give several reasons for the choice by designers to move to a multicore organization rather than increase parallelism within a single processor.

21.3 Why is there a trend toward giving an increasing fraction of chip area to cache memory?

21.4 List some examples of applications that benefit directly from the ability to scale throughput with the number of cores.

21.5 At a top level, what are the main design variables in a multicore organization?

21.6 List some advantages of a shared L2 cache among cores compared to separate dedicated L2 caches for each core.

Problems

21.1 Consider the following problem. A designer has a chip available and must decide what fraction of the chip will be devoted to cache memory (L1, L2, L3). The remainder of the chip will be devoted to one or more complex superscalar and/or SMT cores. Define the following parameters:

- n = maximum number of cores that can be contained on the chip.
- k = actual number of cores implemented ($1 \leq k \leq n$, where n/k is an integer).

$perf(r)$ = sequential performance gain by using the resources equivalent to r cores to form a single processor, where $perf(1) = 1$.

- f =fraction of software that is parallelizable across multiple cores.

Thus, if we construct a chip with n cores, we expect each core to provide sequential performance of 1 and for the n cores to be able to exploit parallelism up to a degree of n parallel threads. Similarly, if the chip has k cores, then each core should exhibit a performance of $perf(r)$ and the chip is able to exploit parallelism up to a degree of k parallel threads. We can modify Amdahl's law ([Equation 21.1](#)) to reflect this situation as follows:

$$\text{Speedup} = \frac{1 - f}{perf(r) + perf(r) \times n}$$

- Justify this modification of Amdahl's law.
- Using Pollack's rule, we set $perf(r) = \sqrt{r}$. Let $n = 16$. We want to plot speedup as a function of r for $f=0.5 ; f=0.9 ; f=0.975 ; f=0.99 ; f=0.999$. The results are available in a document at box.com/COA11e (multicore-performance.pdf). What conclusions can you draw?
- Repeat part (b) for $n = 256$.

21.2 The technical reference manual for the Cortex-A15 says that the GIC is memory mapped. That is, the core processors use memory mapped I/O to communicate with the GIC. Recall from [Chapter 8](#) that with memory mapped I/O, there is a single address space for memory locations and I/O devices. The processor treats the status and data registers of I/O modules as memory locations and uses the same machine instructions to access both memory and I/O devices. Based on this information, what path through the block diagram of [Figure 21.15](#) is used for the core processors to communicate with the GIC?

21.3 In this question we analyze the performance of the following C program on a multithreaded architecture. You should assume that arrays A, B, and C do not overlap in memory.

```
for (i=0; i<328; i++) {
    A[i] = A[i]*B[i];
    C[i] = C[i]+A[i];
}
```

- Our machine is a single-issue, in-order processor. It switches to a different thread every cycle using fixed round robin scheduling. Each of the N threads executes one instruction every N cycles. We allocate the code to the threads such that every thread executes every Nth iteration of the original C code.
- Integer instructions take 1 cycle to execute, floating-point instructions take 4 cycles and memory instructions take 3 cycles. All execution units are fully pipelined. If an instruction cannot issue because its data is not yet available, it inserts a bubble into the pipeline and retries after 1 cycles.
- Below is our program in assembly code for this machine for a single thread executing the entire loop.

```
loop: ld f1, 0 (r1)          ;f1 = A[i]
      ld f2, 0 (r2)          ;f2 = B[i]
      fmul f4, f2, f1        ;f4 = f1*f2
      st f4 0(r1)            ;A[i] = f4
      ld f3, 0(r3)          ;f3 = C[i]
```

```

fadd f5, f4, f3      ;f5 = f4 + f3
st f5 0(r3)          ;C[i] = f5
add r1, r1, 4        ;i++
add r2, r2, 4
add r3, r3, 4
add r4, r4, -1
bnez r4, loop       ;loop

```

- We allocate the assembly code of the loop to N threads such that every thread executes every Nth iteration of the original loop. Write the assembly code that one of the N threads would execute on this multithreaded machine.
- What is the minimum number of threads this machine needs to remain fully utilized issuing an instruction every cycle for our program?
- Could we reach peak performance running this program using fewer threads by rearranging the instructions? Explain briefly.
- What will be the peak performance in flops/cycle for this program?

21.4 For the MOESI protocol, consider any pair of caches. Use the following matrix to indicate which states are permitted for a given cache line; use X for forbidden and checkmark for permitted.

	M	O	E	S	I
M					
O					
E					
S					
I					

21.5 Draw a state transition diagram, including labels on the transitions, for the MOESI protocol, similar to [Figure 20.6](#).

21.6 In directory cache coherence protocols, such as those based on MESI or MOESI, a silent transition is one in which a cache line transitions from one state to another without reporting this change to the central controller.

- For each state in the MESI protocol, indicate to which target states, if any, a silent transition is possible.
- Repeat for MOESI.

Appendix A System Buses

A.1 BUS STRUCTURE

A.2 MULTIPLE-BUS HIERARCHIES

A.3 ELEMENTS OF BUS DESIGN

Bus Types

Method of Arbitration

Timing

A bus is a communication pathway connecting two or more devices. A key characteristic of a bus is that it is a shared transmission medium. Multiple devices connect to the bus, and a signal transmitted by any one device is available for reception by all other devices attached to the bus. If two devices transmit during the same time period, their signals will overlap and become garbled. Thus, only one device at a time can successfully transmit.

Typically, a bus consists of multiple communication pathways, or lines. Each line is capable of transmitting signals representing binary 1 and binary 0. Over time, a sequence of binary digits can be transmitted across a single line. Taken together, several lines of a bus can be used to transmit binary digits simultaneously (in parallel). For example, an 8-bit unit of data can be transmitted over eight bus lines.

Computer systems contain a number of different buses that provide pathways between components at various levels of the computer system hierarchy. A bus that connects major computer components (processor, memory, I/O) is called a system bus. The most common computer interconnection structures are based on the use of one or more system buses.

A.1 Bus Structure

A system bus consists, typically, of about 50 to hundreds of separate lines. Each line is assigned a particular meaning or function. Although there are many different bus designs, on any bus the lines can be classified into three functional groups (**Figure A.1**): data, address, and control lines. In addition, there may be power distribution lines that supply power to the attached modules.

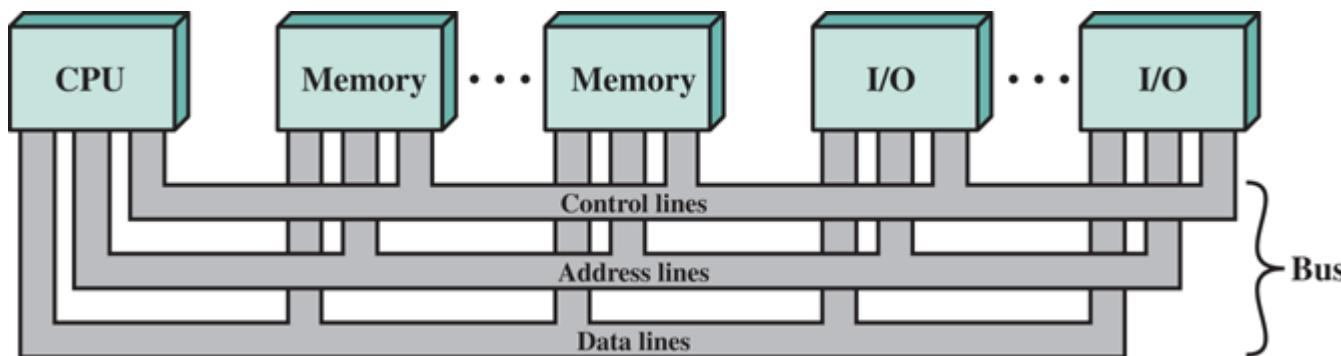

Figure A.1 Bus Interconnection Scheme

The **data lines** provide a path for moving data among system modules. These lines, collectively, are called the *data bus*. The data bus may consist of 32, 64, 128, or even more separate lines, the number of lines being referred to as the *width* of the data bus. Because each line can carry only 1 bit at a time, the number of lines determines how many bits can be transferred at a time. The width of the data bus is a key factor in determining overall system performance. For example, if the data bus is 32 bits wide and each instruction is 64 bits long, then the processor must access the memory module twice during each instruction cycle.

The **address lines** are used to designate the source or destination of the data on the data bus. For example, if the processor wishes to read a word (8, 16, or 32 bits) of data from memory, it puts the address of the desired word on the address lines. Clearly, the width of the **address bus** determines the maximum possible memory capacity of the system. Furthermore, the address lines are generally also used to address I/O ports. Typically, the higher-order bits are used to select a particular module on the bus, and the lower-order bits select a memory location or I/O port within the module. For example, on an 8-bit address bus, address 01111111 and below might reference locations in a memory module (module 0) with 128 words of memory, and address 10000000 and above refer to devices attached to an I/O module (module 1).

The **control lines** are used to control the access to and the use of the data and address lines. Because the data and address lines are shared by all components, there must be a means of controlling their use. Control signals transmit both command and timing information among system modules. Timing signals indicate the validity of data and address information. Command signals specify operations to be performed. Typical control lines include:

- **Memory write:** causes data on the bus to be written into the addressed location.
- **Memory read:** causes data from the addressed location to be placed on the bus.
- **I/O write:** causes data on the bus to be output to the addressed I/O port.
- **I/O read:** causes data from the addressed I/O port to be placed on the bus.
- **Transfer ACK:** indicates that data have been accepted from or placed on the bus.
- **Bus request:** indicates that a module needs to gain control of the bus.
- **Bus grant:** indicates that a requesting module has been granted control of the bus.
- **Interrupt request:** indicates that an interrupt is pending.

Interrupt ACK: acknowledges that the pending interrupt has been recognized.

- **Clock:** is used to synchronize operations.
- **Reset:** initializes all modules.

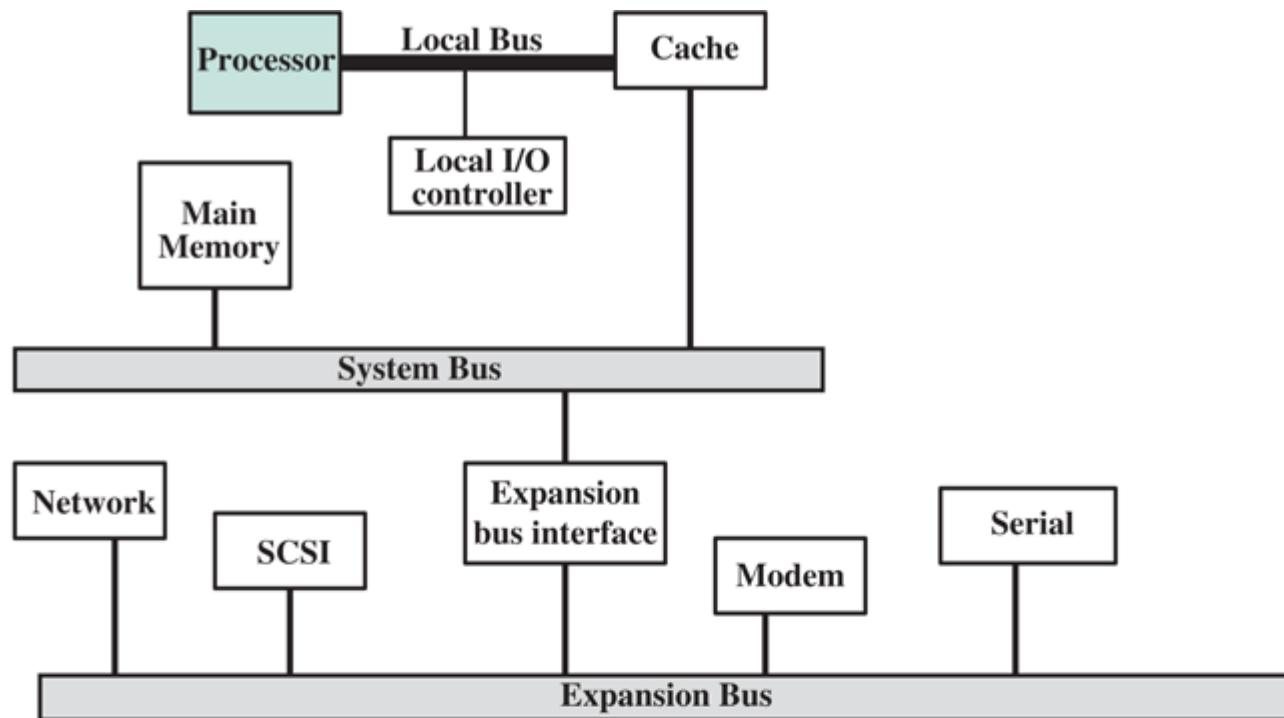

The operation of the bus is as follows. If one module wishes to send data to another, it must do two things: (1) obtain the use of the bus, and (2) transfer data via the bus. If one module wishes to request data from another module, it must (1) obtain the use of the bus, and (2) transfer a request to the other module over the appropriate control and address lines. It must then wait for that second module to send the data.

A.2 Multiple-Bus Hierarchies

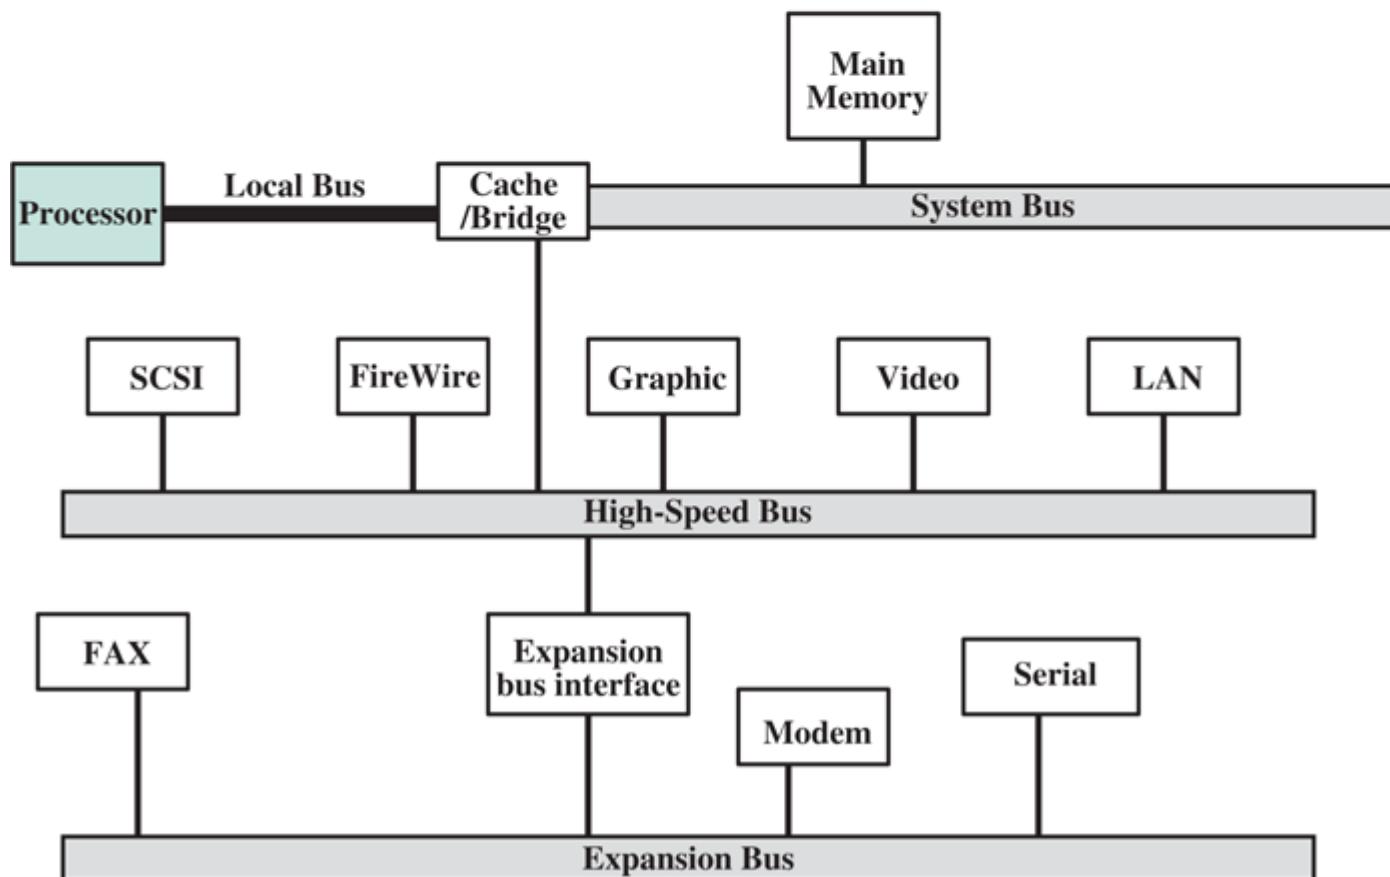

If a great number of devices are connected to the bus, performance will suffer. There are two main causes:

1. In general, the more devices attached to the bus, the greater the bus length and hence the greater the propagation delay. This delay determines the time it takes for devices to coordinate the use of the bus. When control of the bus passes from one device to another frequently, these propagation delays can noticeably affect performance.
2. The bus may become a bottleneck as the aggregate data transfer demand approaches the capacity of the bus. This problem can be countered to some extent by increasing the data rate that the bus can carry and by using wider buses (e.g., increasing the data bus from 32 to 64 bits). However, because the data rates generated by attached devices (e.g., graphics and video controllers, network interfaces) are growing rapidly, this is a race that a single bus is ultimately destined to lose.

Accordingly, most bus-based computer systems use multiple buses, generally laid out in a hierarchy. A typical traditional structure is shown in [Figure A.2a](#). There is a local bus that connects the processor to a cache memory and that may support one or more local devices. The cache memory controller connects the cache not only to this local bus, but also to a system bus to which are attached all of the main memory modules. In contemporary systems, the cache is in the same chip as the processor, and so an external bus or other interconnect scheme is not needed, although there may also be an external cache. As is discussed in [Chapter 4](#), the use of a cache structure insulates the processor from a requirement to access main memory frequently. Hence, main memory can be moved off of the local bus onto a system bus. In this way, I/O transfers to and from the main memory across the system bus do not interfere with the processor's activity.

(a) Traditional Bus Architecture

(b) High-Performance Architecture

Figure A.2 Example Bus Configurations

It is possible to connect I/O controllers directly onto the system bus. A more efficient solution is to make use of one or more expansion buses for this purpose. An expansion bus interface buffers data transfers between the system bus and the I/O controllers on the expansion bus. This arrangement allows the system to support a wide variety of I/O devices and at the same time insulate memory-to-

processor traffic from I/O traffic.

Figure A.2a shows some typical examples of I/O devices that might be attached to the expansion bus. Network connections include local area networks (LANs) such as a 10-Mbps Ethernet and connections to wide area networks (WANs) such as a packet-switching network. SCSI (small computer system interface) is itself a type of bus used to support local disk drives and other peripherals. A serial port could be used to support a printer or scanner.

This traditional bus architecture is reasonably efficient but begins to break down as higher and higher performance is seen in the I/O devices. In response to these growing demands, a common approach taken by industry is to build a high-speed bus that is closely integrated with the rest of the system, requiring only a bridge between the processor's bus and the high-speed bus. This arrangement is sometimes known as a mezzanine architecture.

Figure A.2b shows a typical realization of this approach. Again, there is a local bus that connects the processor to a cache controller, which is in turn connected to a system bus that supports main memory. The cache controller is integrated into a bridge, or buffering device, that connects to the high-speed bus. This bus supports connections to high-speed LANs, such as Fast Ethernet at 100 Mbps, and video and graphics workstation controllers, as well as interface controllers to local peripheral buses, including SCSI and FireWire. The latter is a high-speed bus arrangement specifically designed to support high-capacity I/O devices. Lower-speed devices are still supported off an expansion bus, with an interface buffering traffic between the expansion bus and the high-speed bus.

The advantage of this arrangement is that the high-speed bus brings high-demand devices into closer integration with the processor and at the same time is independent of the processor. Thus, differences in processor and high-speed bus speeds and signal line definitions are tolerated. Changes in processor architecture do not affect the high-speed bus, and vice versa.

A.3 Elements of Bus Design

Although a variety of different bus implementations exist, there are a few basic parameters or design elements that serve to classify and differentiate buses. **Table A.1** lists key elements.

Table A.1 Elements of Bus Design

Type	Bus Width
Dedicated	Address
Multiplexed	Data
Method of Arbitration	Data Transfer Type
Centralized	Read
Distributed	Write
Timing	Read-modify-write
Synchronous	Read-after-write
Asynchronous	Block

Bus Types

Bus lines can be separated into two generic types: dedicated and multiplexed. A dedicated bus line is permanently assigned either to one function or to a physical subset of computer components.

An example of functional dedication is the use of separate dedicated address and data lines, which is common on many buses. However, it is not essential. For example, address and data information may be transmitted over the same set of lines using an Address Valid control line. At the beginning of a data transfer, the address is placed on the bus and the Address Valid line is activated. At this point, each module has a specified period of time to copy the address and determine if it is the addressed module. The address is then removed from the bus, and the same bus connections are used for the subsequent read or write data transfer. This method of using the same lines for multiple purposes is known as *time multiplexing*.

The advantage of time multiplexing is the use of fewer lines, which saves space and, usually, cost. The disadvantage is that more complex circuitry is needed within each module. Also, there is a potential reduction in performance because certain events that share the same lines cannot take place in parallel.

Physical dedication refers to the use of multiple buses, each of which connects only a subset of modules. A typical example is the use of an I/O bus to interconnect all I/O modules; this bus is then connected to the main bus through some type of I/O adapter module. The potential advantage of physical dedication is high throughput, because there is less bus contention. A disadvantage is the

increased size and cost of the system.

Method of Arbitration

In all but the simplest systems, more than one module may need control of the bus. For example, an I/O module may need to read or write directly to memory, without sending the data to the processor. Because only one unit at a time can successfully transmit over the bus, some method of arbitration is needed. The various methods can be roughly classified as being either centralized arbitration or distributed arbitration. In a centralized scheme, a single hardware device, referred to as a *bus controller* or *arbiter*, is responsible for allocating time on the bus. The device may be a separate module or part of the processor. In a distributed scheme, there is no central controller. Rather, each module contains access control logic and the modules act together to share the bus. With both methods of arbitration, the purpose is to designate one device, either the processor or an I/O module, as master. The master may then initiate a data transfer (e.g., read or write) with some other device, which acts as slave for this particular exchange.

Timing

Timing refers to the way in which events are coordinated on the bus. Buses use either synchronous timing or asynchronous timing.

With **synchronous timing**, the occurrence of events on the bus is determined by a clock. The bus includes a clock line upon which a clock transmits a regular sequence of alternating 1s and 0s of equal duration. A single 1–0 transmission is referred to as a *clock cycle* or *bus cycle* and defines a time slot. All other devices on the bus can read the clock line, and all events start at the beginning of a clock cycle. [Figure A.3](#) shows a typical, but simplified, timing diagram for synchronous read and write operations. Most events occupy a single clock cycle. In this simple example, the processor places a memory address on the address lines during the first clock cycle, and may assert various status lines. Once the address lines have stabilized, the processor issues an address enable signal. For a read operation, the processor issues a read command at the start of the second cycle. A memory module recognizes the address and, after a delay of one cycle, places the data on the data lines. The processor reads the data from the data lines and drops the read signal. For a write operation, the processor puts the data on the data lines at the start of the second cycle and issues a write command after the data lines have stabilized. The memory module copies the information from the data lines during the third clock cycle.

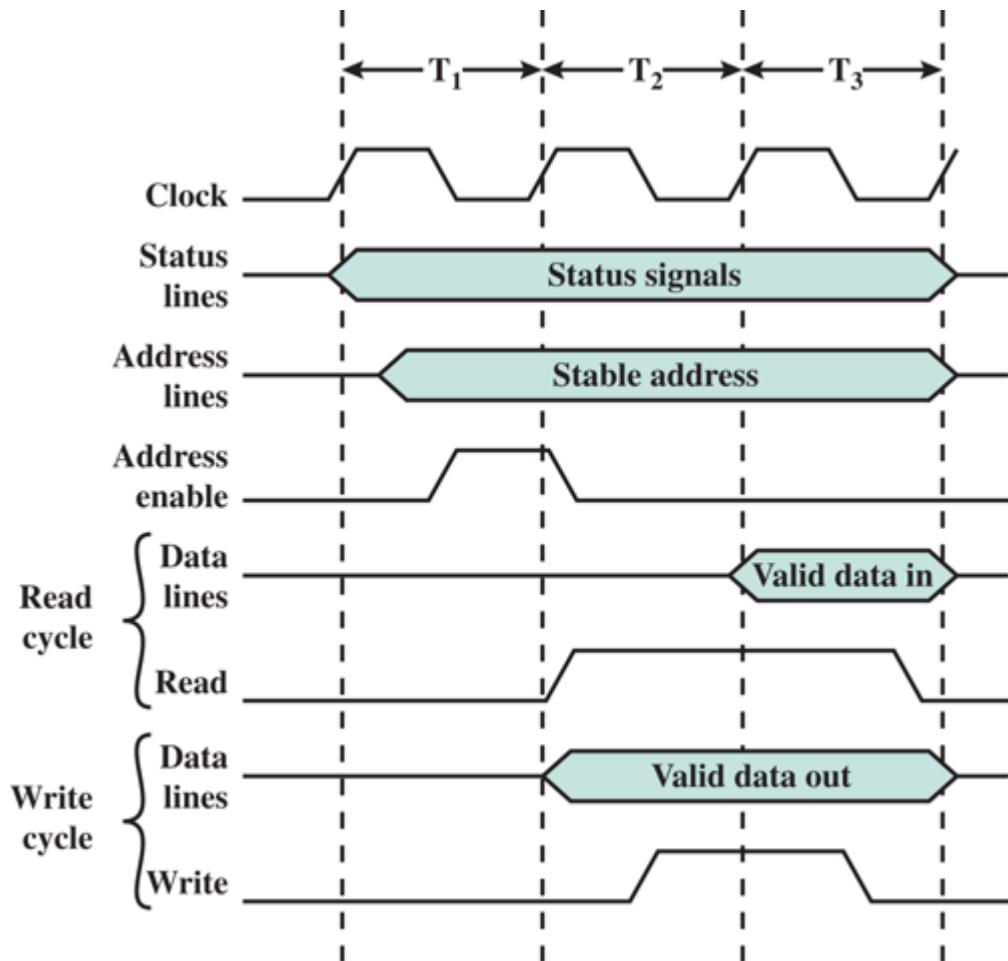

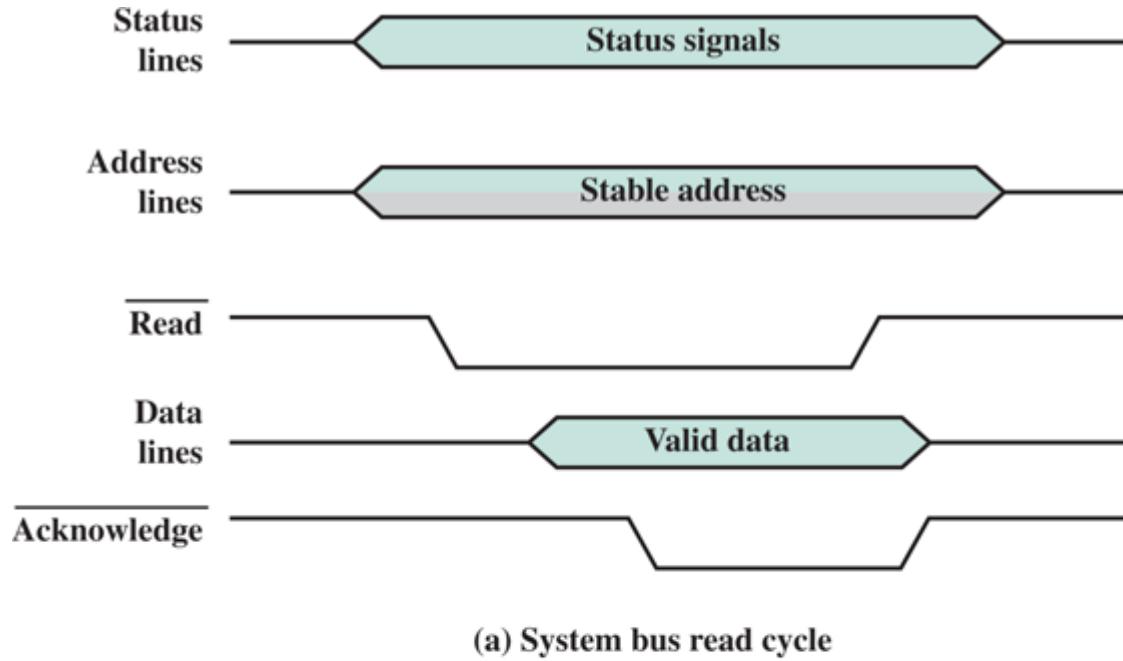

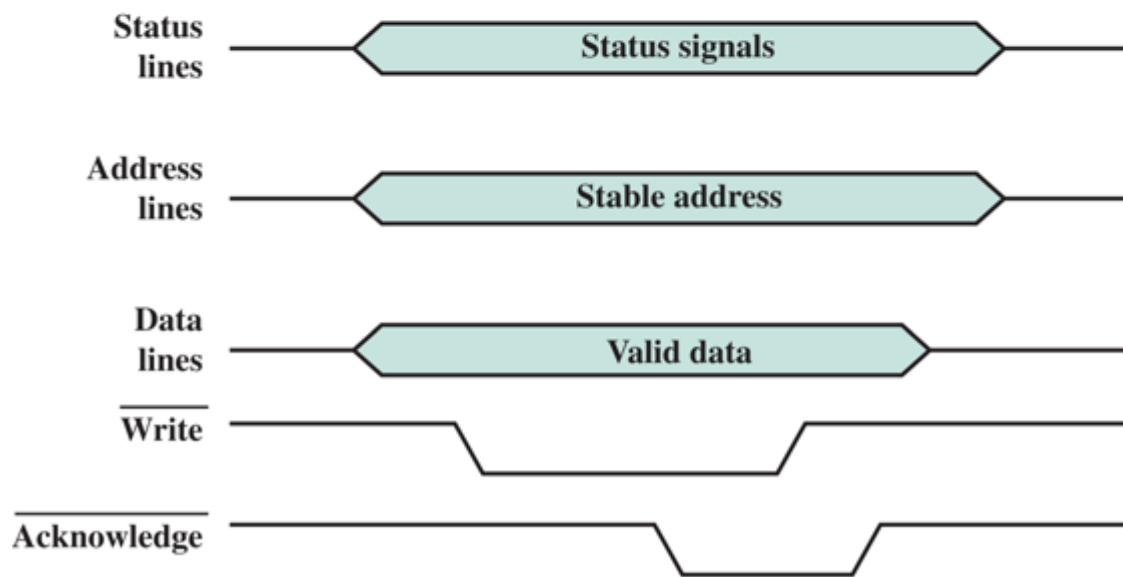

Figure A.3 Timing of Synchronous Bus Operations

With **asynchronous timing**, the occurrence of one event on a bus follows and depends on the occurrence of a previous event. In the simple read example of [Figure A.4a](#), the processor places address and status signals on the bus. After pausing for these signals to stabilize, it issues a read command, indicating the presence of valid address and control signals. The appropriate memory decodes the address and responds by placing the data on the data line. Once the data lines have stabilized, the memory module asserts the acknowledged line to signal the processor that the data are available. Once the master has read the data from the data lines, it deasserts the read signal. This causes the memory module to drop the data and acknowledge lines. Finally, once the acknowledge line is dropped, the master removes the address information.

(a) System bus read cycle

(b) System bus write cycle

Figure A.4 Timing of Asynchronous Bus Operations

Figure A.4b shows a simple asynchronous write operation. In this case, the master places the data on the data line at the same time that it puts signals on the status and address lines. The memory module responds to the write command by copying the data from the data lines and then asserting the acknowledge line. The master then drops the write signal and the memory module drops the acknowledge signal.

Synchronous timing is simpler to implement and test. However, it is less flexible than asynchronous timing. Because all devices on a synchronous bus are tied to a fixed clock rate, the system cannot take advantage of advances in device performance. With asynchronous timing, a mixture of slow and fast devices, using older and newer technology, can share a bus.

Appendix B Victim Cache Strategies

B.1 VICTIM CACHE

B.2 SELECTIVE VICTIM CACHE

[Incoming Blocks from Memory](#)

[Swap Between Direct-Mapped Cache and Victim Cache](#)

This appendix looks at two cache strategies mentioned in [Chapter 5](#): victim cache and selective victim cache.

B.1 Victim Cache

Recall from [Chapter 4](#) that an advantage of the direct mapping technique is that it is simple and inexpensive to implement. Its main disadvantage is that there is a fixed cache location for any given block. Thus, if a program happens to reference words repeatedly from two different blocks that map into the same line, then the blocks will be continually swapped in the cache, and the hit ratio will be low (a phenomenon known as *thrashing*). On the other hand, with fully associative mapping, there is flexibility as to which block to replace when a new block is read into the cache. Replacement algorithms are designed to maximize the hit ratio. The principal disadvantage of associative mapping is the complex circuitry required to examine the tags of all cache lines in parallel.

The victim cache approach, proposed by Jouppi [JOUP90], is a strategy designed to combine the fast hit time of direct mapping, yet still avoid thrashing. To achieve this objective, the direct-mapped cache is supplemented with a small associative cache known as the victim cache. A line removed from the direct-mapped cache is temporarily stored in the victim cache, which maintains a small number of lines using a FIFO (first-in-first-out) replacement strategy. Jouppi found that a four-line victim cache removed 20% to 95% of misses in the direct-mapped cache.

[Figure B.1](#) is a simple block diagram illustrating the location of the victim cache in the overall memory hierarchy. The victim cache can be considered to be part of the L1 cache system. The next lower level of the memory hierarchy can be an L2 cache or the main memory.

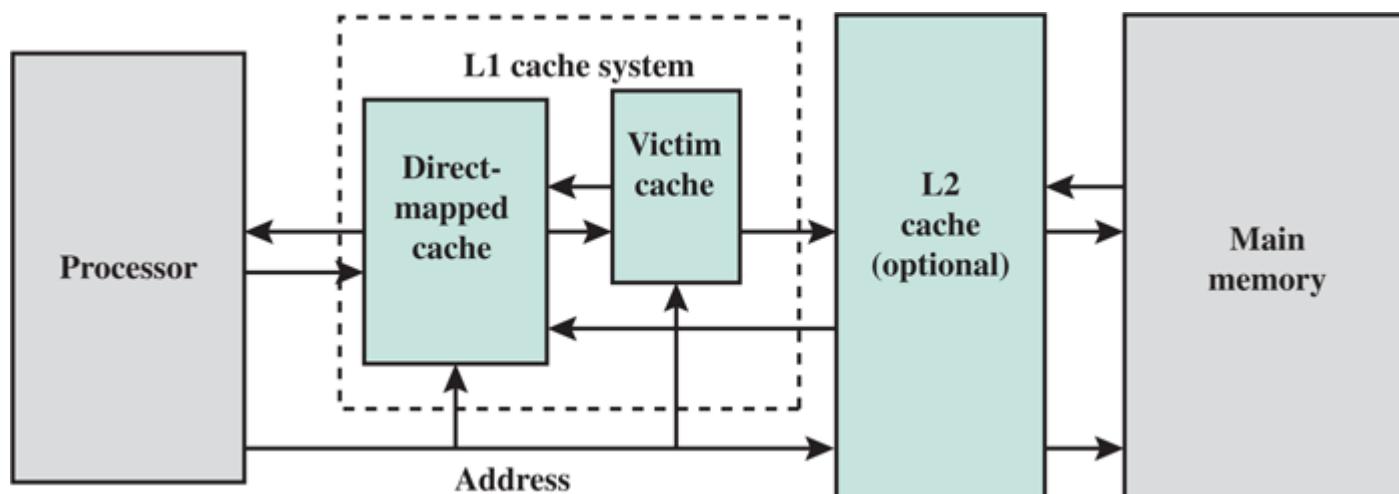

Figure B.1 Position of Victim Cache

[Figure B.2](#) provides a more detailed look at the victim cache organization. In Jouppi's proposal, the victim cache contains four lines of data. The L1 cache is direct-mapped, so that each cache line consists of a block of data from memory plus a small tag (see [Figures 5.7](#) and [5.8](#)). The victim cache is associative, so that each line contains one block of data from memory plus a large tag (see [Figures 5.10](#) and [5.11](#)). For clarity, the tag in the victim cache is depicted as consisting of a tag equal in length to the direct-mapped cache and a comparator. In fact, looking back at [Figures 5.8](#) and [5.11](#), the comparator is equivalent to the line field in the direct-mapped scheme. The tag plus comparator in the victim cache uniquely identify a block of memory, so that a memory reference from the processor can do a parallel search of all entries in the associative cache to determine if the desired line is present.

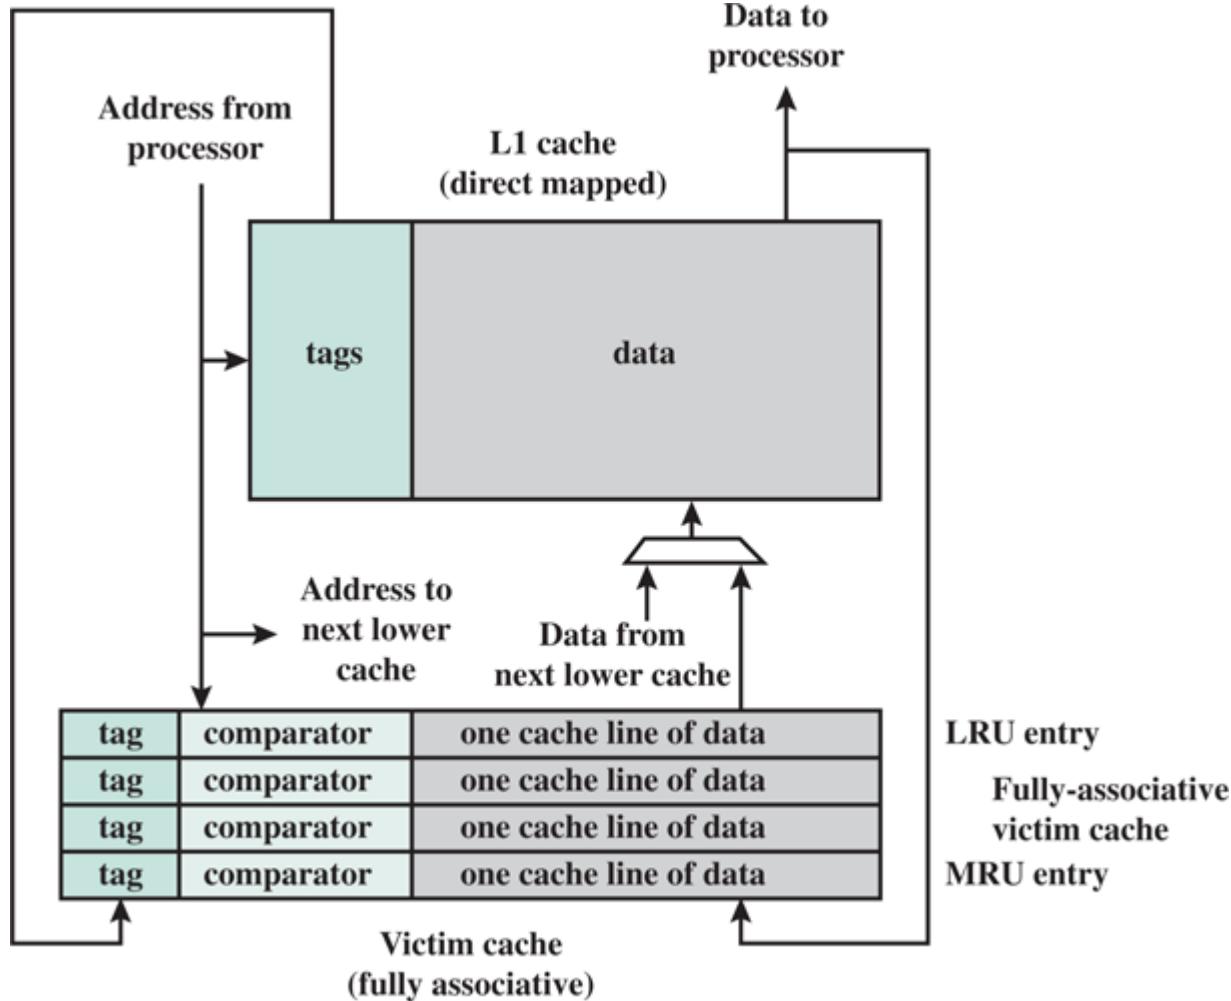

Figure B.2 Victim Cache Organization

Figure B.3 suggests the operation of the victim cache. The data is arranged in such a way that the same line is never present in both the L1 cache and the victim cache at the same time. There are two cases to consider for managing the movement of data between the two caches:

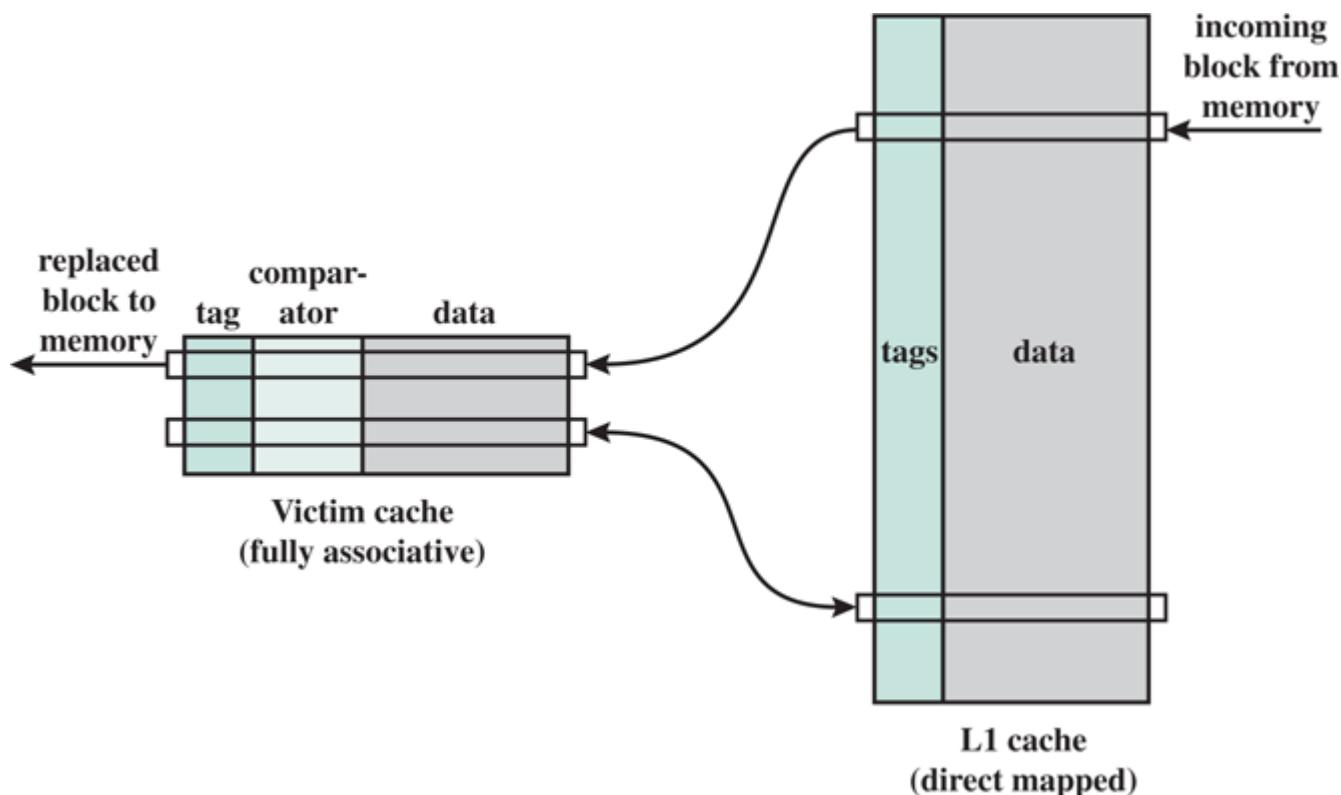

Figure B.3 Victim Cache Operation

Case 1: Processor reference to memory misses in both the L1 cache and the victim cache.

- a. The required block is fetched from main memory (or the L2 cache if present) and placed into the L1 cache.
- b. The replaced block in the main cache is moved to the victim cache. There is no replacement algorithm. With a direct-mapped cache, the line to be replaced is uniquely determined.
- c. The victim cache can be viewed as a FIFO queue or, equivalently, a circular buffer. The item that has been in the victim cache the longest is removed to make room for the incoming line. The replaced line is written back to the main memory if it is dirty (has been updated).

Case 2: Processor reference to memory misses the direct-mapped cache but hits the victim cache.

- a. The block in the victim cache is promoted to the direct-mapped cache.
- b. The replaced block in the main cache is swapped to the victim cache.

Note that with the FIFO discipline, the victim cache achieves true LRU (least recently used) behavior. Any reference to the victim cache pulls the referenced block out of the victim cache; thus the LRU block in the victim cache will, by definition, be the oldest one there.

The term victim is used for the following reason. When a new block is brought into the L1 cache, the replacement algorithm chooses a line to be replaced. That line is the “victim” of the replacement algorithm.

B.2 Selective Victim Cache

[STIL94] proposes an improvement to the victim cache scheme known as selective victim cache. In this scheme, incoming blocks into the first-level cache are placed selectively in the main cache or the victim cache by the use of a prediction scheme based on their past history of use. In addition, interchanges of blocks between the main cache and the victim cache are also performed selectively.

Incoming Blocks from Memory

In the victim cache scheme, incoming blocks from memory (or L2 cache if present) are always loaded into the direct-mapped cache, with one of the direct cache blocks being replaced and moved to the victim cache, which in turn discards one of its blocks (writing it back to memory if necessary). The net effect is that when a new block is brought into the L1 cache, it is a victim cache block that is replaced in the total L1 cache system.

With the selective victim cache, a decision is made of whether to replace the corresponding line in the direct-mapped cache (which is then moved to the victim cache) or to replace a line in the victim cache, choosing the LRU line for replacement. A prediction algorithm is used to determine which of the two conflicting lines is more likely to be referenced in the future. If the incoming line is found to have a higher probability than the conflicting line in the main cache, the latter is moved to the victim cache and the new line takes its place in the main cache; otherwise, the incoming line is directed to the victim cache.

Swap Between Direct-Mapped Cache and Victim Cache

In the victim cache scheme, if there is a miss in the direct-mapped cache and a hit in the victim cache, then there is a swap of lines between the direct-mapped cache and the victim cache. With the selective victim cache, the prediction algorithm is invoked to determine if the accessed block in the victim cache is more likely to be accessed in the future than the block in the main cache it is conflicting with. If the prediction algorithm decides that the block in the victim cache is more likely to be referenced again than the conflicting block in the main cache, an interchange is performed between the two blocks; no such interchange is performed otherwise. In both cases, the block in the victim cache is marked as the most recently used.

The prediction algorithm used in the selective victim cache scheme is referred to as the dynamic exclusion algorithm, proposed in [MAFA92]. Both [MAFA92] and [STIL94] have good descriptions of the algorithm.

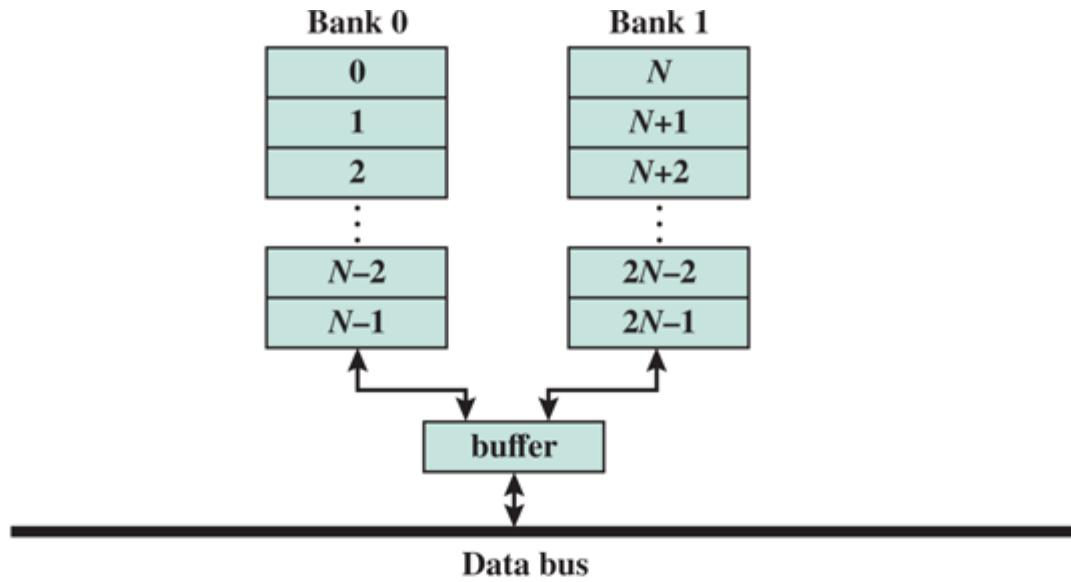

Appendix C Interleaved Memory

Main memory is typically a series of DRAM chips. A number of these chips form a bank, with a port for transfer of data to and from the processor or an intermediate cache. Multiple memory banks can be connected together to form an interleaved memory system. Because each bank can service a request, an interleaved memory system with K banks can service K requests simultaneously, increasing the peak data transfer rate by a factor of K over the data transfer rate of a single bank. In most memory systems, the number of banks is a power of 2; that is, $K = 2^k$ for some integer k .

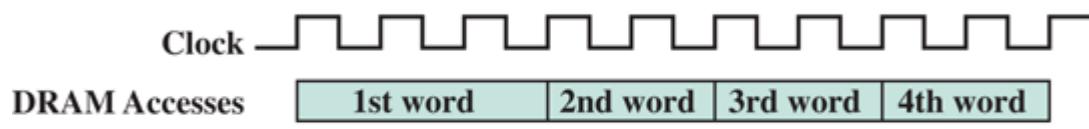

To get a feel for the use of interleaved memory, let us consider a simple system consisting of two DRAM memory banks. If the memory controller does not support interleaving, then the memory addresses are assigned sequentially in the first bank, followed by addresses in the second bank.

Figure C.1a shows this organization for two banks of N words (assuming addressing is at the word level). Typically, the memory controller will perform a burst access (a single bus transaction that reads or writes multiple words) to move data between cache and memory. For example, the cache may have a line size of four 32-bit words and so data is transferred between memory and cache in blocks of four words. All the words in the block come from one bank of DRAM in a non-interleaved memory organization, so the time required to complete the transfer is a linear function of the number of words transferred. **Figure C.1b** shows the timing of the transfer. Note that the time needed to transfer each of the second, third, and fourth words is shorter than the time for the first word. This is because of a feature of contemporary DRAMs known as page-mode access. This is, in effect, a form of on-chip caching on the DRAM chip [JACO08].

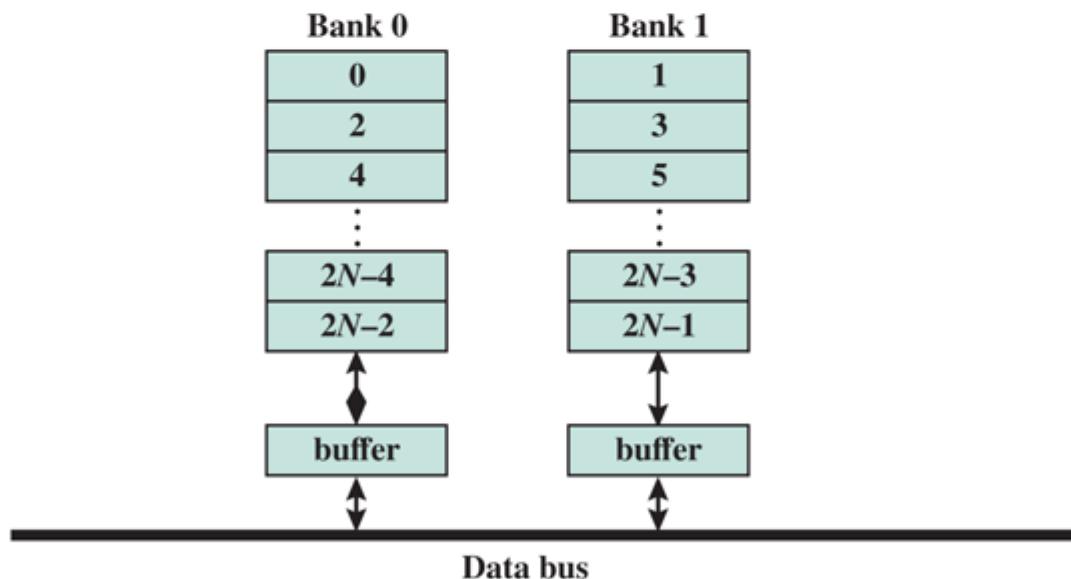

If the memory controller supports interleaved memory, then memory addresses are organized as shown in **Figure C.1**. Memory location addresses alternate between the two banks. This configuration speeds up the burst transfer of four words, as shown in the timing diagram of **Figure C.1d**. Because the four words of a burst access are spread across two physical banks of DRAM, the individual accesses can be overlapped to hide part, or all, of the DRAM access time delay.

Figure C.1 Example of 2-Way Interleaved Memory

Figure C.2 shows the organization of an interleaved memory with 2^k DRAM banks. Multiple memory

banks are connected to a single bus (channel) and differentiated by the lower (least significant) k bits of the address bus. They share the bus by time division and overlapping the operations. If the address length is $m + k$, bits, then the upper (most significant) m bits of the address select a word within a memory bank, while the lower k bits select the given memory bank.

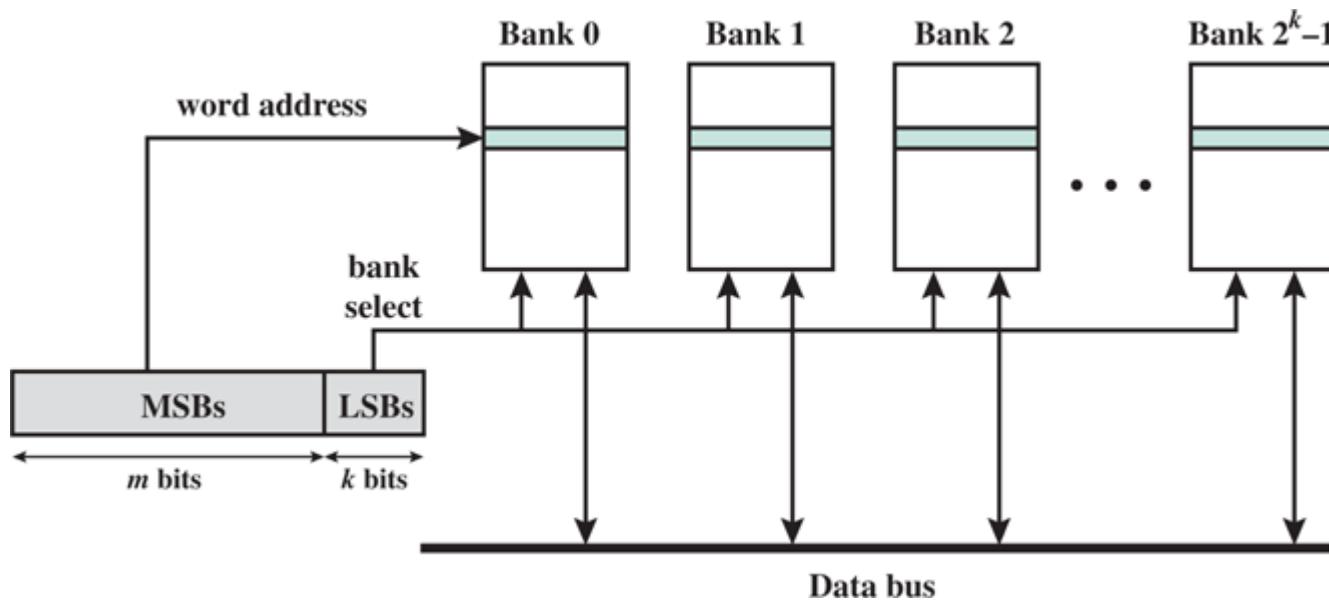

Figure C.2 Interleaved Memory

The interleaved memory system is most effective when the number of memory banks is equal to or an integer multiple of the number of words in a cache line.

Appendix D The International Reference Alphabet

A familiar example of data is **text**, or character strings. While textual data are most convenient for human beings, they cannot, in character form, be easily stored or transmitted by data processing and communications systems. Such systems are designed for binary data. Thus a number of codes have been devised by which characters are represented by a sequence of bits. Perhaps the earliest common example of this is the Morse code. Today, the most commonly used text code is the International Reference Alphabet (IRA).¹ Each character in this code is represented by a unique 7-bit binary code; thus, 128 different characters can be represented. **Table D.1** lists all of the code values. In the table, the bits of each character are labeled from b_7 , which is the most significant bit, to b_1 , the least significant bit. Characters are of two types: printable and control (**Table D.2**). Printable characters are the alphabetic, numeric, and special characters that can be printed on paper or displayed on a screen. For example, the bit representation of the character “K” is $b_7b_6b_5b_4b_3b_2b_1 = 1001011$. Some of the control characters have to do with controlling the printing or displaying of characters; an example is carriage return. Other control characters are concerned with communications procedures.

¹ IRA is defined in ITU-T Recommendation T.50 and was formerly known as International Alphabet Number 5 (IA5). The U.S. national version of IRA is referred to as the American Standard Code for Information Interchange (ASCII).

IRA-encoded characters are almost always stored and transmitted using 8 bits per character. The eighth bit is a parity bit used for error detection. The parity bit is the most significant bit and is therefore labeled b_8 . This bit is set such that the total number of binary 1s in each octet is always odd (odd parity) or always even (even parity). Thus, a transmission error that changes a single bit, or any odd number of bits, can be detected.

Table D.1 The International Reference Alphabet (IRA)

bit position												
	b_7			0	0	0	0	1	1	1	1	1

Table D.2 IRA Control Characters

Format Control											
BS (Backspace): Indicates movement of the printing mechanism or display cursor backward one position.						VT (Vertical Tab): Indicates movement of the printing mechanism or display cursor to the next of a series or preassigned printing lines.					
HT (Horizontal Tab): Indicates movement of the printing mechanism or display cursor forward to the next preassigned “tab” or stopping position.						FF (Form Feed): Indicates movement of the printing mechanism or display cursor to the starting position of the next page, form, or screen.					
LF (Line Feed): Indicates movement of the printing mechanism or display cursor to the start of the next line.						CR (Carriage Return): Indicates movement of the printing mechanism or display cursor to the starting position of the same line.					
Transmission Control											
SOH (Start of Heading): Used to indicate the start of a heading, which may contain address or routing						ACK (Acknowledge): A character transmitted by a receiving device as an affirmation response to a sender. It is used as a positive response to polling messages.					

information.

STX (Start of Text): Used to indicate the start of the text and so also indicates the end of the heading.

ETX (End of Text): Used to terminate the text that was started with STX.

EOT (End of Transmission): Indicates the end of a transmission, which may have included one or more “texts” with their headings.

ENQ (Enquiry): A request for a response from a remote station. It may be used as a “WHO ARE YOU” request for a station to identify itself.

NAK (Negative Acknowledgment): A character transmitted by a receiving device as a negative response to a sender. It is used as a negative response to polling messages.

SYN (Synchronous/Idle): Used by a synchronous transmission system to achieve synchronization. When no data is being sent a synchronous transmission system may send SYN characters continuously.

ETB (End of Transmission Block): Indicates the end of a block of data for communication purposes. It is used for blocking data where the block structure is not necessarily related to the processing format.

Information Separator

FS (File Separator)

GS (Group Separator)

RS (Record Separator)

US (Unit Separator)

Information separators are to be used in an optional manner, except that their hierarchy shall be FS (the most inclusive) to US (the least inclusive).

Miscellaneous

NUL (Null): No character. Used for filling in time or filling space on tape when there are no data.

BEL (Bell): Used when there is need to call human attention. It may control alarm or attention devices.

SO (Shift Out): Indicates that the code combinations that follow shall be interpreted as outside of the standard character set until a SI character is reached.

DLE (Data Link Escape): A character that shall change the meaning of one or more contiguously following characters. It can provide supplementary controls, or permits the sending of data characters having any bit combination.

DC1, DC2, DC3, DC4 (Device Controls): Characters for the control of ancillary devices or special terminal features.

CAN (Cancel): Indicates that the data that precedes it in a message or block should be disregarded (usually because an error has been detected).

SI (Shift In): Indicates that the code combinations that follow shall be interpreted according to the standard character set.

DEL (Delete): Used to obliterate unwanted characters; for example, by overwriting.

SP (Space): A nonprinting character used to separate words, or to move the printing mechanism or display cursor forward by one position.

EM (End of Medium): Indicates the physical end of a tape or other medium, or the end of the required or used portion of the medium.

SUB (Substitute): Substituted for a character that is found to be erroneous or invalid.

ESC (Escape): A character intended to provide code extension in that it gives a specified number of continuously following characters an alternate meaning.

Appendix E Stacks

E.1 STACKS

E.2 STACK IMPLEMENTATION

E.3 EXPRESSION EVALUATION

The stack is a fundamental and important concept in computer science and engineering, with a wide range of uses. This appendix provides an overview.

E.1 Stacks

A *stack* is an ordered set of elements, only one of which can be accessed at a time. The point of access is called the *top* of the stack. The number of elements in the stack, or *length* of the stack, is variable. The last element in the stack is the *base* of the stack. Items may only be added to or deleted from the top of the stack. For this reason, a stack is also known as a *pushdown list*¹ or a *last-in-first-out (LIFO) list*.

¹ A better term would be *place-on-top-of list* because the existing elements of the list are not moved in memory, but a new element is added at the next available memory address.

Figure E.1 shows the basic stack operations. We begin at a point in time when the stack contains some number of elements. A PUSH operation appends one new item to the top of the stack. A POP operation removes the top item from the stack. In both cases, the top of the stack moves accordingly. Binary operators, which require two operands (e.g., multiply, divide, add, subtract), use the top two stack items as operands, pop both items, and push the result back onto the stack. Unary operations, which require only one operand (e.g., logical NOT), use the item on the top of the stack. All of these operations are summarized in **Table E.1**.

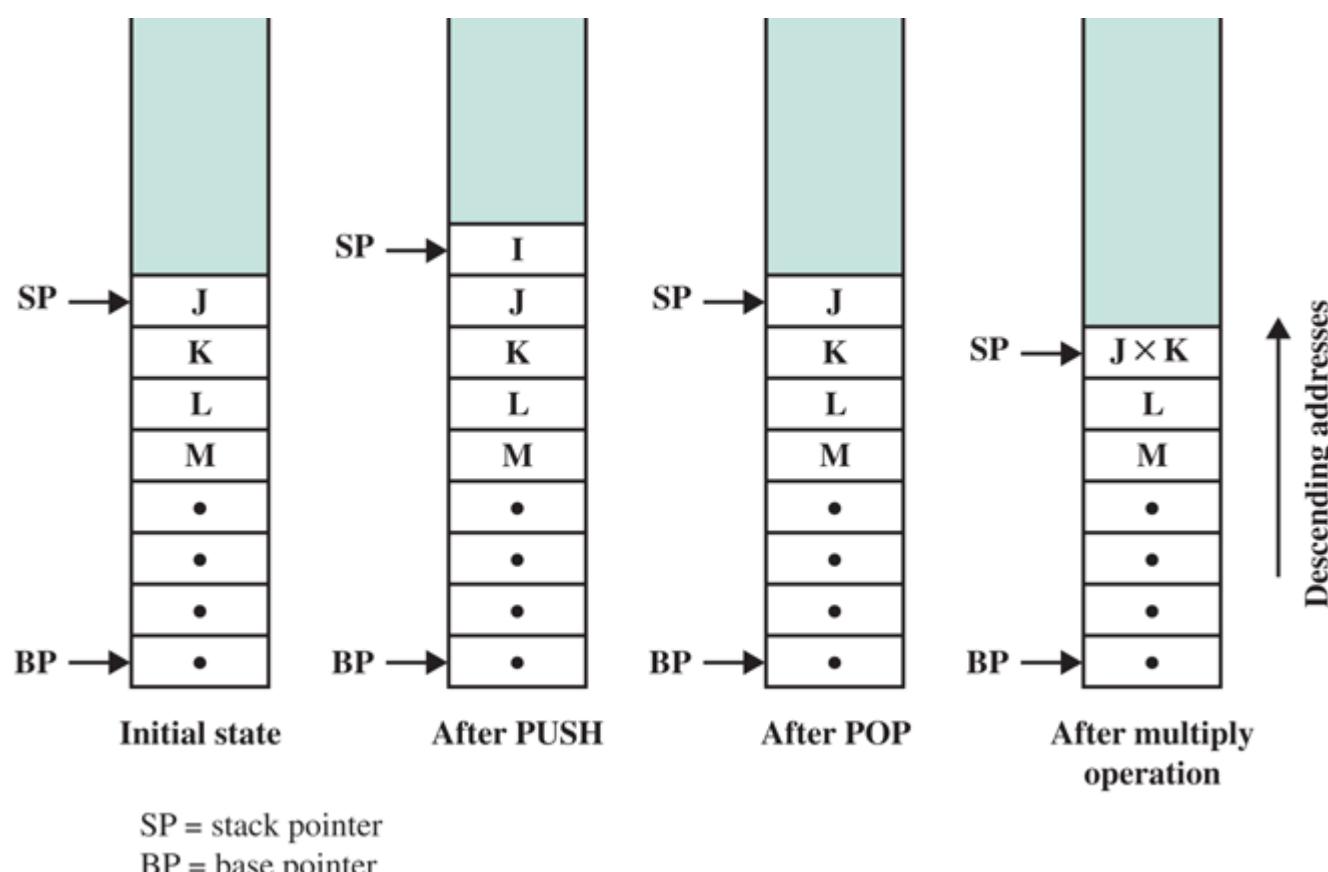

Figure E.1 Basic Stack Operation (full/descending)

Table E.1 Stack-Oriented Operations

PUSH	Append a new element on the top of the stack.
POP	Delete the top element of the stack.

Unary operation	Perform operation on top element of stack. Replace top element with result.
Binary operation	Perform operation on top two elements of stack. Delete top two elements of stack. Place result of operation on top of stack.

E.2 Stack Implementation

The stack is a useful structure to provide as part of a processor implementation. One use, discussed in [Section 13.4](#), is to manage procedure calls and returns. Stacks may also be useful to the programmer. An example of this is expression evaluation, discussed later in this section.

The implementation of a stack depends in part on its potential uses. If it is desired to make stack operations available to the programmer, then the instruction set will include stack-oriented operations, including PUSH, POP, and operations that use the top one or two stack elements as operands. Because all of these operations refer to a unique location, namely the top of the stack, the address of the operand or operands is implicit and need not be included in the instruction. These are the zero-address instructions referred to in [Section 13.1](#).

If the stack mechanism is to be used only by the processor, for such purposes as procedure handling, then there will not be explicit stack-oriented instructions in the instruction set. In either case, the implementation of a stack requires that there be some set of locations used to store the stack elements. A typical approach is illustrated in [Figure E.2](#). A contiguous block of locations is reserved in main memory (or virtual memory) for the stack. Most of the time, the block is partially filled with stack elements and the remainder is available for stack growth.

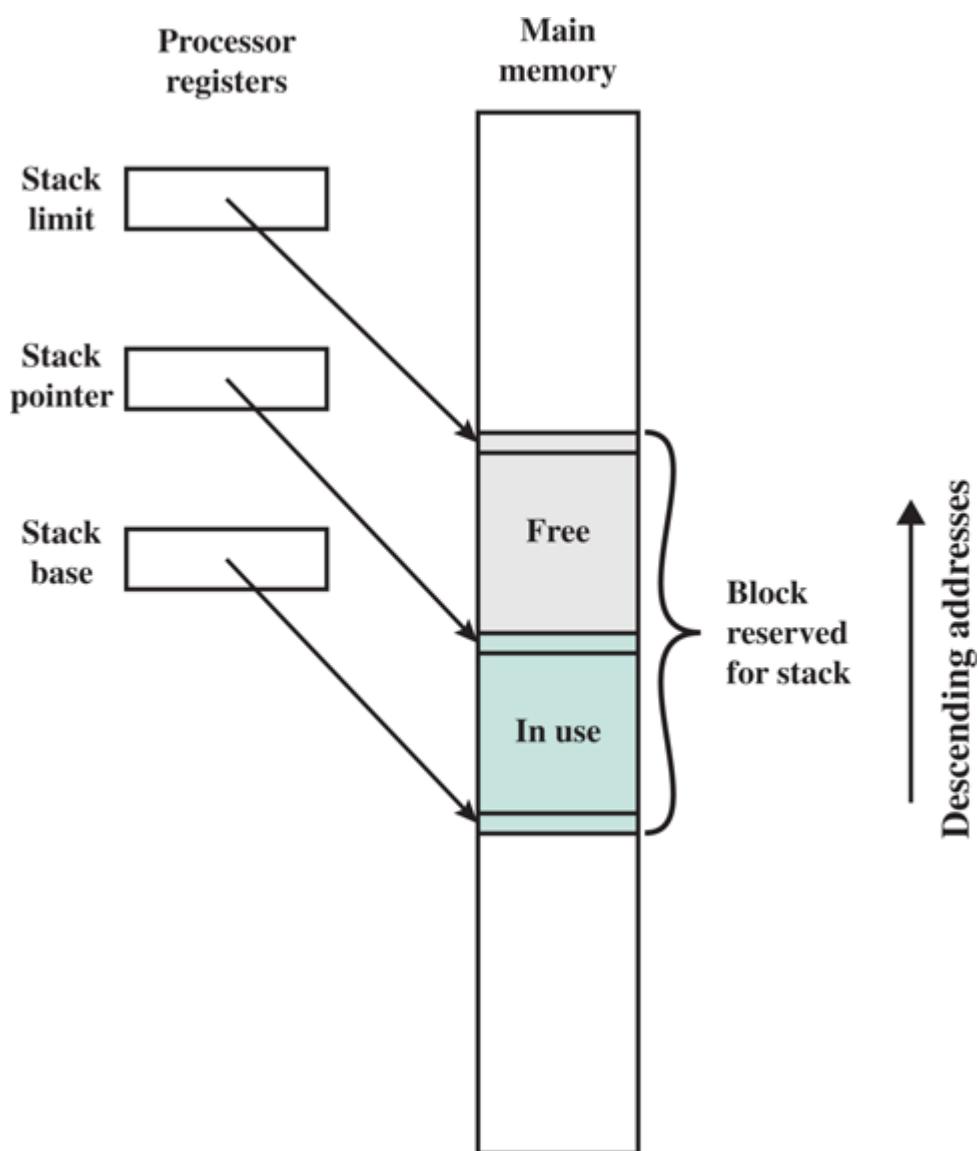

Figure E.2 Typical Stack Organization (full/descending)

Three addresses are needed for proper operation, and these are often stored in processor registers:

- **Stack pointer (SP):** Contains the address of the top of the stack. If an item is appended to or deleted from the stack, the pointer is incremented or decremented to contain the address of the new top of the stack.
- **Stack base:** Contains the address of the bottom location in the reserved block. If an attempt is made to POP when the stack is empty, an error is reported.
- **Stack limit:** Contains the address of the other end of the reserved block. If an attempt is made to PUSH when the block is fully utilized for the stack, an error is reported.

Stack implementations have two key attributes:

- **Ascending/descending:** An ascending stack grows in the direction of ascending addresses, starting from a low address and progressing to a higher address. That is, an ascending stack is one in which the SP is incremented when items are pushed and decremented when items are pulled. A descending stack grows in the direction of descending addresses, starting from a high address and progressing to a lower one. Most machines implement descending stacks as a default.
- **Full/empty:** This is a misleading terminology, because it does not refer to whether the stack is completely full or completely empty. Rather, the SP can either point to the top item in the stack (full method), or the next free space on the stack (an empty method). For the full method, when the stack is completely full, the SP points to the upper limit of the stack. For the empty method, when the stack is completely empty, the SP points to the base of the stack.

Figure E.1 is an example of a descending/full implementation (assuming that numerically lower addresses are depicted higher on the page). The ARM architecture allows the system programmer to specify the use of ascending or descending, empty or full stack operations. The x86 architecture uses a descending/empty convention.

E.3 Expression Evaluation

Mathematical formulas are usually expressed in what is known as **infix** notation. In this form, a binary operator appears between the operands (e.g., $a + b$). For complex expressions, parentheses are used to determine the order of evaluation of expressions. For example, $a + (b \times c)$ will yield a different result than $(a + b) \times c$. To minimize the use of parentheses, operations have an implied precedence.

Generally, multiplication takes precedence over addition, so that $a + b \times c$ is equivalent to $a + (b \times c)$.

An alternative technique is known as **reverse Polish**, or **postfix**, notation. In this notation, the operator follows its two operands. For example,

$$\begin{array}{ll} a + b & \text{becomes } a\ b\ + \\ a + (b \times c) & \text{becomes } a\ b\ c\ \times\ + \\ (a + b) \times c & \text{becomes } a\ b\ +\ c\ \times \end{array}$$

Note that, regardless of the complexity of an expression, no parentheses are required when using reverse Polish.

The advantage of postfix notation is that an expression in this form is easily evaluated using a stack. An expression in postfix notation is scanned from left to right. For each element of the expression, the following rules are applied:

1. If the element is a variable or constant, push it onto the stack.
2. If the element is an operator, pop the top two items of the stack, perform the operation, and push the result.

After the entire expression has been scanned, the result is on the top of the stack.

The simplicity of this algorithm makes it a convenient one for evaluating expressions. Accordingly, many compilers will take an expression in a high-level language, convert it to postfix notation, and then generate the machine instructions from that notation. [Figure E.3](#) shows the sequence of machine instructions for evaluating $f = (a - b) / (c + d \times e)$ using stack-oriented instructions. The figure also shows the use of one-address and two-address instructions. Note that, even though the stack-oriented rules were not used in the last two cases, the postfix notation served as a guide for generating the machine instructions. The sequence of events for the stack program is shown in [Figure E.4](#).

	Stack	General Registers	Single Register
	Push a	Load R1, a	Load d
	Push b	Subtract R1, b	Multiply e
	Subtract	Load R2, d	Add c
	Push c	Multiply R2, e	Store f
	Push d	Add R2, c	Load a

	Push e	Divide R1, R2	Subtract b
	Multiply	Store R1, f	Divide f
	Add		Store f
	Divide		
	Pop f		
Number of instructions	10	7	8
Memory access	$10\text{op} + 6d$	$7\text{op} + 6d$	$8\text{op} + 8d$

Figure E.3 Comparison of Three Programs to Calculate $f = e + \frac{a - b}{(d \times e)}$

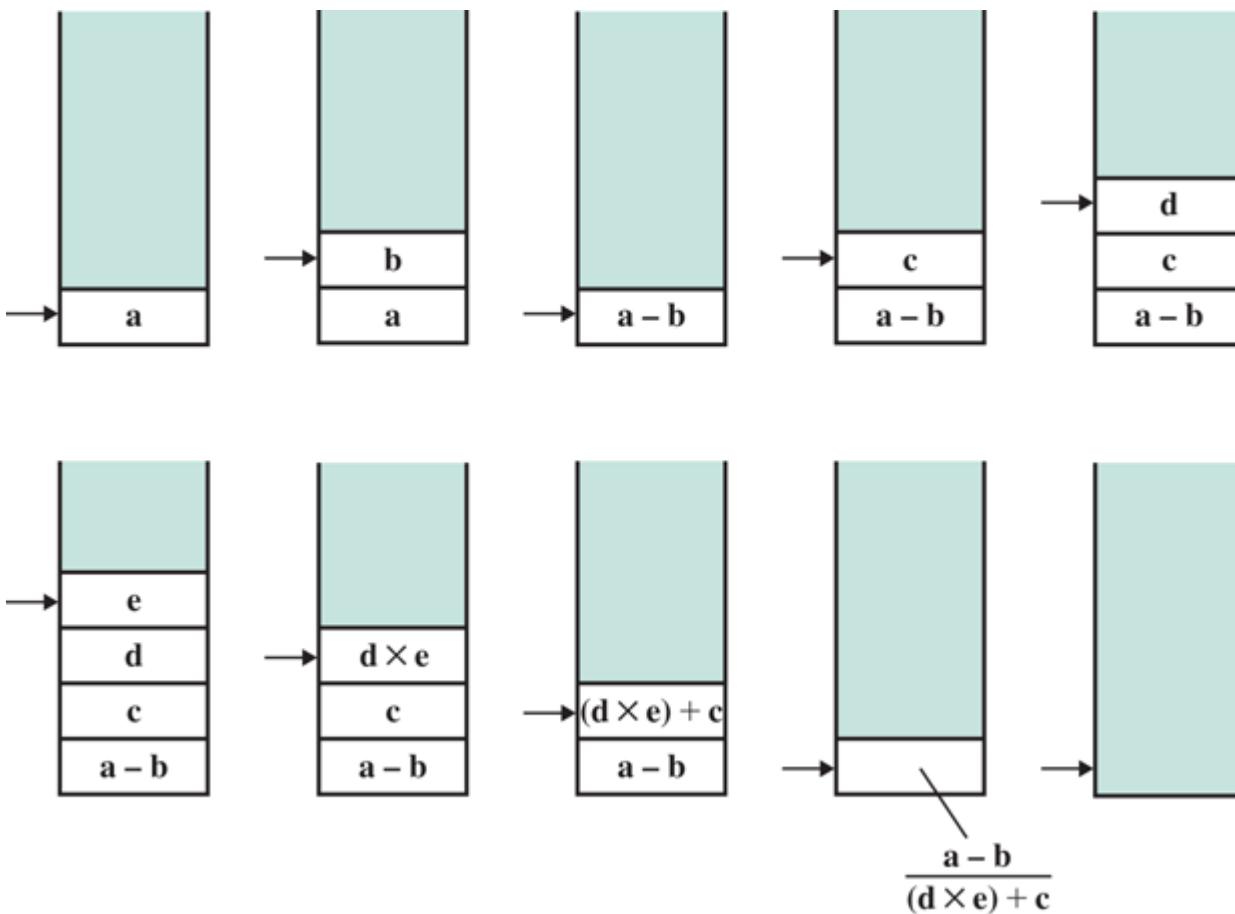

Figure E.4 Use of Stack to Compute $f = (a - b) / [(d \times e) + c]$

The process of converting an infix expression to a postfix expression is itself most easily accomplished using a stack. The following algorithm is due to Dijkstra [DIJK63]. The infix expression is scanned from left to right, and the postfix expression is developed and output during the scan. The steps are as follows:

1. Examine the next element in the input.
2. If it is an operand, output it.

3. If it is an opening parenthesis, push it onto the stack.
4. If it is an operator, then
 - If the top of the stack is an opening parenthesis, then push the operator.
 - If it has higher priority than the top of the stack (multiply and divide have higher priority than add and subtract), then push the operator.
 - Else, pop operation from stack to output, and repeat step 4.
5. If it is a closing parenthesis, pop operators to the output until an opening parenthesis is encountered. Pop and discard the opening parenthesis.
6. If there is more input, go to step 1.
7. If there is no more input, unstack the remaining operands.

Figure E.5 illustrates the use of this algorithm. This example should give the reader some feel for the power of stack-based algorithms.

Figure E.5 Conversion of an Expression from Infix to Postfix Notation

Input	Output	Stack (top on right)
$A + B \times C + (D + E) \times F$	empty	empty
$+ B \times C + (D + E) \times F$	A	empty
$B \times C + (D + E) \times F$	A	+
$\times C + (D + E) \times F$	A B	+
$C + (D + E) \times F$	A B	+x

Appendix F Recursive Procedures

F.1 RECURSION

F.2 ACTIVATION TREE REPRESENTATION

[Fibonacci Numbers](#)

[Ackermann's Function](#)

F.3 STACK IMPLEMENTATION

F.4 RECURSION AND ITERATION

Recursion is an important concept that cuts across many areas of computer science. Daniel McCracken, a noted computer science educator [MCCR87] considers recursion to be fundamental in computer science, whether understood as a mathematical concept, a programming technique, a way of expressing an algorithm, or a problem-solving approach.

Chapter 13 briefly mentions recursive procedures and the concept warrants elaboration, which is done in this appendix. Many students find recursion a difficult concept to grasp. Accordingly, this appendix covers a number of examples and uses various methods of description and presentation.

F.1 Recursion

One of the classic examples of recursion is the factorial function. The factorial of a positive integer is computed as that integer times all of the integers below it up to and including 1. For example, $\text{factorial}(5)$ is the same as $5 \times 4 \times 3 \times 2 \times 1$, and $\text{factorial}(3)$ is $3 \times 2 \times 1$. Now suppose that you want to compute the factorial of 27, and you already know the value of $\text{factorial}(26)$. Then, you don't need to compute $27 \times 26 \times 25 \times \dots \times 1$. Instead, you need only compute $27 \times \text{factorial}(26)$. Similarly, if you know the value of $\text{factorial}(53)$, then the value of $\text{factorial}(54)$ is computed as $\text{factorial}(54) = 54 \times \text{factorial}(53)$.

Thus, in general, we can state that $\text{factorial}(n) = n \times \text{factorial}(n - 1)$. However, as written, this definition involves an infinite recurrence, with the procedure calling itself recursively indefinitely. We need a condition that will stop the recursion; this is known as a **base case**. For the factorial function, the base case is $n = 1$, with $\text{factorial}(1) = 1$. We can then write the factorial function in C as follows:

```
int factorial(int n)
{
    if(n == 1)
        return 1;
    else
        return n * factorial(n - 1);
}
```

The base case, or halting case, of a function is the value that can be expressed without any more recursive calls. Every recursive function must have at least one base case (many functions have more than one). If it doesn't, the function will not work correctly most of the time, and will most likely cause the program to crash. The **general case** is one in which a recursive call takes place. In the case of a factorial, the general case occurs when $n > 1$, meaning we use the equation and recursive definition $n! = n * (n - 1)!$.

The reader may at first be uncomfortable with the concept of a function or procedure that calls itself. We look at how to implement such a function in a later section. For now, just assume that it does work—that a function can call itself without causing an error condition in the operating system.

So far, what we have seen presents the essence of recursion in programming. First, it involves a function that calls itself. And second, the function definition must include a base case that enables the function to terminate the recursive process.

The factorial function is an example of the use of recursion to program a mathematical algorithm. However, recursion is far more versatile. It is often appropriate for dealing with linked lists, tree structures, and search and sort algorithms. As an example, consider the binary search algorithm. Let `sortedArray[]` be an array sorted in descending order. The binary search algorithm locates a particular value in the sorted list. If the value is found, the algorithm returns the position of the value. If the value is not in the list, then the algorithm returns the negative of the insertion position:

```
int BinarySearch(int sortedArray[], int key, int first, int last) {
    if (first <= last) {
        int mid = (first + last) / 2;
```

```
if (key == sortedArray[mid])
    return mid; /* found */
else if (key < sortedArray[mid])
    return BinarySearch(sortedArray, key, first, mid-1);
else /* key > sortedArray[mid] */
    return BinarySearch(sortedArray, key, mid+1, last);
}
return -(first); /* not found */
}
```

F.2 Activation Tree Representation

To facilitate the understanding of recursive procedures, [HAYN95] introduced the activation tree. The recursion tree is a tree where each node is the “current environment.” That is, each node contains parameters, local variables, and return values. Using this technique, it is easy to identify a node as a particular procedure executing in a particular environment. The parent of a node is the procedure that called the node. The children of a node are the procedures, which that node calls.

Figure F.1a shows the generic form of an activation tree node. The node includes the function name, the parameters passed to the function, and the values returned by the function. If the function name appears multiple times in the function definition, then each is distinguished by a unique subscript.

Figure F.1b shows an example of the call/return structure of a procedure that has been called. The circled numbers in the nodes indicate the order in which nodes are activated. The dynamic execution of the program follows depth first traversal of the activation tree. The top node is the first invocation of the function. Multiple invocations from a node are listed as children, with the invocations left to right. All of this should be clear as we examine two examples.

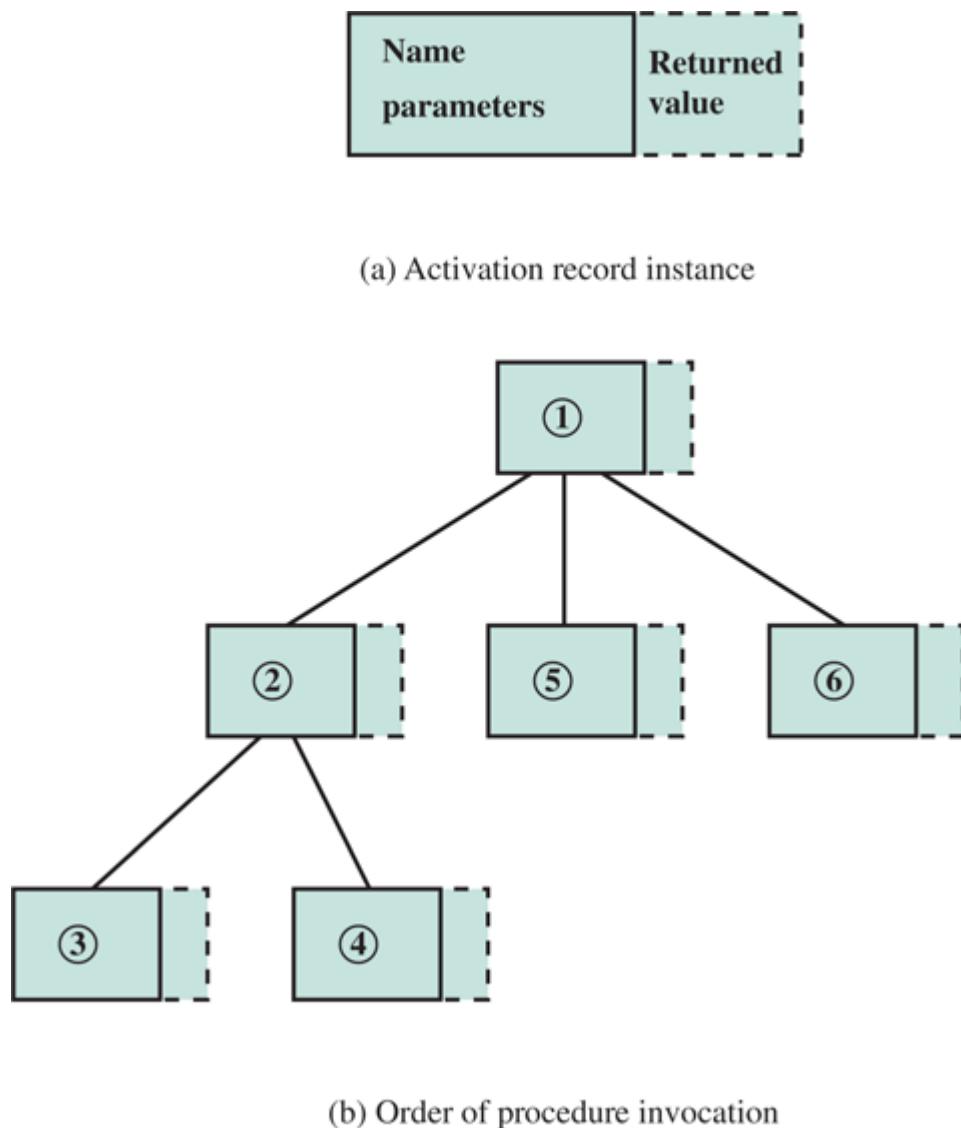

Figure F.1 Activation Record Conventions

Fibonacci numbers are defined as follows:

$$\begin{aligned}\text{Fib}(k) &= \text{Fib}(k-1) + \text{Fib}(k-2); \\ \text{Fib}(2) &= 1; \\ \text{Fib}(1) &= 1;\end{aligned}$$

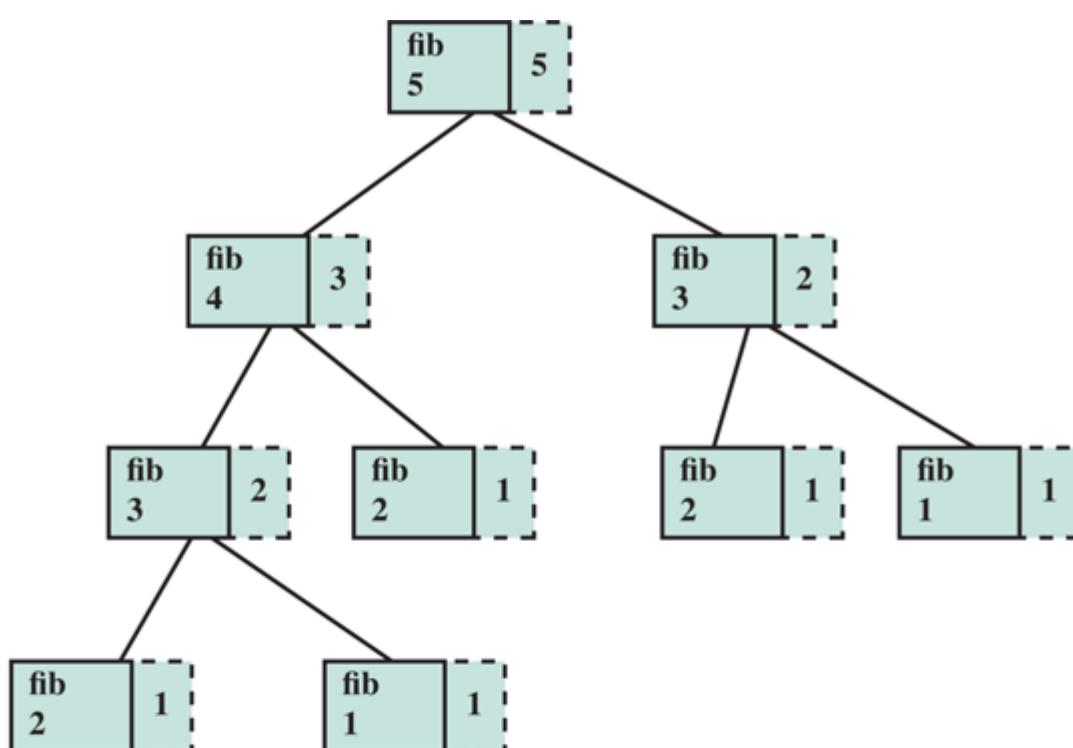

That is, each Fibonacci number is the sum of the preceding two numbers. It turns out that Fibonacci series occurs in many contexts in nature. The start of the series is as follows:

1 1 2 3 5 8 13 21 34 55 89 144 233 377 610 987

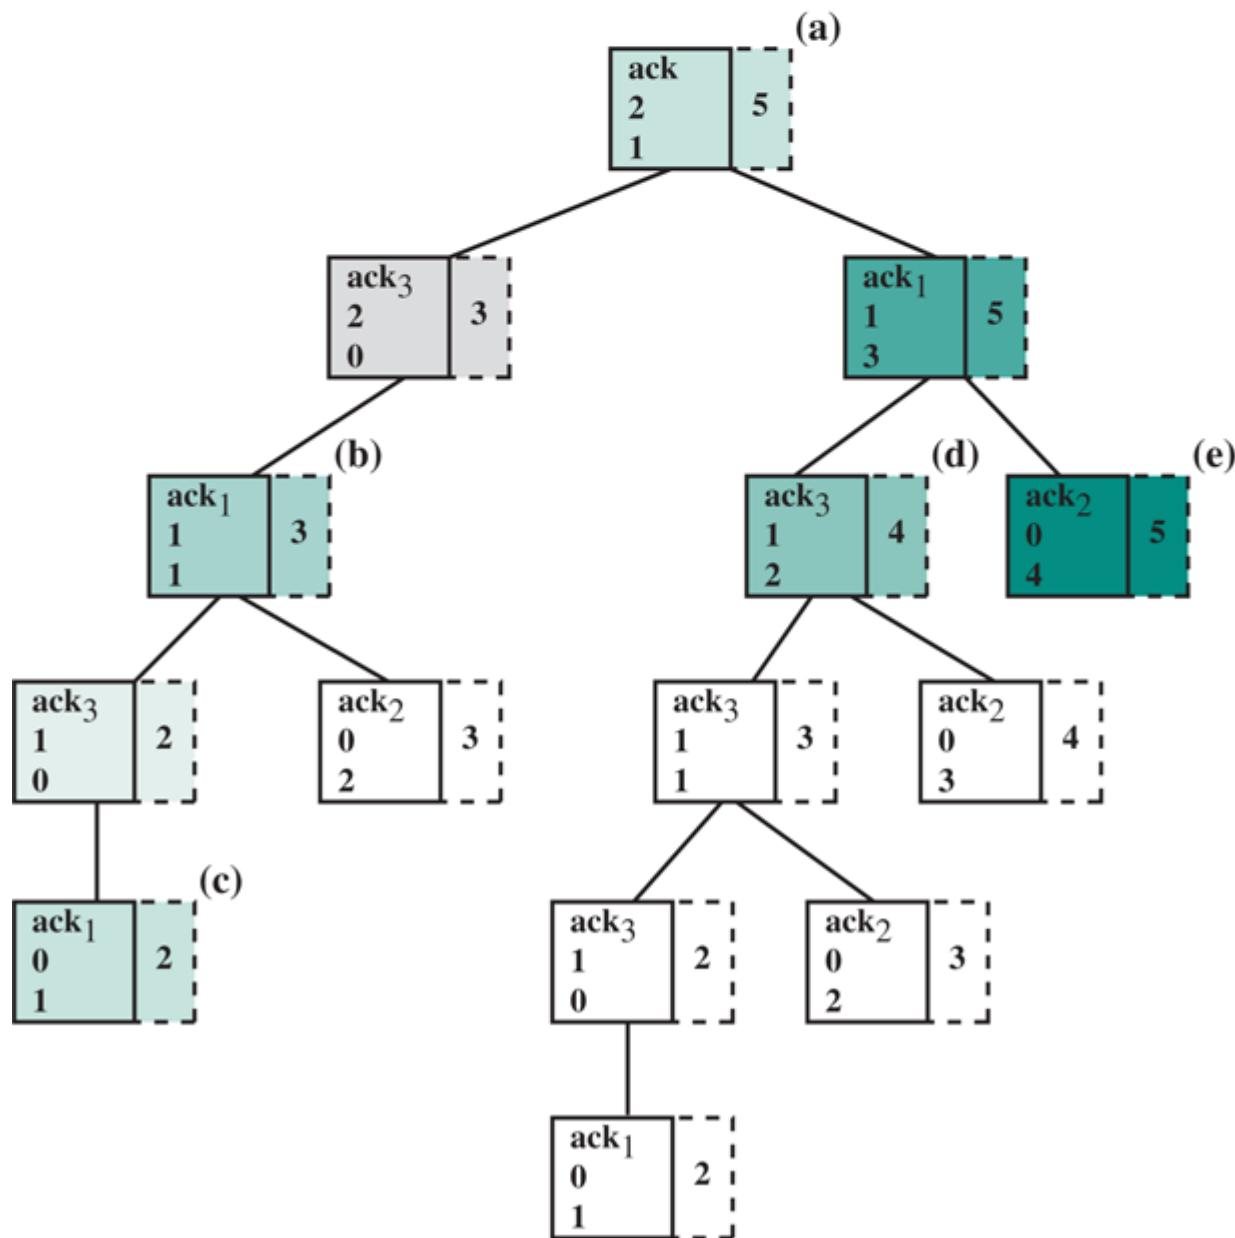

Here is a recursive program for the Fibonacci series:

```
int function fib(n)
{
    if (n == 1 || n == 2)
        return 1;
    else
        return fib(n-1) + fib(n-2);
}
```

Figure F.2a shows the activation tree for $\text{fib}(5)$, which yields a result of 5. The topology of the tree is derived from the execution, and the execution is closely tied to the inductive definition (which was used to write the function). For example, the activation tree shows that the node for $\text{Fib}(5)$ has two children: $\text{Fib}(4)$ and $\text{Fib}(3)$. That is, the value calculated for $\text{Fib}(5)$ must use the values calculated for $\text{Fib}(4)$ and $\text{Fib}(3)$. The activation tree has the return values placed in the right-side box, making the return value accessible to the student. According to the definition of Fib , the values for $\text{Fib}(4)$ and $\text{Fib}(3)$ must be added together in order to obtain the value for $\text{Fib}(5)$. If we replace the “5” in $\text{Fib}(5)$ by “ n ”, then the activation tree tells us that $\text{Fib}(n)$ is a function of $\text{Fib}(n-1)$ and $\text{Fib}(n-2)$. The leaves of the activation tree correspond to the base case(s) of the inductive definition. Thus, $\text{Fib}(2)$ returns immediately with the value of 1.

(a) Activation tree for Fibonacci (5)

(b) Activation tree for Ackermann (2, 1)

Figure F.2 Recursion Examples

Here is a corresponding execution trace:

Figure F.3a repeats **Figure F.2a**, showing the sequence in which the activation records are visited. This is a depth-first traversal of the tree, with a left-to-right sequence at each level.

(a) Activation tree for Fibonacci (5)

(b) Activation tree for Ackermann (2, 1)

Figure F.3 Recursion Examples: Execution Trace

Ackermann's Function

A more interesting recursive function is the deceptively simple Ackermann's function:

```
int ack(int m, int n) {
    if (m==0) return (n + 1);
    if (n==0) return (ack (m-1,1));
    return (ack (m-1, ack(m, n-1) ) );
}
```

In this case, the function is invoked recursively but more than that, the function appears as an argument inside the recursive use of the function. The value of this function grows very rapidly, even for small inputs, and even though increases only result from addition of 1.. For example, A(4, 2) contains 19,729 decimal digits.

To clarify the operation of this function, we label each recursive call with a unique subscript. In each case, it is the same function; the subscripts simply make it easier to keep track of what is happening:

```
int ack(int m, int n) {
    if (m==0) return (n + 1);
    if (n==0) return (ack1 (m-1,1));
    return (ack2 (m-1, ack3 (m, n-1) ) );
}
```

Figure F.2b shows the activation tree for $\text{ack}(2, 1)$, which has the following execution trace:

```

Entering: ACK, Argument list: (2 1) // (a)
    Entering: ACK, Argument list: (2 0)
        Entering: ACK, Argument list: (1 1) // (b)
            Entering: ACK, Argument list: (1 0)
                Entering: ACK, Argument list: (0 1) // (c)
                    Exiting: ACK, Value: 2
                Exiting: ACK, Value: 2
            Entering: ACK, Argument list: (0 2)
                Exiting: ACK, Value: 3
            Exiting: ACK, Value: 3
        Exiting: ACK, Value: 3
    Entering: ACK, Argument list: (1 3)
        Entering: ACK, Argument list: (1 2) // (d)
            Entering: ACK, Argument list: (1 1)
                Entering: ACK, Argument list: (1 0)
                    Entering: ACK, Argument list: (0 1)
                        Exiting: ACK, Value: 2
                    Exiting: ACK, Value: 2
                Entering: ACK, Argument list: (0 2)
                    Exiting: ACK, Value: 3
                Exiting: ACK, Value: 3
            Exiting: ACK, Value: 3
        Entering: ACK, Argument list: (0 3)
            Exiting: ACK, Value: 4
        Exiting: ACK, Value: 4
    Entering: ACK, Argument list: (0 4) // (e)
        Exiting: ACK, Value: 5
    Exiting: ACK, Value: 5
Exiting: ACK, Value: 5

```

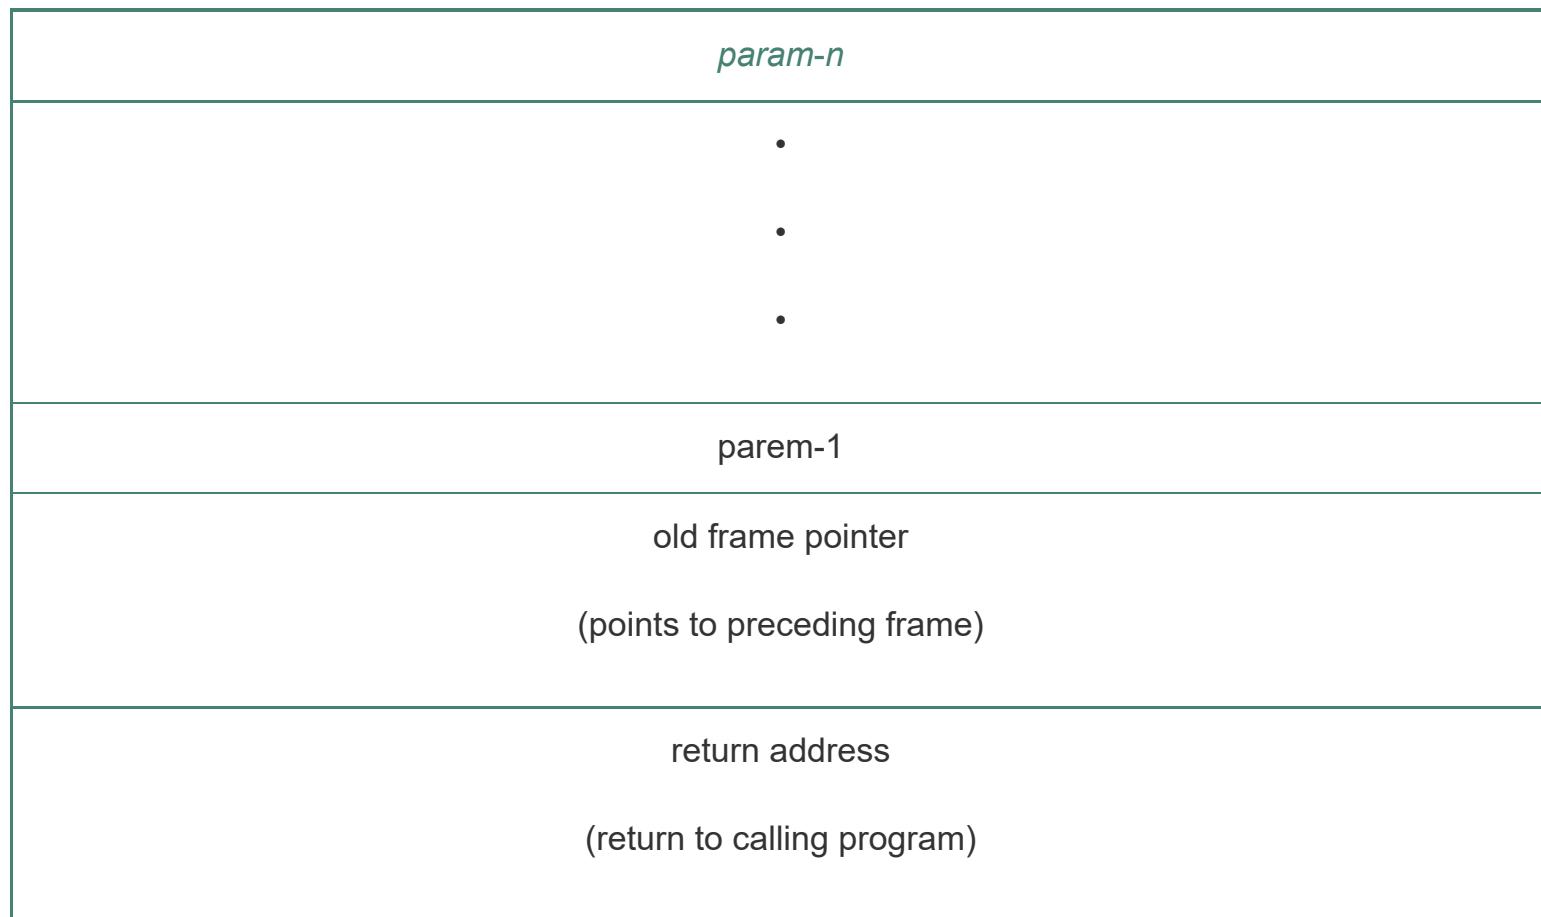

Some of the lines in the execution trace have labels that correspond to labels on the activation tree. This is for illustrative purposes only.

Figure F.3b shows the sequence in which the activation records are visited.

F.3 Stack Implementation

Implementation of recursive procedures in programming languages almost always involves the use of a stack. Each call of the procedure causes a stack frame, or activation record instance, to be pushed onto the control stack. As discussed in [Chapter 13 \(Figure 13.10\)](#), a stack frame includes a return address, passed parameters, a frame pointer, and perhaps other bookkeeping information. When the called procedure returns to the calling procedure, the stack for the called procedure is popped from the stack.

The exact contents and organization of a stack frame depend on the implementation. For our purposes, we consider a “model” stack frame that includes the following elements, illustrated with the top of the stack at the top of the diagram:

Associated with the stack are a stack pointer, which points to the current top element of the stack, and a frame pointer, which points to the old frame pointer field in the top frame. When a call is made from the current program, a new frame is created by:

1. Push the return address of the calling program.
2. Push the current frame pointer.
3. Push all parameters to be passed to the called program.

The called program may access the passed parameters. The called program may call another program, resulting in a new stack frame being pushed onto the stack. When the called program returns:

1. Pop all the elements of the current frame from the stack.
2. If any parameters are to be returned to the calling program, push these onto the stack, where

- they become part of the calling program's stack frame.
3. Update the stack pointer to the new top of the stack.
 4. Update the frame pointer to the value that was in the old frame pointer field that has just been popped from the stack.
 5. Resume execution at the return address that has just been popped from the stack.

The preceding technique works whether the programs are distinct or all the same. That is, the same technique works with a recursive program that calls itself as well as the more usual situation.

Figure F.4 shows the control stack at the labeled points in **Figure F.2b** for the function Ackermann (2, 1).

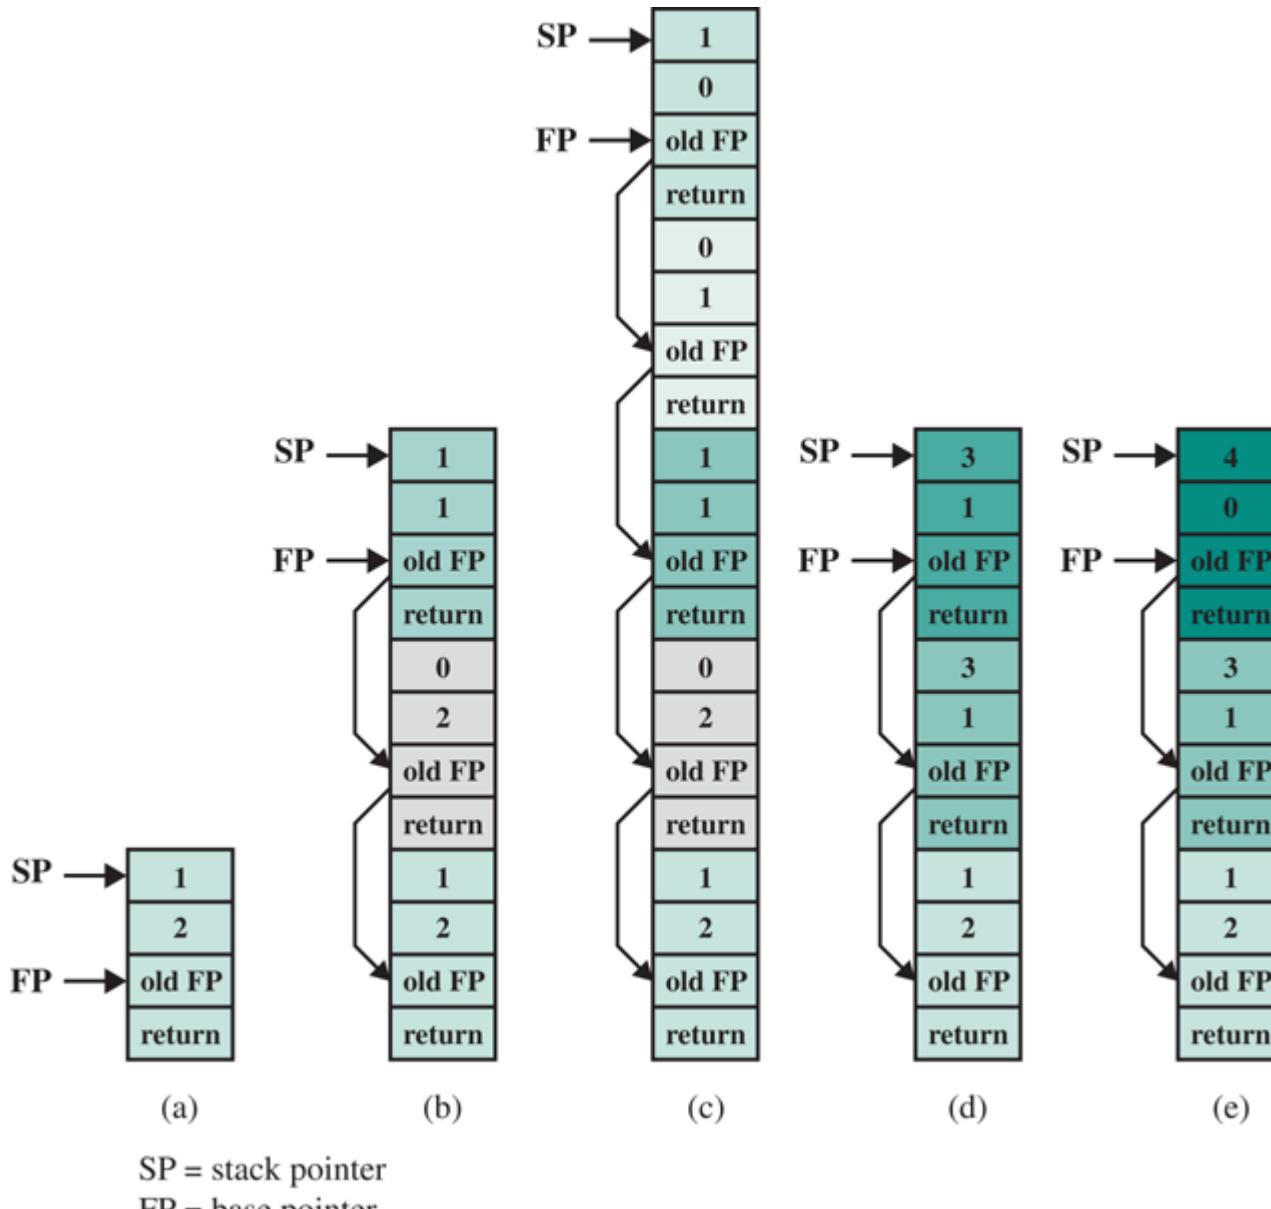

Figure F.4 Snapshots of Stack During Execution of **Figure F.2b**

F.4 Recursion And Iteration

It can be shown that any recursive definition of an algorithm can be rewritten using only iteration, that is, using only loop constructs [RICE65]. In many cases, the recursive definition is more compact in a programming language that allows recursion, and is more understandable, particularly if the function operates on a recursive data structure such as a tree. However, typically a recursive program uses both more memory and more processing time than an equivalent iterative solution.

As an example, consider the factorial function, which we defined as:

```
int factorial(int n)
{
    if(n == 1)
        return 1;
    else
        return n * factorial(n - 1);
}
```

This can easily be rewritten iteratively as:

```
int factorial(int n)
{
    int nfactorial;
    for (nfactorial = 1; n != 0; --n)
        nfactorial *= n;
    return nfactorial;
}
```

Now, to compute $\text{factorial}(n)$ recursively would require n instances of the variable to be created on the control stack and n calls and returns, which generates n stack frame creations and deletions. In the iterative solution, there is a single variable, and only one stack frame created.

However, there are many cases in which the recursive technique is more natural and easier to program. Consider the binary search algorithm introduced earlier. To repeat, the recursive version is as follows:

```
int BinarySearch(int sortedArray[], int key, int first, int last) {
    if (first <= last) {
        int mid = (first + last) / 2;
        if (key == sortedArray[mid])
            return mid;                                /* found */
        else if (key < sortedArray[mid])
            return BinarySearch(sortedArray, key, first, mid-1);
        else                                         /* key > sortedArray[mid] */
            return BinarySearch(sortedArray, key, mid+1, last);
    }
    return -(first);                                /* not found */
```

```
}
```

Here is an iterative version:

```
int BinarySearch(int sortedArray[], int key, int first, int last) {  
    int low = first;  
    int high = last;  
    while (low <= high) {  
        int mid = (low + high) / 2;  
        if (key == sortedArray[mid])  
            return mid; /* found */  
        else if (key < sortedArray[mid])  
            high = mid - 1;  
        else /* key > sortedArray[mid] */  
            low = mid + 1;  
    }  
    return -(first); /* not found */  
}
```

The iterative algorithm requires two temporary variables, and even given knowledge of the algorithm it is more difficult to understand the process by simple inspection, although the two algorithms are very similar in their steps.

Table F.1 summarizes some of the differences between recursion and iteration.

Table F.1 Properties of Iteration and Recursion

Property	Iteration Loop	Recursive Procedure
Repetition	Execute the same block of code repeatedly to obtain the result; signal the intent to repeat by looping back to the loop entrance.	Execute the same block of code repeatedly to obtain the result; signal the intent to repeat by calling itself.
Terminating conditions	In order to guarantee that it will terminate, a loop must have one or more conditions that cause it to terminate and it must be guaranteed at some point to hit one of these conditions.	In order to guarantee that it will terminate, a recursive function requires a base case that causes the function to stop recursing.
State	Current state is updated as the loop progresses.	Current state is passed as parameters.

This appendix expands on some topics referenced in [Chapters 16](#) through [18](#).

G.1 Pipeline Reservation Tables

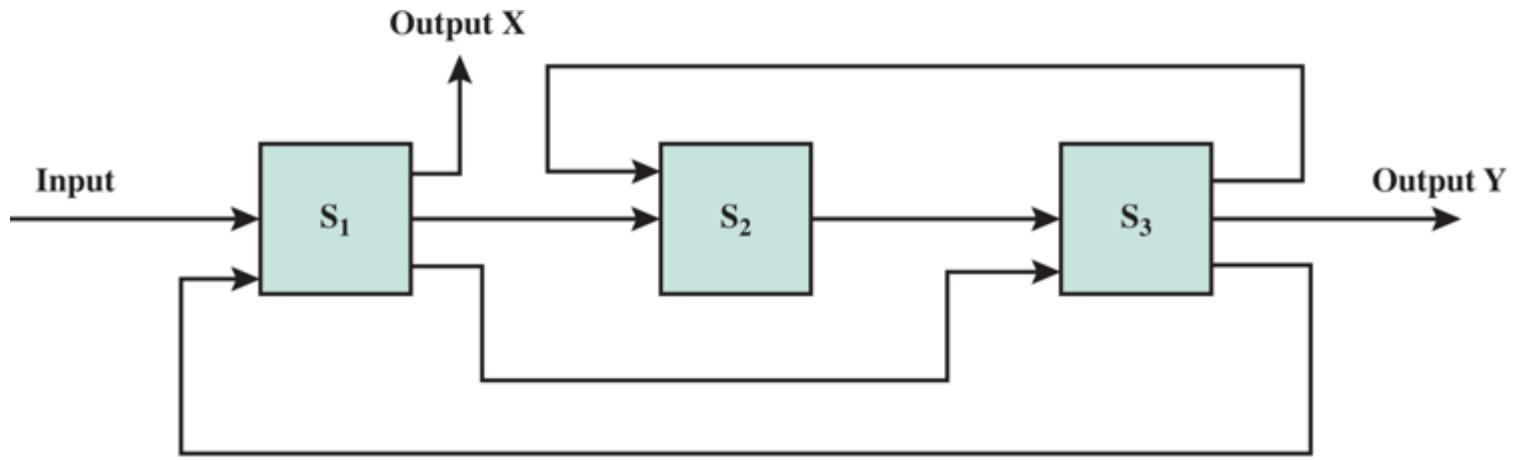

A central problem in pipeline design is that of ensuring that the pipeline can achieve the highest throughput consistent with avoiding structural hazards. That is, we would like to feed instructions into the pipeline at the highest rate that can be achieved without having collisions in the use of a shared resource. One of the earliest techniques introduced for this purpose is the reservation table ([DAVI71], [DAVI75], [PATE76]).

A reservation table is a timing diagram that shows the flow of data through a pipeline and indicates which resources are needed at each time interval by an instruction flowing through the pipeline.

Reservation Tables for Dynamic Pipelines

First, we look at the more general case of a dynamic pipeline. A dynamic pipeline is one that can be reconfigured to support different functions at different times. Further, such a pipeline might involve feedforward and feedback connections. Most instruction pipelines will not exhibit all of this flexibility, although some dynamic features may appear in some implementations. In any case, a static pipeline, which performs a fixed function without feedback or feedforward loops is just a special case for which the same principles apply.

Figure G.1a shows a multifunction dynamic pipeline. Two reservation tables are shown in **Figures G.1b** and **G.1c**, corresponding to a function X and a function Y. In the reservation table, the rows correspond to resources (in this case pipeline stages), the columns to time units, and an entry in row i , column j indicates that station i is busy at time j .

(a) A three-stage pipeline

	1	2	3	4	5	6	7	8	time
S ₁	X					X		X	
S ₂		X		X					
S ₃			X		X		X		

(b) Reservation table for function X

	1	2	3	4	5	6	time
S ₁	Y				Y		
S ₂			Y				
S ₃		Y		Y		Y	

(c) Reservation table for function Y

Figure G.1 Pipeline with Feedforward and Feedback Connections for Two Different Functions

The number of time units (clock cycles) between two initiations of a pipeline is the **latency** between them. Any attempt by two or more initiations to use the same pipeline resource at the same time will cause a **collision**. It is readily seen that a collision will occur if two instructions are initiated with a latency equal to the distance between two entries in a given row. From an examination of the reservation table, we can obtain a list of these forbidden latencies and build a **collision vector**:¹

¹ The online simulation used with this book defines the collision vector beginning with C₀. However, a latency of 0

will always produce a collision, so this convention is not followed in the literature. Also, some treatments of reservation tables use the reverse order for the collision vector: (C_1, C_2, \dots, C_n) .

$$(C_1, C_2, \dots, C_n)$$

where

$C_i = 1$ if i is a forbidden latency; that is, initiating a pipeline instruction i time units after the preceding instruction results in a resource collision

$C_i = 0$ if i is a permitted latency

n = largest value in the collision list.

Although these examples do not show it, there may be multiple consecutive entries in a row. This corresponds to a case in which a given pipeline stage requires multiple time units. There may also be multiple entries in a column, indicating the use of multiple resources in parallel.

To determine whether a given latency is forbidden or permitted, we can take two copies of the reservation table pattern and slide one to the right and see if any collisions occur at a given latency.

Figure G.2 shows that latencies 2 and 5 are forbidden. In the figure, the designation X_1 refers to the first initiation of function X, and X_2 refers to the second initiation. By inspection, we can also see that latencies 2, 4, 5, and 7 are all forbidden.

	1	2	3	4	5	6	7	8	9	10
S_1	X_1		X_2			X_1		X_1, X_2		X_2
S_2		X_1		X_1, X_2		X_2

	1	2	3	4	5	6	7	8	9	10	11
S_1	X_1					X_1, X_2		X_1			
S_2		X_1		X_1			X_2		X_2		\dots
S_3			X_1		X_1		X_1	X_2		X_2	

(b) Collision with scheduling latency 5

Figure G.2 Collisions with Forbidden Latencies 2 and 5 Using the Pipeline in Figure G.1 for the Function X

Latencies 1, 3, and 6 are permitted. Any latency greater than 7 is clearly permitted. Thus, the collision

vector for function X is:

$$C_X = (0101101)$$

We must be careful how we interpret the collision vector. Although a latency of 1 is permitted, we cannot issue a sequence of instructions, each with a latency of 1 to the preceding instruction. To see this, consider that the third instruction would have a latency of 2 relative to the first instruction, which is forbidden. Instead, we need a sequence of latencies that are permissible with respect to all preceding instructions. A **latency cycle** is a latency sequence that repeats the same subsequence indefinitely.

Figure G.3 illustrates latency cycles for our example that do not cause collisions. For example, **Figure G.3a** implies that successive initiations of new tasks are separated by one cycle and eight cycles alternately.

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21

Instruction Pipeline Example

Let us look now at the construction of a reservation table for a typical pipeline. Consider the following example. [Figure G.4](#) illustrates the pipeline and indicates the approximate amount of time for each stage. A straightforward attempt to develop a reservation table yields the result in [Figure G.5a](#). To develop this table, we use a fixed clock rate and synchronize all processing with this fixed clock. Each stage performs its function within one or more clock periods and shifts results to the next stage on the clock edge. For this example, we choose a 20-ns clock.

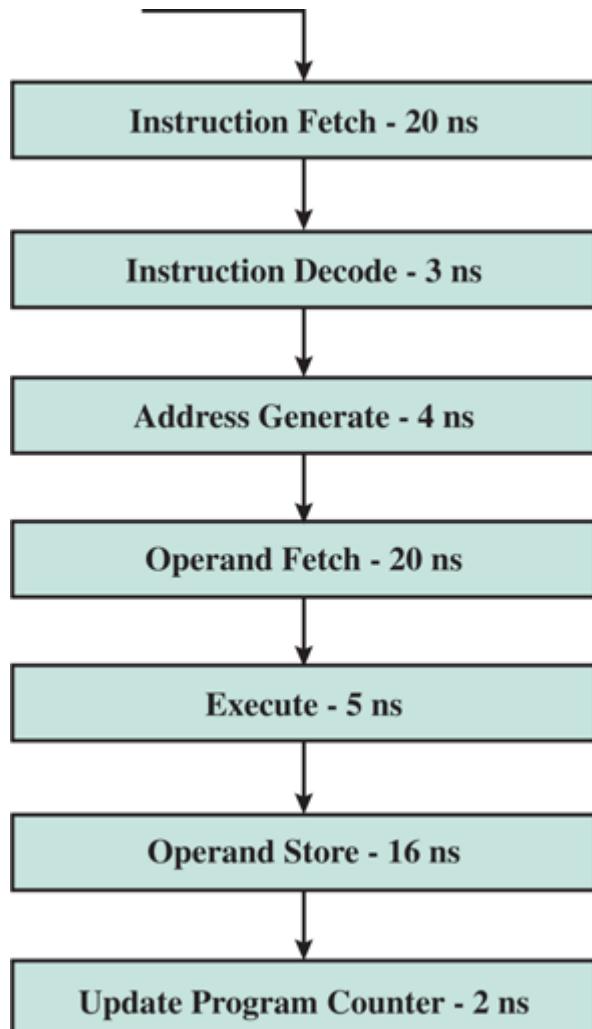

Figure G.4 An Instruction Pipeline

Instr Dec					X											
Addr Gen						X										
Execute										X						
Update PC																X

(b) Reservation table: second attempt

Figure G.5 Reservation Table for an Instruction Pipeline

However, we need to keep in mind that the rows of the table are supposed to correspond to resources, not simply pipeline stages. In [Figure G.5b](#), we modify the reservation table to reflect that the memory operations are using the same functional unit. Here, the only permissible latency is 15.

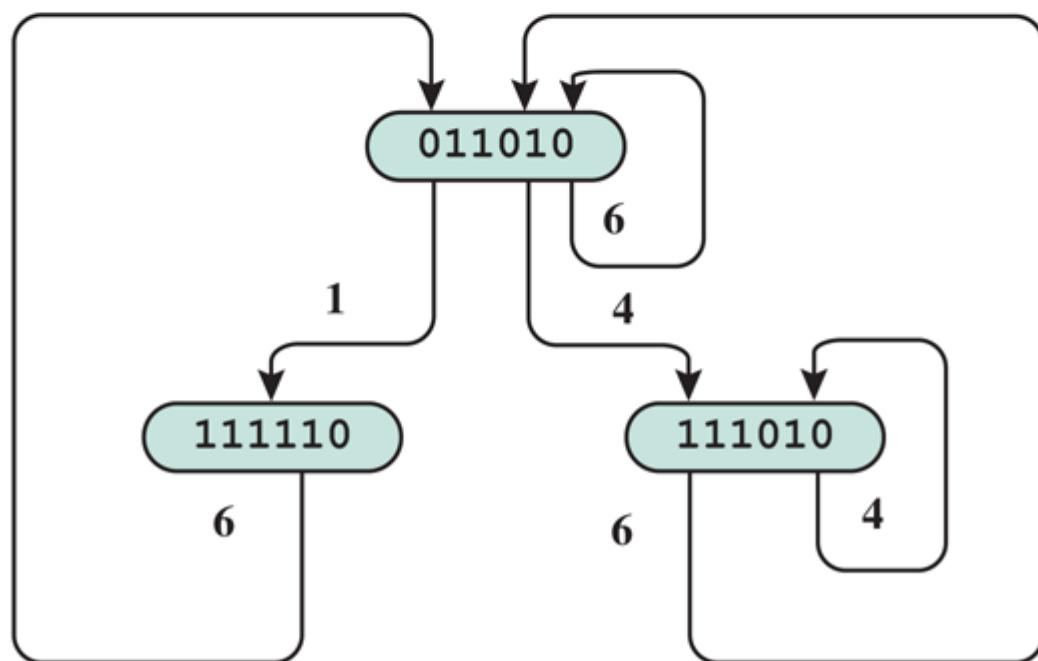

Now suppose that we implement an on-chip cache and reduce memory access time to one clock cycle. The revised reservation table is shown in [Figure G.6a](#). By sliding one copy of the reservation table pattern over another, we easily discover that the collision vector is 011010. The question then arises as to what schedule will provide the lowest average latency. As [Figure G.3](#) indicates, there are a number of possibilities for any given collision vector.

time →

	1	2	3	4	5	6	7

Addr Gen							
Execute					X		
Update PC							X

Collision vector = 011010

(a) Reservation table

(b) State transition diagram

Figure G.6 Reservation Table and State Transition Diagram for Revised Instruction Pipeline

A convenient tool for determining when we can initiate a new process into the pipeline and avoid collisions, when some operations are already in the pipeline, is the collision vector state transition diagram. The procedure for creating the state diagram is as follows:

1. Shift the collision vector left one position, inserting a 0 in the rightmost position. Each 1-bit shift corresponds to an increase in latency by 1.
2. Continue shifting until a 0 bit emerges from the left end. When a 0 bit emerges after p shifts, this means that p is a permissible latency.

3. The resulting collision vector represents the collisions that can be caused by the instruction currently in the pipeline. The original collision vector represents the collisions that can be caused by the instruction that we now insert into the pipeline. To represent all the collision possibilities, we create a new state by bitwise-ORing the initial collision vector with the shifted register.
4. Repeat this process from the initial state for all permissible shifts.
5. Repeat this process from all newly created states for all permissible shifts. In each case, bitwise OR with the original collision vector.

Figure G.6b shows the result for the reservation table of **Figure G.6a**. The state diagram shows that, after we have initiated an operation into an empty pipeline, we can initiate a new operation into the pipeline after 1 cycle. However, this brings us to a state where we cannot initiate another operation until 6 more time units. This gives us an average latency of 3.5 for a seven-stage pipeline, which is not very good. Alternatively, we can wait for 4 time units after the initial operation begins, and then initiate a new operation every 4 cycles. This yields even poorer performance, with an average latency of 4.

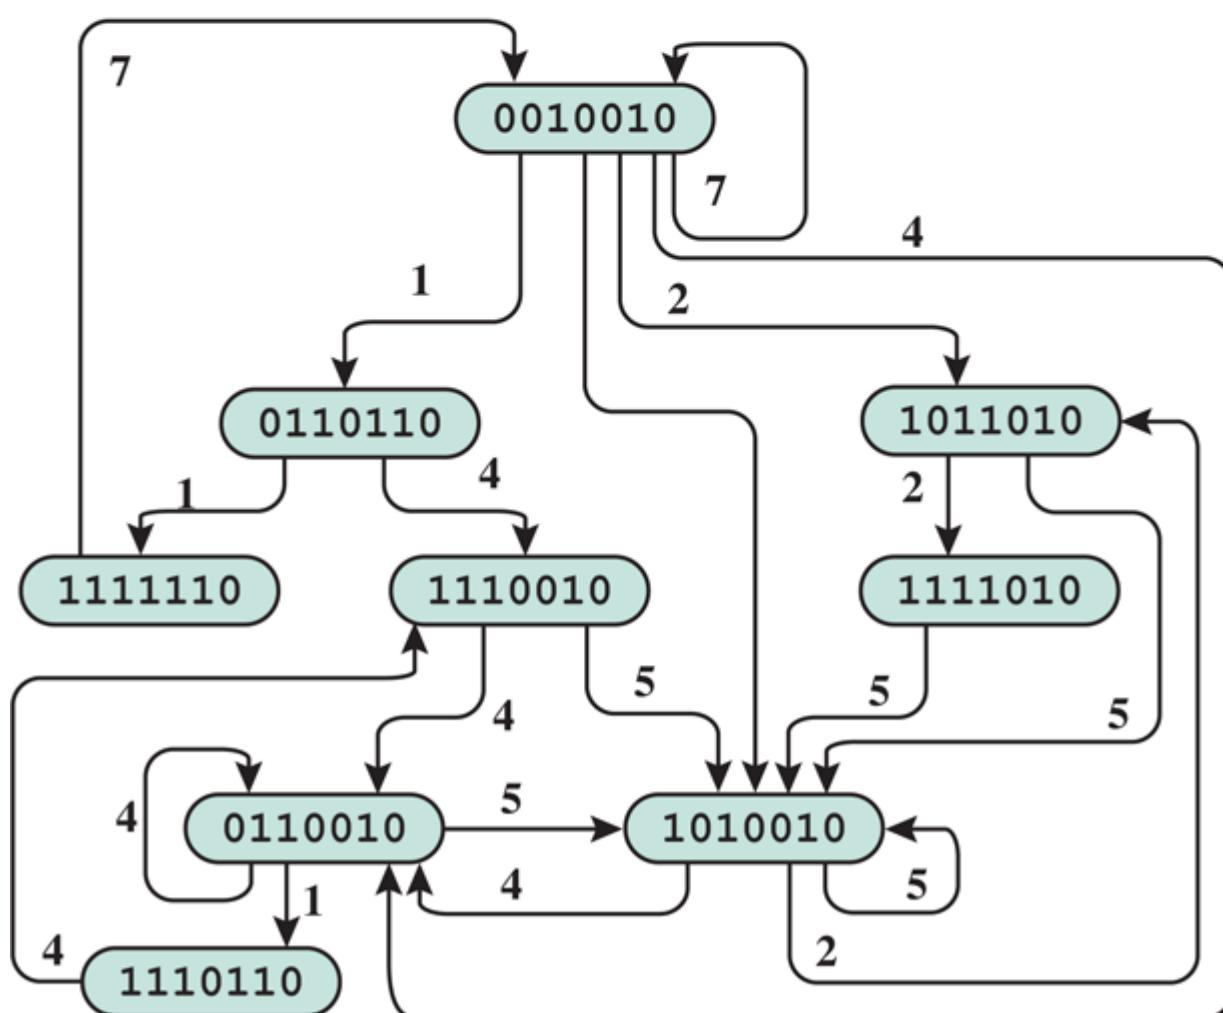

A clever way to achieve better performance is to actually introduce a deliberate delay into the pipeline. Suppose that we put a one-cycle delay after the execute stage. This results, in effect, in an 8-stage pipeline. The reservation table is shown in **Figure G.7a**, where the entry D indicates a delay. This yields a collision vector of 0011010. We now have latency possibilities of 1, 2, 4, and 7. **Figure G.7b** shows the resulting state transition diagram.² We now look for a closed loop, or cycle, through the state diagram that yields the minimum average latency.

² All the states have an arc back to the beginning with a latency of 7, in addition to those noted. These are not shown for clarity.

	time

Instr Dec		X						
Addr Gen			X					
Execute					X	D		
Update PC								X

Collision vector = 0011010

(a) Reservation table

(b) State transition diagram

Figure G.7 Reservation Table and State Transition Diagram for Instruction Pipeline with Delay Inserted

One possibility is the greedy cycle. A **greedy cycle** is one whose edges are all made with minimum

latencies from their respective starting positions; that is, at each state, they choose the exiting edge with the smallest latency value. In this case, the greedy cycle has latency values 1, 1, 7, so that the average latency is $9 / 3 = 3$. A careful study of the diagram shows that, in this case, no other cycle produces a smaller average latency.

G.2 Reorder Buffers

As was mentioned in [Chapter 18](#), a common superscalar technique to support out-of-order completion is the reorder buffer [SMIT88]. The reorder buffer is temporary storage for results completed out of order that are then committed to the register file in program order.

To explain the operation of the reorder buffer, we first need to look at a technique that supports in-order completion, known as the result shift register.

In-Order Completion

With in-order completion, an instruction is dispatched and allowed to modify the machine state (register values, interrupt status) only if no preceding instruction has caused an interrupt condition. This restriction ensures that an instruction will not be retired until preceding instructions have completed any changes to the register file.

The processor controls the writing of results to registers by means of a **result shift register**.³ The result shift register is a table with as many entries (rows) as there are pipeline stages in the longest execution pipeline ([Figure G.8](#)). Each entry, if valid, refers to a single instruction, and consists of four fields:

³ The term *shift register* is somewhat misleading. The shift is not a bitwise shift, left or right, but rather a shift of all of the entries in the data structure up one entry position, with the topmost entry shifted out of the structure.

Stage	Functional Unit Source	Destination Register	Valid Bit	Program Counter
1				
2				
3				
4				
5				
⋮	⋮	⋮	⋮	⋮
⋮	⋮	⋮	⋮	⋮
⋮	⋮	⋮	⋮	⋮
N				

Figure G.8 Result Shift Register

- **Functional unit source:** the functional unit that will be supplying the result.
- **Destination register:** the destination register for the result.
- **Valid bit:** indicates whether this entry currently contains valid information.
- **Program counter:** location of the instruction.

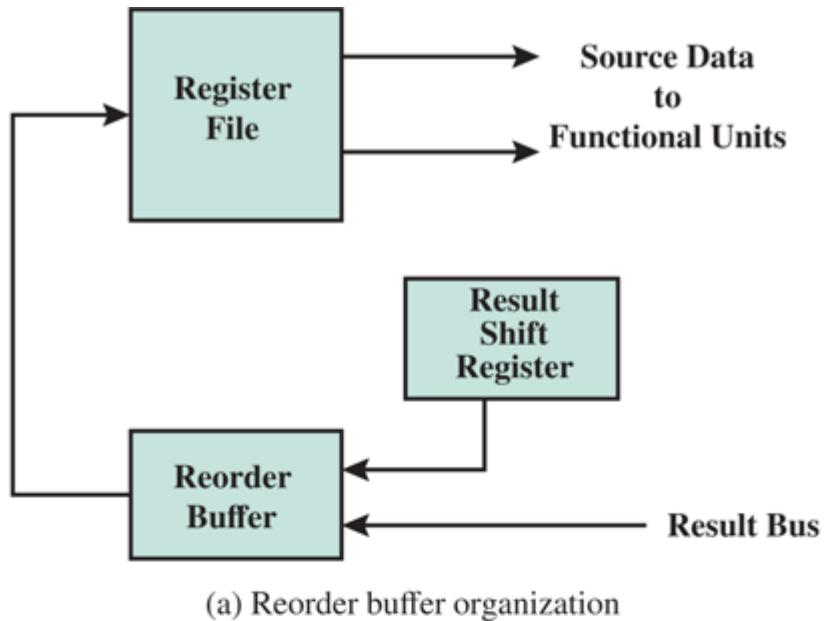

An instruction that takes i clock periods reserves stage i of the result shift register at the time it issues. If the valid bit of stage i is already set, then instruction issue is held until the next clock period, and

stage i is checked once again. When an entry can be made, the four fields of the entry are filled in. At the same time, all entries in the result shift register from 1 through $i - 1$ that are not in use are filled with null information, but the valid bit is set. This prevents a following short-latency instruction from reserving any of the lines preceding i , and therefore ensures that no instruction is issued if it will finish execution before a logically preceding instruction.

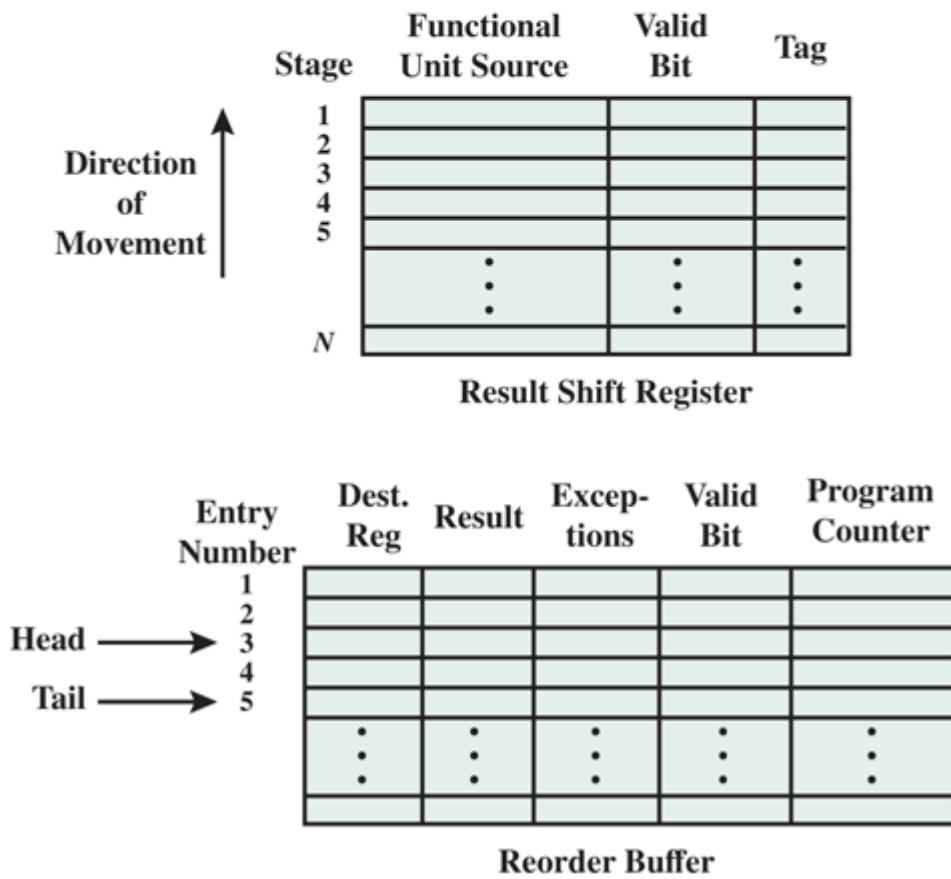

Finally, at each clock cycle, entry 1 of the register is deleted, the remaining entries are shifted up one row, and a null entry is placed in row N .

Out-of-Order Completion

The reorder buffer is used to support out-of-order completion by delaying the retiring of a completed instruction until results can be posted in the logically correct order. [Figure G.9a](#) shows the organization for this approach. A modified result shift register is still used, but this now provides input to the reorder buffer. Results from completed instructions also provide input to the reorder buffer. The update of registers with results from completed instructions takes place through the reorder buffer, which, as the name suggests, reorders results from completed instructions to assure correct execution.

(a) Reorder buffer organization

(b) Reorder buffer and associated result shift register

Figure G.9 Reorder Buffer Implementation

Figure G.9b shows the details of the two data structures used in this approach. The **reorder buffer** is a circular buffer with head and tail pointers. Entries between the head and the tail are considered valid.⁴ When an instruction issues, the next available reorder buffer entry, pointed to by the tail pointer, is given to the issuing instruction. The entry number value for this instruction is used as a tag to identify the entry in the buffer reserved for the instruction. The tag is placed in the result shift register along with other control information. The tail pointer is then incremented, modulo the buffer size. The result shift register differs from the one used earlier because there is a field containing a reorder tag instead of a field specifying a destination register.

- 4 If the head is greater than the tail, the valid entries are from the head to the end of the buffer, then from the beginning of the buffer to the tail.

When an instruction completes, results are sent to the reorder buffer. The tag from the result shift register is used to guide them to the correct reorder buffer entry. When an entry at the head of the reorder buffer contains valid results (its instruction has completed), the results are written into the registers.

Note that the entries in the reorder buffer are in the order in which the instructions are issued. Thus the reorder buffer enforces a write to the registers in the logically correct order. That is, the reorder buffer serves as temporary storage for results that may be completed out of order, and then commits these results to the register file in program order. The result shift register is not strictly necessary in this arrangement, but does provide an indexing mechanism into the reorder buffer so that it is not necessary to do an associative lookup after each instruction completion.

G.3 Tomasulo's Algorithm

Tomasulo's algorithm was developed for the IBM 360/91 floating point unit [TOMA67]. It was subsequently used in a number of IBM 360/370 machines, CDC 6600/7600 machines, PowerPC implementations, and other processors. The algorithm minimizes RAW hazards by tracking when operands for instructions are available. It also minimizes WAW and WAR hazards by the renaming of registers to remove artificial dependencies and the use of buffers, known as reservation stations, that permit data to be temporarily stored, thus eliminating the need to read from the register file once the data are available.

The reservation stations fetch and store instruction operands as soon as they are available. Source operands point to either the register file or to other reservation stations. Each reservation station corresponds to one instruction. Once all source operands are available, the instruction is sent for execution, provided a functional unit is also available. Once execution is complete, the result is buffered at the reservation station. Thus, the functional unit is free to execute another instruction. The reservation station then sends the result to the register file and any other reservation station that is waiting on that result. WAW hazards are handled since only the last instruction (in program order) actually writes to the registers. The other results are buffered in other reservation stations and are eventually sent to any instructions waiting for those results. WAR hazards are handled since reservation stations can get source operands from either the register file or other reservation stations (in other words, from another instruction). In Tomasulo's algorithm, the control logic is distributed among the reservation stations.

An example of the organization for Tomasulo's algorithm is shown in [Figure G.10](#). This is the organization for the original implementation of the floating point unit of the IBM 360/91.

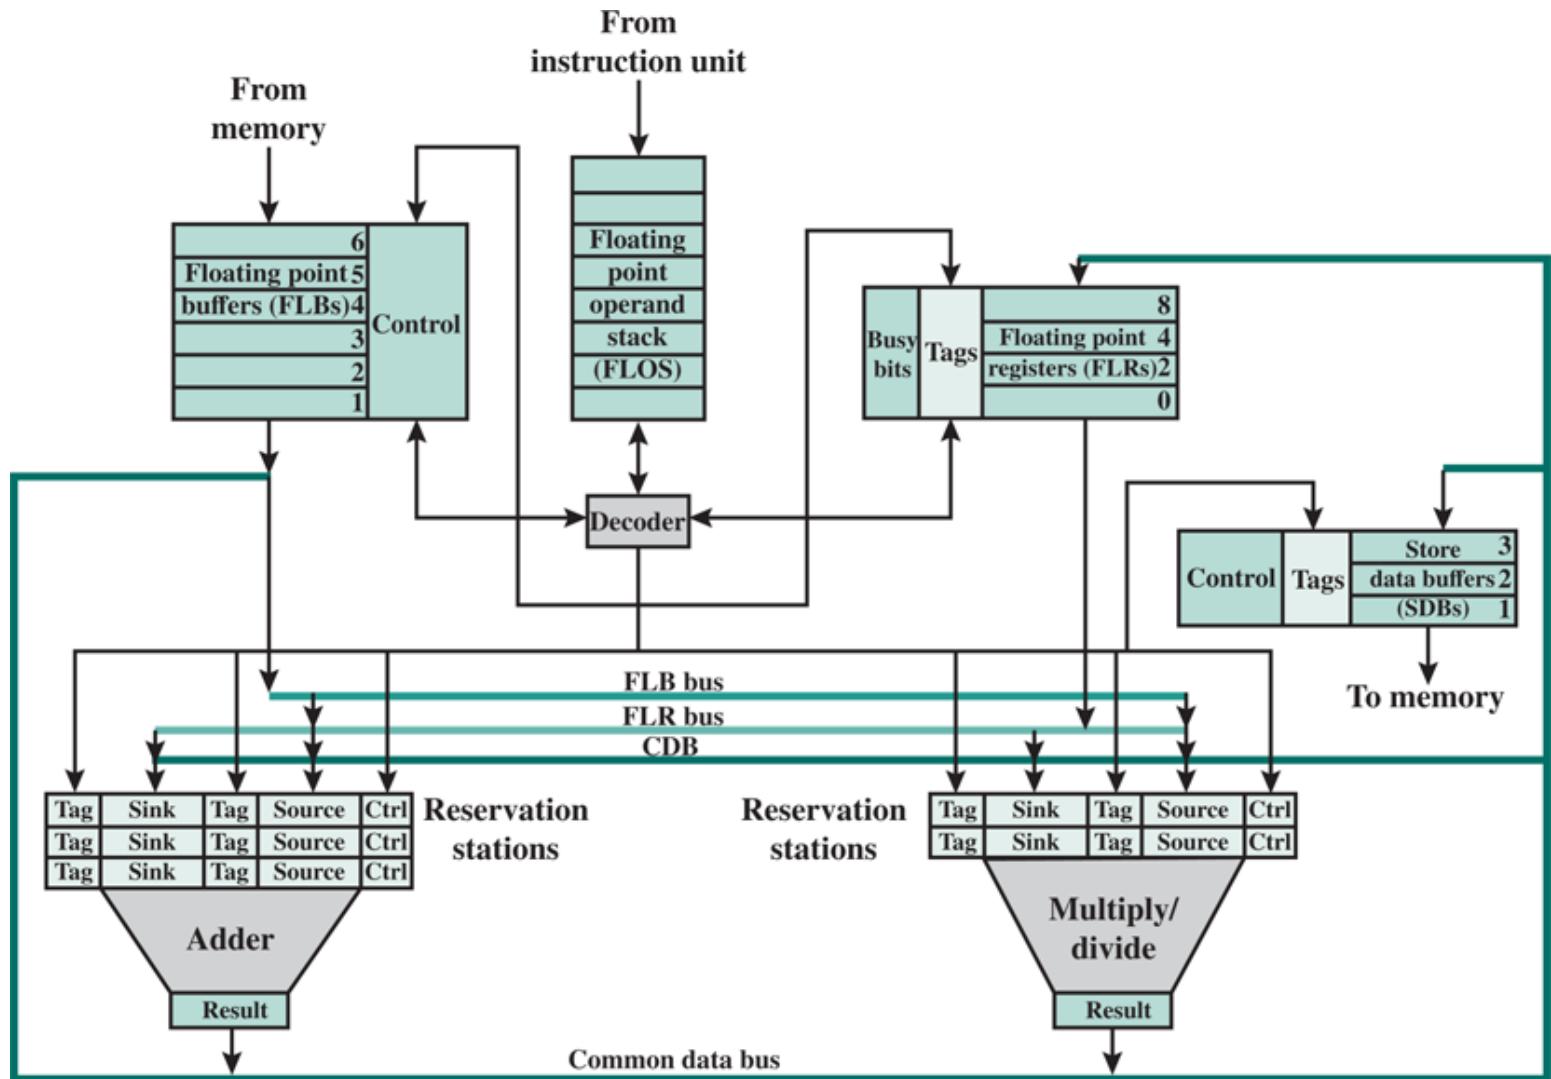

Figure G.10 Basic Structure of a Floating-Point Unit Using Tomasulo's Algorithm

To get a feel for the algorithm, let us follow an instruction through the stages of a typical Tomasulo processor. Note that each stage here may correspond to more than one actual pipeline stage:

- **Fetch:** Just like in a simple scalar processor, instructions are fetched from instruction memory. Unlike a simple scalar processor, instructions are likely to be fetched in batches of two or more at a time.
- **Issue:** The processor determines which reservation station to issue the instruction to, based on what type of functional unit it requires, and the availability of space in the reservation stations. Instructions can be issued to reservation stations regardless of whether or not their operands are available. If an operand is not available to be read from the register file immediately, this must be because the value associated with that register has not yet been calculated. If this is the case, then the operand will be updated with the result of an instruction that has already been issued, which instruction is therefore already assigned to a reservation station. Hence, as the issue unit issues the instruction to its reservation station, it renames any references to outstanding registers with an identifier tag which indicates which functional unit will produce the result, and which virtual register identifier the result will be identified as. The issue unit also renames any result registers associated with the new instruction to a virtual register identifier so that it can tell subsequent instructions where to find the results of this instruction.
- **Execute:** The execution stage of a processor implementing Tomasulo's algorithm consists of a number of functional units, each with their own reservation station. The reservation station holds a small number of instructions that have been issued, but cannot yet be executed. When an instruction becomes ready to be executed because of operand values becoming available (by

being broadcast on the common data bus), and the functional unit is ready to accept a new instruction, the reservation station passes the instruction to the functional unit, where the instruction's real execution takes place: arithmetic operations are calculated, memory is accessed.

- **Writeback:** The final stage an instruction goes through is writeback. This is similar in many ways to a simple pipelined machine: when the result of an instruction has been calculated, the value is driven on one of a number of common data buses, to be sent to the register file. This bus is also monitored by other parts of the machine so that the value may be used immediately by waiting instructions.

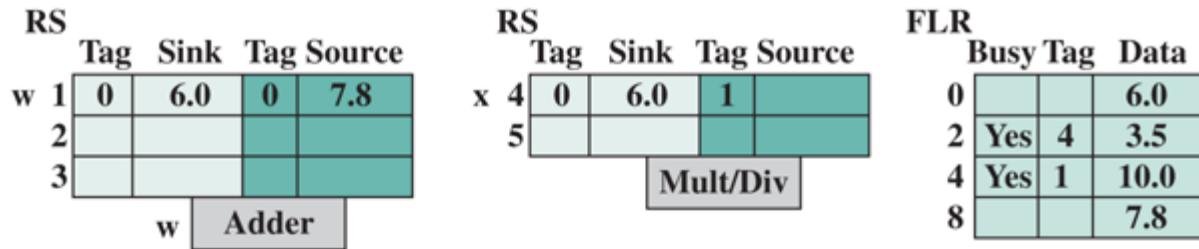

To get a feel for the algorithm, we present an example for a typical processor organization using Tomasulo's algorithm. We assume that each instruction includes references to three floating-point registers as operands. Up to two instructions can be dispatched (in program order) at a time. We also assume that an instruction can begin execution in the same cycle that it dispatched to a reservation station. Latencies for floating point add and multiply operations are two and three cycles per instruction, respectively. An instruction can forward its result to dependent instructions during its last execution cycle, and a dependent instruction can begin execution in the next cycle. Tag values 1, 2, and 3 are used to identify the three reservation stations of the adder functional unit, while values 4 and 5 are used to identify the two reservation stations of the multiply/divide functional unit.

The example sequence consists of the following program fragment:

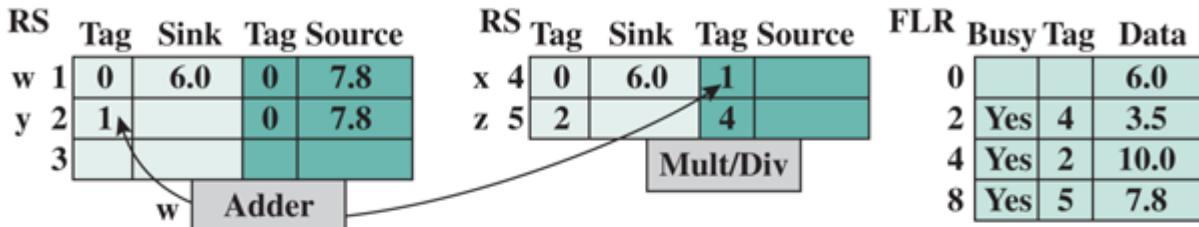

```
w: R4 ← R0 + R8  
x: R2 ← R0 × R4  
y: R4 ← R4 + R8  
z: R8 ← R4 × R2
```

The initial values of registers R0, R2, R4, and R8 are 6.0, 3.5, 10.0, and 7.8, respectively. [Figure G.11](#) illustrates six cycles of execution of the program.

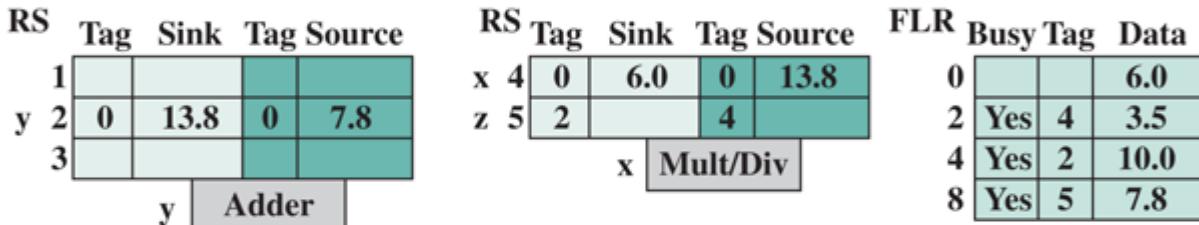

CYCLE 1: Dispatched instructions: w, x (in order)

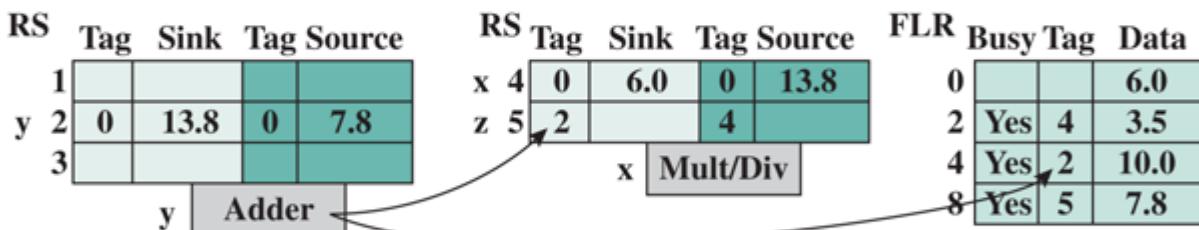

CYCLE 2: Dispatched instructions: y, z (in order)

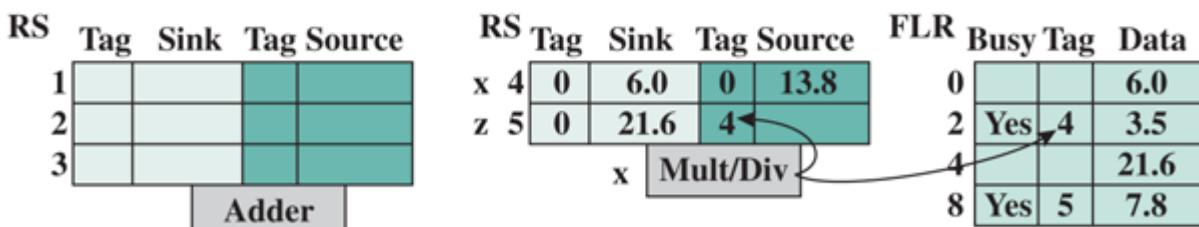

CYCLE 3: Dispatched instructions:

CYCLE 4: Dispatched instructions:

CYCLE 5: Dispatched instructions:

CYCLE 6: Dispatched instructions:

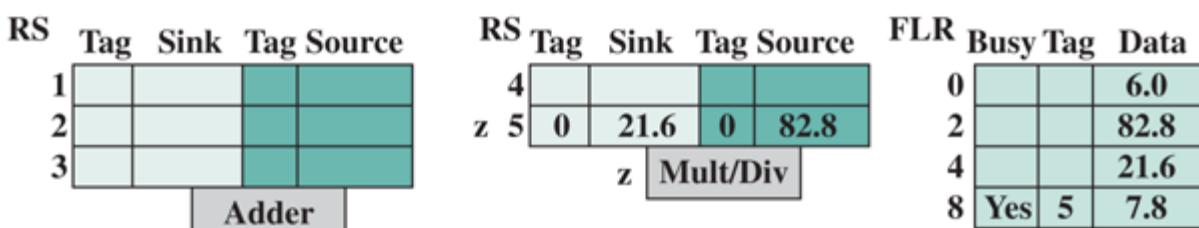

Figure G.11 Illustration of Tomasulo's Algorithm on an Example Instruction Sequence

- **Cycle 1:** Instructions w and x are dispatched (in order) to reservation stations (RSs) 1 and 4, respectively. The busy bits of the destination registers for these instructions (R4 for w, R2 for x) are set in the floating point register (FLR) file. The tag field for R2 is set to 4, indicating that the instruction in RS 4 will produce the result for updating R2. Similarly, the tag field for R4 is set to 1, indicating that the instruction in RS 1 will produce the result for updating R4. Note that in the RS entries, one of the two source operands is placed in the sink field. This serves as a temporary storage location. The other operand will be combined with the value in the sink field to produce the destination operand value. Both operands for instruction w are available, so it begins execution immediately (indicated by the w next to the Adder function). Instruction x requires the result (R4) of instruction w, so it cannot yet execute. Instead, the tag bit for the source operand is set to 1, referring to entry 1 in the RS file. This tag indicates that the instruction in RS 1 will produce the needed source operand.
- **Cycle 2:** Instructions y and z are dispatched (in order) to RSs 2 and 5, respectively. The busy bit for the destination register of z (R8) is set in the FLR file. Instruction y needs R8 as a source register. Because the busy bit is set for this R8, indicating that the value in the FLR is no longer valid, the tag for R4 is picked up and placed in the RS entry for that source register. Furthermore, because R4 will be updated by y, the tag for R4 is updated to the value 2, indicating that the value for R4 in the FLR file will not be valid until the completion of instruction y. Similarly, when z is dispatched, it is placed in RS entry 5. Instruction z needs R4 and R8 as sources and so the tags for these registers are put in the RS entry for z. Also, the adder function for w completes at the end of cycle 2, and the result will be fed to the two RS entries with a tag value of 1. These RS entries will pick up the result via the common data bus (CBD). This value (13.8) will show up at the beginning of cycle 3. Instruction z will update R8, so its tag value (5) is entered in the FLR file entry for R8.
- **Cycle 3:** At the beginning of this cycle, the appropriate value for R4 (13.8) is placed in the instruction entries for y and x. Instruction y begins execution in the adder unit and instruction x begins execution in the multiply/divide unit.
- **Cycle 4:** Instruction y completes at the end of this cycle, and broadcasts its result (21.6). This result is recorded in the RS entry for instruction z and in R4 itself in the FLR. Note that this result is posted to R4 even though the preceding instruction (x) has not completed. This out-of-order completion is possible because, in effect, instructions work with renamed registers, with the register name consisting of the original register name plus the associated tag value at the time the instruction is dispatched.
- **Cycle 5:** Instruction x completes at the end of this cycle and broadcasts its result (82.8). This result is recorded in the RS entry for instruction z and the FLR entry for R2.
- **Cycle 6:** Instruction z begins execution. R8 is thus not valid until z completes.

G.4 Scoreboarding

Scoreboarding is hardware-based dynamic instruction scheduling technique that is used as an alternative to register renaming to achieve pipeline efficiency. In essence, scoreboardding is a bookkeeping technique that allows instructions to execute whenever they are not dependent on previous instructions and no structural hazards are present. This technique, also known as Thornton's algorithm, was initially developed for the CDC 6600 [THOR64, THOR70, THOR80]. Variations on the scoreboardding technique have been implemented on a number of machines.

Figure G.12 is a block diagram that illustrates the role of the scoreboard in a processor organization. We assume a single instruction pipeline for the fetch, decode, and instruction issue stages. The remainder of the pipeline is a superscalar architecture with parallel pipelines for different functional units and/or replicated functional units, with each parallel pipeline including one or more execute stages and a write backstage. The scoreboard is a central unit that exchanges information with the issue stage and the execute stages. It also interacts with the register file.

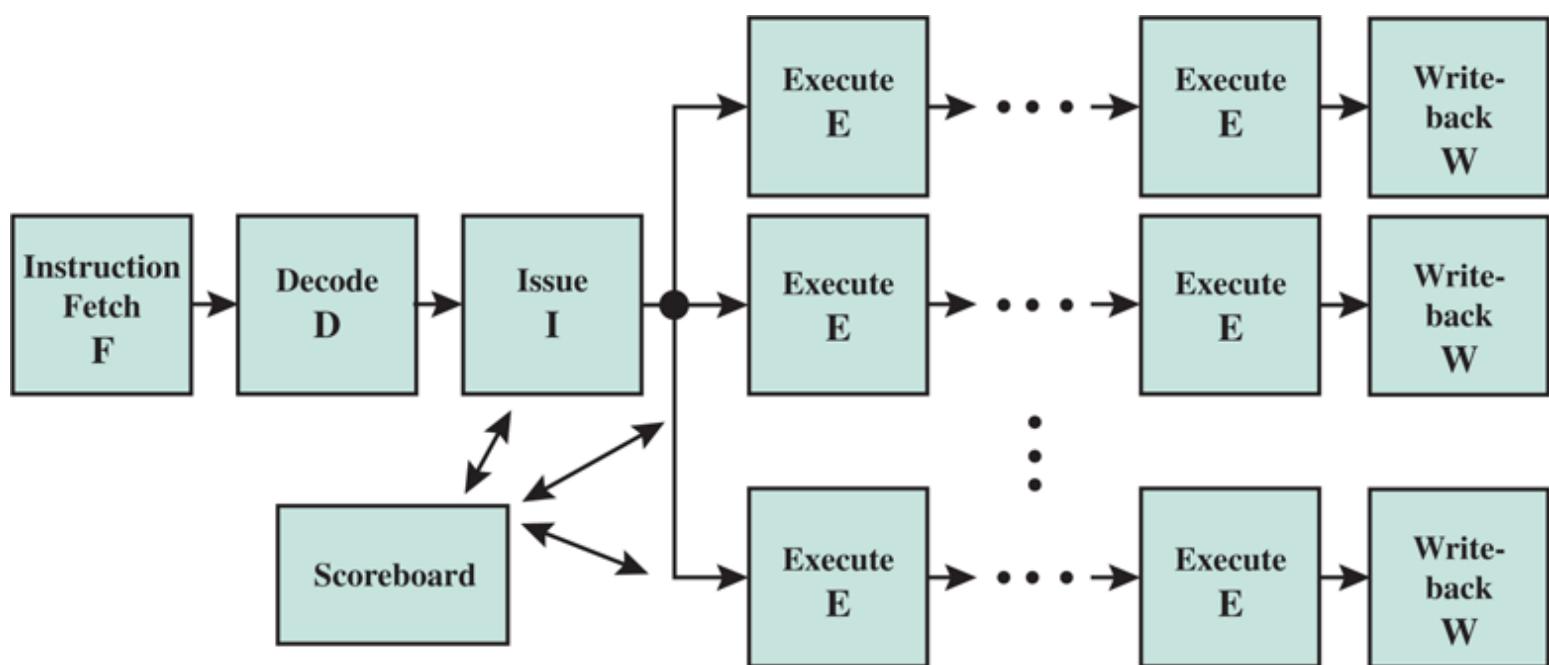

Figure G.12 Block Diagram of a CDC 6600-Style Processor

Scoreboard Operation

The scoreboard can be viewed as consisting of two tables, one with an entry for each functional unit, and one with an entry for each register. Each functional unit entry indicates whether there is an instruction pending for the functional unit, and if so which instruction is pending. The entry also indicates which registers are reserved by this functional unit for input, and whether the registers are currently available for this instruction. Each register entry tells which functional unit, if any, has this register reserved for output. As each new instruction is brought up, the conditions at the instant of issuance are set in the scoreboard. If no waiting is required, the execution of the instruction is begun immediately under control of the functional unit. If waiting is required (for example, an input operand may not yet be available in the register file), the scoreboard controls the delay, and when ready, allows the unit to begin its execution.

From the point of view of an instruction, execution proceeds as follows:

1. Check availability of functional unit and result register. If either is already reserved, the instruction is not issued until the reserved resource becomes available. This is a resource hazard or a WAW hazard, depending on where the conflict occurred. New reservations get stalled. An example of a functional unit conflict:

```
R6 ← R1 + R2
R5 ← R3 + R4
```

Both instructions use the Add functional unit, a situation in which the second instruction must wait for the first to complete that functional unit. However, if there are multiple Add units, the instructions may proceed in parallel. An example of a result register conflict:

```
R6 ← R1 + R2
R6 ← R4 × R5
```

Both instructions call for register R6 for the result, thus the second instruction must wait for the first to be completed.

2. Enter reservations for functional unit and result register. If one or both source registers is reserved, the instruction cannot be issued, but the machine can keep entering reservations. This is a RAW hazard. For example:

```
R6 ← R1 / R2
R7 ← R5 + R6 (conflict on this instruction)
R3 ← R2 × R4 (this instruction free to execute)
```

The second instruction is issued but held in the Divide unit until R6 is ready.

3. When source registers contain valid data, read the data and issue the instruction to the functional unit. The functional unit now executes the instruction under local control.
4. When the functional unit has completed the instruction, it checks to see if it can write its output to its result register (this is impossible if the register is reserved as a source by another functional unit, and that functional unit already has it marked as available, a WAR hazard). For example:

```
R3 ← R1 / R2
R5 ← R4 × R3 (RAW conflict on R3)
R4 ← R0 + R6 (WAR conflict on R4)
```

In this example, the WAR conflict on R4 is the direct result of a RAW conflict on R3. Because the instructions are issued on consecutive cycles and because the Add function is much faster than the Divide or Multiply, the addition is accomplished and ready for entry in the result register R4 in advance of the start of Multiply. The RAW conflict on R3 causes the Multiply to hold until that input operand is ready. This holds up the entry of R4 into the Multiply unit also. The WAR conflicts are resolved by holding the result in the functional unit until the register is available.

Scoreboard control thus directs the functional unit in starting, obtaining its operands, and storing its results. Each unit, once started, proceeds independently until just before the result is produced. The unit then sends a signal to the scoreboard requesting permission to release its results to the result register. The scoreboard determines when the path to the result register is clear and signals the requesting unit to release its result. The releasing unit's reservations are then cleared, and all units

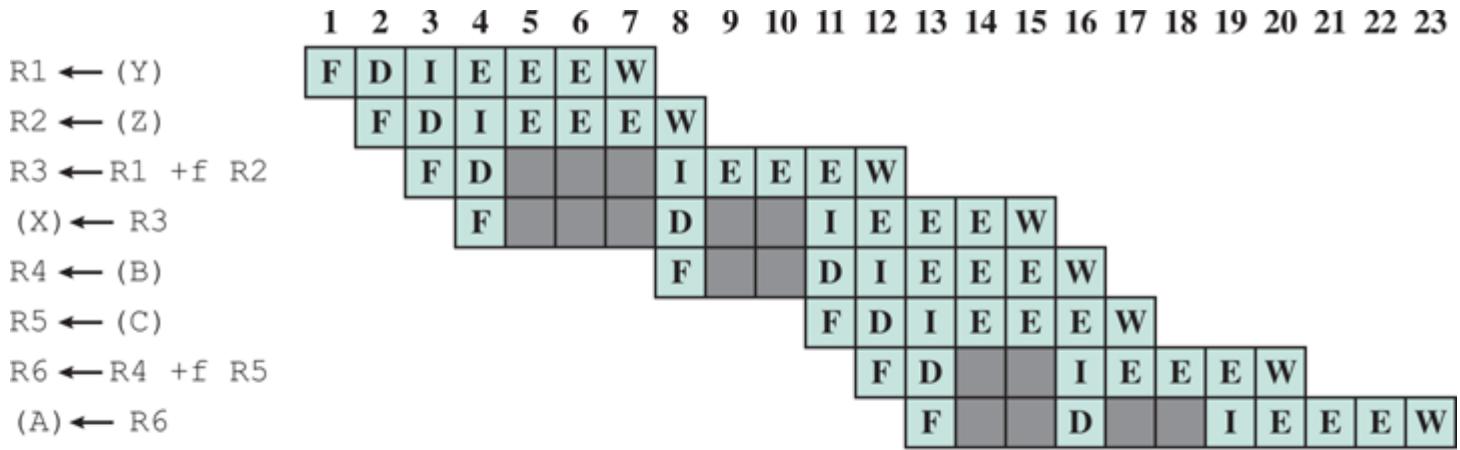

waiting for the result are signaled to read the result for their respective computations.

Scoreboard Example

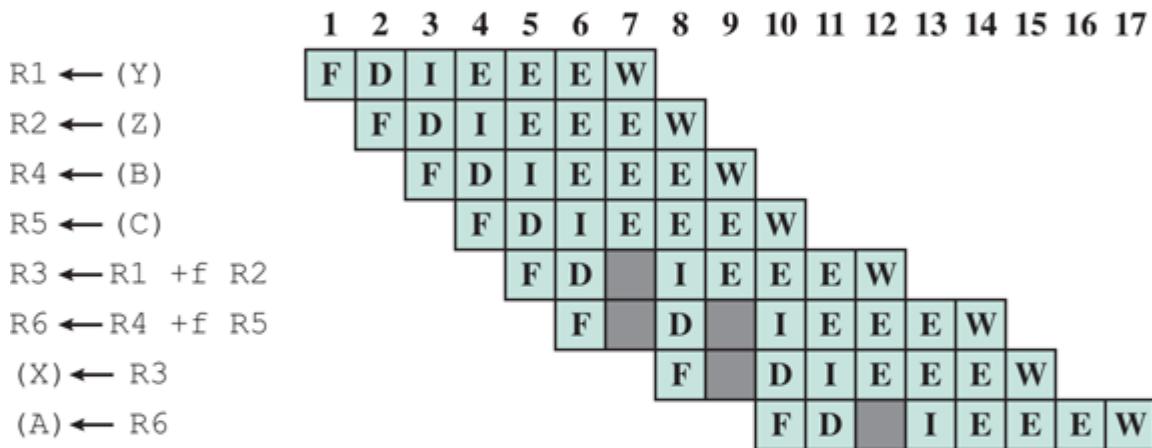

Consider the following example. Assume a pipeline organization with three execute stages. Consider the following program fragment:

$R1 \leftarrow (Y)$	<i>Load register R1 from memory location Y</i>
$R2 \leftarrow (Z)$	<i>Load register R2 from memory location Z</i>
$R3 \leftarrow R1 +f R2$	<i>Floating add R1 and R2; store in R3</i>
$(X) \leftarrow R3$	<i>Store result in memory location X</i>
$R4 \leftarrow (B)$	<i>Load register R4 from memory location B</i>
$R5 \leftarrow (C)$	<i>Load register R5 from memory location C</i>
$R6 \leftarrow R4 *f R5$	<i>Floating multiply R4 and R5; store in R6</i>
$(A) \leftarrow R6$	<i>Store result in memory location A</i>

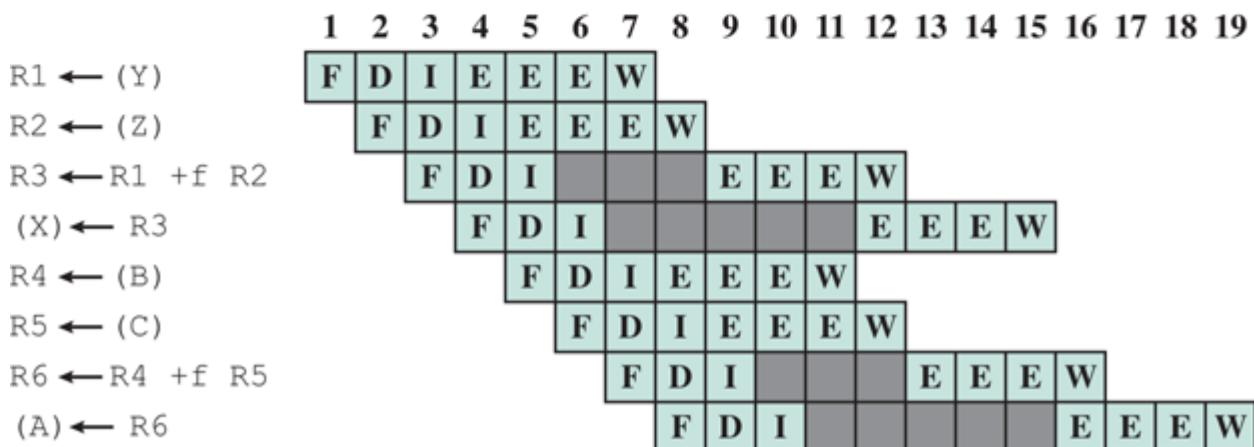

Figure G.13a shows a straightforward pipeline implementation that assumes no parallel execution units and no attempts to circumvent hazards. The diagram assumes that load and store instructions take three execution cycles, as do multiply and add instructions. **Figure G.13b** shows the result of instruction scheduling at compile time. With instructions appropriately reordered, six clock cycles are saved. Finally, **Figure G.13c** shows the result of using the hardware scoreboard rather than the compiler to improve performance. In this example, 4 cycles are saved compared to the original pipeline.

Figure G.13 Pipelined Execution Example

Glossary

absolute address

An address in a computer language that identifies a storage location or a device without the use of any intermediate reference.

accumulator

The name of the CPU register in a single-address instruction format. The accumulator, or AC, is implicitly one of the two operands for the instruction.

address bus

That portion of a system bus used for the transfer of an address. Typically, the address identifies a main memory location or an I/O device.

address space

The range of addresses (memory, I/O) that can be referenced.

arithmetic and logic unit (ALU)

A part of a computer that performs arithmetic operations, logic operations, and related operations.

ASCII

American Standard Code for Information Interchange. ASCII is a 7-bit code used to represent numeric, alphabetic, and special printable characters. It also includes codes for *control characters*, which are not printed or displayed but specify some control function.

assembly language

A computer-oriented language whose instructions are usually in one-to-one correspondence with computer instructions and that may provide facilities such as the use of macroinstructions.

Synonymous with *computer-dependent language*.

associative memory

A memory whose storage locations are identified by their contents, or by a part of their contents, rather than by their names or positions.

asynchronous timing

A technique in which the occurrence of one event on a bus follows and depends on the occurrence of a previous event.

autoindexing

A form of indexed addressing in which the index register is automatically incremented or decremented with each memory reference.

base

In the numeration system commonly used in scientific papers, the number that is raised to the power denoted by the exponent and then multiplied by the mantissa to determine the real number represented (e.g., the number 10 in the expression $2.7 \times 10^2 = 270$).

base address

A numeric value that is used as a reference in the calculation of addresses in the execution of a computer program.

binary operator

An operator that represents an operation on two and only two operands.

bit

In the pure binary numeration system, either of the digits 0 and 1.

block multiplexor channel

A multiplexer channel that interleaves blocks of data. See also *byte multiplexor channel*. Contrast with *selector channel*.

branch prediction

A mechanism used by the processor to predict the outcome of a program branch prior to its execution.

buffer

Storage used to compensate for a difference in rate of flow of data, or time of occurrence of events, when transferring data from one device to another.

bus

A shared communications path consisting of one or a collection of lines. In some computer systems, a common bus connects the CPU, memory, and I/O components. Since the lines are shared by all components, only one component at a time can successfully transmit.

bus arbitration

The process of determining which competing bus master will be permitted access to the bus.

bus master

A device attached to a bus that is capable of initiating and controlling communication on the bus.

byte

A sequence of eight bits. Also referred to as an *octet*.

byte multiplexor channel

A multiplexer channel that interleaves bytes of data. See also *block multiplexor channel*. Contrast with *selector channel*.

cache

A relatively small fast memory interposed between a larger, slower memory and the logic that accesses the larger memory. The cache holds recently accessed data, and is designed to speed up subsequent access to the same data.

cache coherence protocol

A mechanism to maintain data validity among multiple caches so that every data access will always acquire the most recent version of the contents of a main memory word.

cache hit

A required memory location is found in the cache. That is, there is a cache line assigned to the block of memory containing the required memory location.

cache line

A block of data associated with a cache tag and the unit of transfer between cache and memory.

cache memory

A special buffer storage, smaller and faster than main storage, that is used to hold a copy of instructions and data in main storage that are likely to be needed next by the processor and that have been obtained automatically from main storage.

cache miss

A failure to find the required memory location in the cache. That is, there is no cache line assigned to the block of memory containing the required memory location.

CD-ROM

Compact Disk Read-Only Memory. A nonerasable disk used for storing computer data. The standard system uses 12-cm disks and can hold more than 550 Mbytes.

central processing unit (CPU)

That portion of a computer that fetches and executes instructions. It consists of an Arithmetic and Logic Unit (ALU), a control unit, and registers. Often simply referred to as a *processor*. In today's multicore era, the term *CPU* has fallen out of favor.

chip

A small unpackaged functional element made by subdividing a wafer of semiconductor material. Sometimes referred to as a die.

C/ISC

Complex Instruction Set Computer. A processor where each instruction can perform several low-level operations. Instructions may be variable in length and use a number of addressing modes, requiring complex circuitry to decode them.

cluster

A group of interconnected, whole computers working together as a unified computing resource that can create the illusion of being one machine. The term *whole computer* means a system that can run on its own, apart from the cluster.

combinational circuit

A logic device whose output values, at any given instant, depend only upon the input values at that time. A combinational circuit is a special case of a sequential circuit that does not have a storage capability. Synonymous with *combinatorial circuit*.

compact disk (CD)

A nonerasable disk that stores digitized audio information.

computer architecture

Those attributes of a system visible to a programmer or, put another way, those attributes that have a direct impact on the logical execution of a program. Examples of architectural attributes include the instruction set, the number of bits used to represent various data types (e.g., numbers, characters), I/O mechanisms, and techniques for addressing memory.

computer instruction

An instruction that can be recognized by the processing unit of the computer for which it is designed. Synonymous with *machine instruction*.

computer instruction set

A complete set of the operators of the instructions of a computer together with a description of the types of meanings that can be attributed to their operands. Synonymous with *machine instruction set*.

computer organization

Refers to the operational units and their interconnections that realize the architectural specifications. Organizational attributes include those hardware details transparent to the

programmer, such as control signals; interfaces between the computer and peripherals; and the memory technology used.

conditional jump

A jump that takes place only when the instruction that specifies it is executed and specified conditions are satisfied. Contrast with *unconditional jump*.

condition code

A code that reflects the result of a previous operation (e.g., arithmetic). A CPU may include one or more condition codes, which may be stored separately within the CPU or as part of a larger control register. Also known as a *flag*.

control bus

That portion of a system bus used for the transfer of control signals.

control registers

CPU registers employed to control CPU operation. Most of these registers are not user visible.

control storage

A portion of storage that contains microcode.

control unit

That part of the CPU that controls CPU operations, including ALU operations, the movement of data within the CPU, and the exchange of data and control signals across external interfaces (e.g., the system bus).

core

An individual processing unit on a processor chip (see *processor*). A core is equivalent in functionality to a CPU on a single-CPU system.

daisy chain

A method of device interconnection for determining interrupt priority by connecting the interrupt sources serially.

data bus

That portion of a system bus used for the transfer of data.

data communication

Data transfer between devices. The term generally excludes I/O.

decoder

A device that has a number of input lines of which any number may carry signals and a number of output lines of which not more than one may carry a signal, there being a one-to-one correspondence between the outputs and the combinations of input signals.

demand paging

The transfer of a page from auxiliary storage to real storage at the moment of need.

direct access

The capability to obtain data from a storage device or to enter data into a storage device in a sequence independent of their relative position, by means of addresses that indicate the physical location of the data.

direct address

An address that designates the storage location of an item of data to be treated as operand. Synonymous with *one-level address*.

direct memory access (DMA)

A form of I/O in which a special module, called a *DMA module*, controls the exchange of data between main memory and an I/O module. The CPU sends a request for the transfer of a block of data to the DMA module and is interrupted only after the entire block has been transferred.

disabled interrupt

A condition, usually created by the CPU, during which the CPU will ignore interrupt request signals of a specified class.

diskette

A flexible magnetic disk enclosed in a protective container. Synonymous with *flexible disk*.

disk pack

An assembly of magnetic disks that can be removed as a whole from a disk drive, together with a container from which the assembly must be separated when operating.

disk stripping

A type of disk array mapping in which logically contiguous blocks of data, or strips, are mapped round-robin to consecutive array members. A set of logically consecutive strips that maps exactly one strip to each array member is referred to as a stripe.

dynamic RAM

A RAM whose cells are implemented using capacitors. A dynamic RAM will gradually lose its data unless it is periodically refreshed.

emulation

The imitation of all or part of one system by another, primarily by hardware, so that the imitating system accepts the same data, executes the same programs, and achieves the same results as the imitated system.

enabled interrupt

A condition, usually created by the CPU, during which the CPU will respond to interrupt request signals of a specified class.

erasable optical disk

A disk that uses optical technology but that can be easily erased and rewritten. Both 3.25-inch and 5.25-inch disks are in use. A typical capacity is 650 Mbytes.

error-correcting code

A code in which each character or signal conforms to specific rules of construction so that deviations from these rules indicate the presence of an error and in which some or all of the detected errors can be corrected automatically.

error-detecting code

A code in which each character or signal conforms to specific rules of construction so that deviations from these rules indicate the presence of an error.

execute cycle

That portion of the instruction cycle during which the CPU performs the operation specified by the instruction opcode.

fetch cycle

That portion of the instruction cycle during which the CPU fetches from memory the instruction to be executed.

firmware

Microcode stored in read-only memory.

fixed-point representation system

A radix numeration system in which the radix point is implicitly fixed in the series of digit places by some convention upon which agreement has been reached.

flip-flop

A circuit or device containing active elements, capable of assuming either one of two stable states at a given time. Synonymous with *bistable circuit, toggle*.

floating-point representation system

A numeration system in which a real number is represented by a pair of distinct numerals, the real number being the product of the fixed-point part, one of the numerals, and a value obtained by raising the implicit floating-point base to a power denoted by the exponent in the floating-point representation, indicated by the second numeral.

G

Prefix meaning 2^{30} .

gate

An electronic circuit that produces an output signal that is a simple Boolean operation on its input signals.

general-purpose register

A register, usually explicitly addressable, within a set of registers, that can be used for different purposes, for example, as an accumulator, as an index register, or as a special handler of data.

global variable

A variable defined in one portion of a computer program and used in at least one other portion of that computer program.

high-performance computing (HPC)

A research area dealing with supercomputers and the software that runs on supercomputers. The emphasis is on scientific applications, which may involve heavy use of vector and matrix computation, and parallel algorithms.

immediate address

The contents of an address part that contains the value of an operand rather than an address. Synonymous with *zero-level address*.

indexed address

An address that is modified by the content of an index register prior to or during the execution of a computer instruction.

indexing

A technique of address modification by means of index registers.

index register

A register whose contents can be used to modify an operand address during the execution of

computer instructions; it can also be used as a counter. An index register may be used to control the execution of a loop, to control the use of an array, as a switch, for table lookup, or as a pointer.

indirect address

An address of a storage location that contains an address.

indirect cycle

That portion of the instruction cycle during which the CPU performs a memory access to convert an indirect address into a direct address.

input-output (I/O)

Pertaining to either input or output, or both. Refers to the movement of data between a computer and a directly attached peripheral.

instruction address register

A special-purpose register used to hold the address of the next instruction to be executed.

instruction cycle

The processing performed by a CPU to execute a single instruction.

instruction format

The layout of a computer instruction as a sequence of bits. The format divides the instruction into fields, corresponding to the constituent elements of the instruction (e.g., opcode, operands).

instruction issue

The process of initiating instruction execution in the processor's functional units. This occurs when an instruction moves from the decode stage of the pipeline to the first execute stage of the pipeline.

instruction register

A register that is used to hold an instruction for interpretation.

instruction set architecture (ISA)

Defines instruction formats, instruction opcodes, registers, instruction and data memory, the effect of executed instructions on the registers and memory, and an algorithm for controlling instruction execution.

integrated circuit (IC)

A tiny piece of solid material, such as silicon, upon which is etched or imprinted a collection of electronic components and their interconnections.

interrupt

A suspension of a process, such as the execution of a computer program, caused by an event external to that process, and performed in such a way that the process can be resumed.

Synonymous with *interruption*.

interrupt cycle

That portion of the instruction cycle during which the CPU checks for interrupts. If an enabled interrupt is pending, the CPU saves the current program state and resumes processing at an interrupt-handler routine.

interrupt-driven I/O

A form of I/O. The CPU issues an I/O command, continues to execute subsequent instructions, and is interrupted by the I/O module when the latter has completed its work.

I/O channel

A relatively complex I/O module that relieves the CPU of the details of I/O operations. An I/O channel will execute a sequence of I/O commands from main memory without the need for CPU involvement.

I/O controller

A relatively simple I/O module that requires detailed control from the CPU or an I/O channel. Synonymous with *device controller*.

I/O module

One of the major component types of a computer. It is responsible for the control of one or more external devices (peripherals) and for the exchange of data between those devices and main memory and/or CPU registers.

I/O processor

An I/O module with its own processor, capable of executing its own specialized I/O instructions or, in some cases, general-purpose machine instructions.

isolated I/O

A method of addressing I/O modules and external devices. The I/O address space is treated separately from main memory address space. Specific I/O machine instructions must be used. Compare to *memory-mapped I/O*.

k

Prefix meaning $2^{10} = 1024$. Thus, 2kb = 2048bits.

local variable

A variable that is defined and used only in one specified portion of a computer program.

locality of reference

The tendency of a processor to access the same set of memory locations repetitively over a short period of time.

M

Prefix meaning $2^{20} = 1,048,576$. Thus, 2Mb = 2,097,152bits.

magnetic disk

A flat circular plate with a magnetizable surface layer, on one or both sides of which data can be stored.

magnetic tape

A tape with a magnetizable surface layer on which data can be stored by magnetic recording.

mainframe

A term originally referring to the cabinet containing the central processor unit or “main frame” of a large batch machine. After the emergence of smaller minicomputer designs in the early 1970s, the traditional larger machines were described as mainframe computers, or mainframes. Typical characteristics of a mainframe are that it supports a large database, has elaborate I/O hardware, and is used in a central data processing facility.

main memory

Program-addressable storage from which instructions and other data can be loaded directly into registers for subsequent execution or processing.

memory address register (MAR)

A register, in a processing unit, that contains the address of the storage location being accessed.

memory buffer register (MBR)

A register that contains data read from memory or data to be written to memory.

memory cycle time

The inverse of the rate at which memory can be accessed. It is the minimum time between the response to one access request (read or write) and the response to the next access request.

memory management unit (MMU)

A hardware module that supports virtual memory and paging by translating virtual addresses into physical addresses.

memory-mapped I/O

A method of addressing I/O modules and external devices. A single address space is used for both main memory and I/O addresses, and the same machine instructions are used both for memory read/write and for I/O.

memory protection unit (MPU)

A hardware module that prohibits one program in memory from accidentally accessing memory assigned to another active program. Using various methods, a protective boundary is created around the program, and instructions within the program are prohibited from referencing data outside of that boundary.

microcomputer

A computer system whose processing unit is a microprocessor. A basic microcomputer includes a microprocessor, storage, and an input/output facility, which may or may not be on one chip.

microinstruction

An instruction that controls data flow and sequencing in a processor at a more fundamental level than machine instructions. Individual machine instructions and perhaps other functions may be implemented by microprograms.

micro-operation

An elementary CPU operation, performed during one clock pulse.

microprocessor

A processor whose elements have been miniaturized into one or a few integrated circuits.

microprogram

A sequence of microinstructions that are in special storage where they can be dynamically accessed to perform various functions.

microprogrammed CPU

A CPU whose control unit is implemented using microprogramming.

microprogramming language

An instruction set used to specify microprograms.

multiplexer

A combinational circuit that connects multiple inputs to a single output. At any time, only one of the inputs is selected to be passed to the output.

multiplexor channel

A channel designed to operate with a number of I/O devices simultaneously. Several I/O devices can transfer records at the same time by interleaving items of data. See also *byte multiplexor channel*, *block multiplexor channel*.

multiprocessor

A computer that has two or more processors that have common access to a main storage.

multiprogramming

A mode of operation that provides for the interleaved execution of two or more computer programs by a single processor.

multitasking

A mode of operation that provides for the concurrent performance or interleaved execution of two or more computer tasks. The same as multiprogramming, using different terminology.

nonuniform memory access (NUMA) multiprocessor

A shared-memory multiprocessor in which the access time from a given processor to a word in memory varies with the location of the memory word.

nonvolatile memory

Memory whose contents are stable and do not require a constant power source.

nucleus

That portion of an operating system that contains its basic and most frequently used functions. Often, the nucleus remains resident in main memory.

ones complement representation

Used to represent binary integers. A positive integer is represented as in sign magnitude. A negative integer is represented by reversing each bit in the representation of a positive integer of the same magnitude.

opcode

Abbreviated form for *operation code*.

operand

An entity on which an operation is performed.

operating system

Software that controls the execution of programs and that provides services such as resource allocation, scheduling, input/output control, and data management.

operation code

A code used to represent the operations of a computer. Usually abbreviated to opcode.

orthogonality

A principle by which two variables or dimensions are independent of one another. In the context of an instruction set, the term is generally used to indicate that other elements of an instruction (address mode, number of operands, length of operand) are independent of (not determined by) opcode.

page

In a virtual storage system, a fixed-length block that has a virtual address and that is transferred as

a unit between real storage and auxiliary storage.

page fault

Occurs when the page containing a referenced word is not in main memory. This causes an interrupt and requires the operating system to bring in the needed page.

page frame

An area of main storage used to hold a page.

parity bit

A binary digit appended to a group of binary digits to make the sum of all the digits either always odd (odd parity) or always even (even parity).

peripheral equipment

In a computer system, with respect to a particular processing unit, any equipment that provides the processing unit with outside communication. Synonymous with *peripheral device*.

pipeline

A processor organization in which the processor consists of a number of stages, allowing multiple instructions to be executed concurrently.

predicated execution

A mechanism that supports the conditional execution of individual instructions. This makes it possible to execute speculatively both branches of a branch instruction and retain the results of the branch that is ultimately taken.

printed circuit board

A rigid, flat board that holds and interconnects chips and other electronic components.

process

A program in execution. A process is controlled and scheduled by the operating system.

process control block

The manifestation of a process in an operating system. It is a data structure containing information about the characteristics and state of the process.

processor

A physical piece of silicon containing one or more cores. The processor is the computer component that interprets and executes instructions. A processor may contain multiple cores.

processor cycle time

The time required for the shortest well-defined CPU micro-operation. It is the basic unit of time for measuring all CPU actions. Synonymous with *machine cycle time*.

program counter

Instruction address register.

programmable logic array (PLA)

An array of gates whose interconnections can be programmed to perform a specific logical function.

programmable read-only memory (PROM)

Semiconductor memory whose contents may be set only once. The writing process is performed electrically and may be performed by the user at a time later than original chip fabrication.

programmed I/O

A form of I/O in which the CPU issues an I/O command to an I/O module and must then wait for the operation to be complete before proceeding.

program status word (PSW)

An area in storage used to indicate the order in which instructions are executed, and to hold and indicate the status of the computer system. Synonymous with *processor status word*.

random-access memory (RAM)

Memory in which each addressable location has a unique addressing mechanism. The time to access a given location is independent of the sequence of prior access.

read-only memory (ROM)

Semiconductor memory whose contents cannot be altered, except by destroying the storage unit. Nonerasable memory.

redundant array of independent disks (RAID)

A disk array in which part of the physical storage capacity is used to store redundant information about user data stored on the remainder of the storage capacity. The redundant information enables regeneration of user data in the event that one of the array's member disks or the access path to it fails.

registers

High-speed memory internal to the CPU. Some registers are user visible; that is, available to the programmer via the machine instruction set. Other registers are used only by the CPU, for control purposes.

RISC

Reduced Instruction Set Computer. A processor architecture that reduces chip complexity by using simpler instructions of constant length.

rounding

The elimination of the rightmost digits in the significand to produce a result that is close to the exact result but which fits into the available bits.

scalar

A quantity characterized by a single value.

secondary memory

Memory located outside the computer system itself; that is, it cannot be processed directly by the processor. It must first be copied into main memory. Examples include disk and tape.

selector channel

An I/O channel designed to operate with only one I/O device at a time. Once the I/O device is selected, a complete record is transferred one byte at a time. Contrast with *block multiplexor channel*, *multiplexor channel*.

semiconductor

A solid crystalline substance, such as silicon or germanium, whose electrical conductivity is intermediate between insulators and good conductors. Used to fabricate transistors and solid-state components.

semiconductor memory

An electronic data storage device, often used as computer memory, implemented on a semiconductor-based integrated circuit. Examples of semiconductor memory include non-volatile memory such as read-only memory (ROM), magnetoresistive random access memory (MRAM), and flash memory. It also includes volatile memory such as static random access memory (SRAM) and dynamic random access memory (DRAM).

sequential circuit

A digital logic circuit whose output depends on the current input plus the state of the circuit.

Sequential circuits thus possess the attribute of memory.

sign-magnitude representation

Used to represent binary integers. In an N -bit word, the leftmost bit is the sign ($0 = \text{positive}$, $1 = \text{negative}$) and the remaining $N - 1$ bits comprise the magnitude of the number.

solid-state component

A component whose operation depends on the control of electric or magnetic phenomena in solids (e.g., transistor crystal diode, ferrite core).

solid state drive

An all-electronic storage device that is an alternative to a hard disk drive. Also called a “solid state disk” and “electronic disk.” Employed in myriad products, such as smartphones, MP3 players, digital cameras and laptop computers, solid state drives (SSDs) are faster than hard disks because there is zero latency (no read/write head to move). They are also more rugged and offer greater protection in hostile environments.

speculative execution

The execution of instructions along one path of a branch. If it later turns out that this branch was not taken, then the results of the speculative execution are discarded.

stack

An ordered list in which items are appended to and deleted from the same end of the list, known as the top. That is, the next item appended to the list is put on the top, and the next item to be removed from the list is the item that has been in the list the shortest time. This method is characterized as last-in-first-out.

static RAM

A RAM whose cells are implemented using flip-flops. A static RAM will hold its data as long as power is supplied to it; no periodic refresh is required.

superpipelined processor

A processor design in which the instruction pipeline consists of many very small stages, so that more than one pipeline stage can be executed during one clock cycle and so that a large number of instructions may be in the pipeline at the same time.

superscalar processor

A processor design that includes multiple-instruction pipelines, so that more than one instruction can be executing in the same pipeline stage simultaneously.

symmetric multiprocessing (SMP)

A form of multiprocessing that allows the operating system to execute on any available processor or on several available processors simultaneously.

synchronous timing

clock
A technique in which the occurrence of events on a bus is determined by a clock. The clock defines equal-width time slots, and events begin only at the beginning of a time slot.

system bus

A bus used to interconnect major computer components (CPU, memory, I/O).

truth table

A table that describes a logic function by listing all possible combinations of input values and indicating, for each combination, the output value.

twos complement representation

Used to represent binary integers. A positive integer is represented as in sign magnitude. A negative number is represented by taking the Boolean complement of each bit of the corresponding positive number, then adding 1 to the resulting bit pattern viewed as an unsigned integer.

unary operator

An operator that represents an operation on one and only one operand.

unconditional jump

A jump that takes place whenever the instruction that specified it is executed.

uniprocessing

Sequential execution of instructions by a processing unit, or independent use of a processing unit in a multiprocessing system.

user-visible registers

CPU registers that may be referenced by the programmer. The instruction-set format allows one or more registers to be specified as operands or addresses of operands.

vector

A quantity usually characterized by an ordered set of scalars.

very long instruction word (VLIW)

Refers to the use of instructions that contain multiple operations. In effect, multiple instructions are contained in a single word. Typically, a VLIW is constructed by the compiler, which places operations that may be executed in parallel in the same word.

virtual storage

The storage space that may be regarded as addressable main storage by the user of a computer system in which virtual addresses are mapped into real addresses. The size of virtual storage is limited by the addressing scheme of the computer system and the amount of auxiliary storage available, but not by the actual number of main storage locations.

volatile memory

A memory in which a constant electrical power source is required to maintain the contents of memory. If the power is switched off, the stored information is lost.

word

An ordered set of bytes or bits that is the normal unit in which information may be stored, transmitted, or operated on within a given computer. Typically, if a processor has a fixed-length instruction set, then the instruction length equals the word length.

THE WILLIAM STALLINGS BOOKS ON COMPUTER AND DATA COMMUNICATIONS TECHNOLOGY

DATA AND COMPUTER COMMUNICATIONS, TENTH EDITION

A comprehensive survey that has become the standard in the field, covering (1) data communications, including transmission, media, signal encoding, link control, and multiplexing; (2) communication networks, including circuit- and packet-switched, frame relay, ATM, and LANs; and (3) the TCP/IP protocol suite, including IPv6, TCP, MIME, and HTTP, as well as a detailed treatment of network security. **Received the 2007 Text and Academic Authors Association (TAA) award for the best Computer Science and Engineering Textbook of the year.**

WIRELESS COMMUNICATION NETWORKS AND SYSTEMS (with Cory Beard)

A comprehensive, state-of-the art survey. The book covers fundamental wireless communications topics, including antennas and propagation, signal encoding techniques, spread spectrum, and error correction techniques. Satellite, cellular, wireless local loop networks, and wireless LANs, including Bluetooth and 802.11 are examined. In addition, wireless mobile networks and applications are covered.

COMPUTER SECURITY, FOURTH EDITION (with Lawrie Brown)

A comprehensive treatment of computer security technology, including algorithms, protocols, and applications. The book covers cryptography, authentication, access control, database security, cloud security, intrusion detection and prevention, malicious software, denial of service, firewalls, software security, physical security, human factors, auditing, legal and ethical aspects, and trusted systems. **Received the 2008 TAA award for the best Computer Science and Engineering Textbook of the year.**

OPERATING SYSTEMS, NINTH EDITION

A state-of-the art survey of operating system principles. The book covers fundamental technology as well as contemporary design issues, such as threads, SMPs, multicore, real-time systems, multiprocessor scheduling, embedded OSs, distributed systems, clusters, security, and object-oriented design. **Third, fourth, and sixth editions received the TAA award for the best Computer Science and Engineering Textbook of the year.**

CRYPTOGRAPHY AND NETWORK SECURITY, SEVENTH EDITION

A tutorial and survey on network security technology. Each of the basic building blocks of network security, including conventional and public-key cryptography, authentication, and digital signatures, are covered. The book provides a thorough mathematical background for algorithms such as AES and RSA. Important network security tools and applications, including S/MIME, IPSecurity, Kerberos, SSL/TLS, network access control, and Wi-Fi security are covered. In addition, methods for countering hackers and viruses are explored. **Second edition received the TAA award for the best Computer Science and Engineering Textbook of 1999.**

NETWORK SECURITY ESSENTIALS, SIXTH EDITION

A tutorial and survey on network security technology. The book covers important network security tools and applications, including S/MIME, IP Security, Kerberos, SSL/TLS, network access control, and Wi-Fi security. In addition, methods for countering hackers and viruses are explored.

BUSINESS DATA COMMUNICATIONS, SEVENTH EDITION (with Tom Case)

A comprehensive presentation of data communications and telecommunications from a business perspective. The book covers voice, data, image, and video communications and applications technology and includes a number of case studies. Topics covered include data communications, TCP/IP, cloud computing, Internet protocols, and applications, LANs and WANs, network security, adnetwork management.

FOUNDATIONS OF MODERN NETWORKING: SDN, NFV, QoE, IoT, and Cloud

An in-depth up-to-date survey and tutorial on Software Defined Networking, Network Functions Virtualization, Quality of Experience, Internet of Things, and Cloud Computing and Networking. The book examines standards, technologies, and deployment issues. In addition, security and career topics are covered.
